Editor Biography

Dr. Kempf-Leonard is Professor of Sociology, Crime and Justice Studies, and Political Economy at the University of Texas at Dallas. Prior to her appointment at UTD in 2000, she was Associate Professor and Graduate Director of Criminology and Criminal Justice at the University of Missouri at St. Louis. She also served for ten years as a gubernatorial appointee to the Missouri Juvenile Justice Advisory Group. She received her Ph.D. at the University of Pennsylvania in 1986; M.A. at the University of Pennsylvania in 1983; M.S. at the Pennsylvania State University in 1982; B.S. at the University of Nebraska in 1980.

Her book *Minorities in Juvenile Justice* won the 1997 Gustavus Myers Award for Human Rights in North America. Her publications have appeared in: *Criminology*, *Justice Quarterly*, *Journal of Criminal Law & Criminology*, *Crime & Delinquency*, *Journal of Quantitative Criminology*, *Advances in Criminological Theory*, *Punishment & Society*, *Corrections Management Quarterly*, *the Journal of Criminal Justice*, *Criminal Justice Policy Review*, *The Justice Professional*, *Youth and Society*, *The Corporate Finance Reader*, and *The Modern Gang Reader*.

Foreword

Not long ago, and perhaps still today, many would expect an encyclopedia of social measurement to be about quantitative social science. The *Encyclopedia of Social Measurement* excellently defies this expectation by covering and integrating both qualitative and quantitative approaches to social science and social measurement. The *Encyclopedia of Social Measurement* is the best and strongest sign I have seen in a long time that the barren opposition between quantitative and qualitative research, which has afflicted the social sciences for half a century, is on its way out for good. As if the Science Wars proper—between the social and natural sciences—were not enough, some social scientists found it fitting to invent another war within the social sciences, in effect a civil war, between quantitative and qualitative social science. Often younger faculty and doctoral students would be forced to take sides, and the war would reproduce within disciplines and departments, sometimes with devastating effects. This, no doubt, has set social science back. We cannot thank the editors and contributors to the *Encyclopedia of Social Measurement* enough for showing us there is an effective way out of the malaise.

This volume demonstrates that the sharp separation often seen in the literature between qualitative and quantitative methods of measurement is a spurious one. The separation is an unfortunate artifact of power relations and time constraints in graduate training; it is not a logical consequence of what graduates and scholars need to know to do their studies and do them well. The *Encyclopedia of Social Measurement* shows that good social science is opposed to an either/or and stands for a both/and on the question of qualitative versus quantitative methods. Good social science is problem-driven and not methodology-driven, in the sense that it employs those methods which

for a given problematic best help answer the research questions at hand. To use a simple metaphor, asking whether social science is best served by qualitative or quantitative methods is about as intelligent as asking a carpenter whether a hammer or a saw is the better tool.

So far every effort has been unsuccessful in the social sciences at arriving at one canon for how to do science, most conspicuously the attempt at emulating the natural science model. Different explanations exist of this phenomenon, from Anthony Giddens' so-called double hermeneutic to Hubert Dreyfus' tacit skills argument. It is a great strength of the *Encyclopedia of Social Measurement* that it stays clear of the unity of science argument for social science, and of any other attempts at imposing one dominant paradigm on what social science is and how it should be conducted. The editors and most of the contributors have rightly seen that success in social science and social measurement lies with the type of methodological and epistemological pluralism, which is a distinguishing feature of the encyclopedia. Together with its impressive substantive breadth—covering the full range of social measurement from anthropology, sociology, political science, economics, and business administration over urban studies, environment, geography, demography, history, criminology, and law to neuroscience, biomedicine, nursing, psychology, linguistics, and communication—this healthy pluralism will prove the *Encyclopedia of Social Measurement* to be a robust and indispensable companion to all working social scientists for many years to come.

Preface

Methodology . . . [has] developed as a bent of mind rather than as a system of organized principles and procedures. The methodologist is a scholar who is above all analytical in his approach to his subject matter. He tells other scholars what they have done, or might do, rather than what they should do. He tells them what order of finding has emerged from their research, not what kind of result is or is not preferable. This kind of analytical approach requires self-awareness on the one hand, and tolerance, on the other. The methodologist knows that the same goal can be reached by alternative roads.

(Lazarsfeld and Rosenberg, 1955, p. 4)

In the social sciences we use methodology to try to answer questions about how and why people behave as they do. Some types of behavior are very common or routine, while others happen rarely or only in certain situations. When you realize that every conceivable type of behavior is within the realm of possible subjects for us to study, you can begin to appreciate the scope of social science. Beyond identifying human activities and the boundaries in which they occur, social scientists also want to explain why behaviors happen. In looking for causes, social scientists pursue all dimensions of the social world. We look at personal traits of individuals, characteristics of interactions between people, and contextual features of the communities and cultures in which they live. We study people who lived in the past, try to improve the quality of life today, and anticipate what the future will hold. It is difficult to think of a topic that involves people for which a social scientist could not investigate.

Given all we do, it is good that there are so many of us. You will find social scientists in university departments as professors of sociology, psychology, anthropology, political science, and economics. You will also find professors of geography, history, philosophy, math, management, planning, finance, journalism, architecture, humanities, and art who are social scientists. Even this multidisciplinary list is not exhaustive. There are important and prevalent social science investigations that influence decision-making in the world outside of universities too. Social scientists are world-wide and work in all branches of government, large and small organizations, and many types of businesses. Daily life for most people is influenced

by social science research in marketing, insurance, and government. However, not everyone in these positions is a social scientist; the distinction involves scientific inquiry, or the approach used to try to answer questions about behavior. As the definition cited above conveys, good science includes tolerance and appreciation for many methodological paths. This encyclopedia of social science methodology provides 356 entries written by social scientists about what they do.

The entries in this encyclopedia cover many forms of measurement used by social scientists to study behavior. Eleven substantive sections delineate social sciences and the research processes they follow to measure and provide knowledge on a wide range of topics. The encyclopedia has an extensive index too, because many topics include issues that are relevant in more than one section. From many perspectives and strategies, these volumes describe the research questions social scientists ask, the sources and methods they use to collect information, and the techniques they use to analyze these data and provide answers to the important questions.

Each section includes entries that address important components of quantitative and qualitative research methods, which are dissected and illustrated with examples from diverse fields of study. The articles convey research basics in sufficient detail to explain even the most complicated statistical technique, and references for additional information are noted for each topic. Most entries describe actual research experiences to illustrate both the realm of possibilities and the potential challenges that might be encountered. Some entries describe major contributions and the social scientists who made them. The authors are accomplished methodologists in their fields of study. They explain the steps necessary to accomplish the measurement goals, as well as provide their practical advice for ways in which to overcome the likely obstacles.

Collectively, the entries in this encyclopedia also convey that no single approach, type of data, or technique of analysis reigns supreme. Indeed, plenty of disagreements exist among social scientists about what constitutes the “best” measurement strategy. Often distinctions are made between quantitative and qualitative methodologies, or are

discipline-specific. Some preferences can be linked to a specific field of study or research topic; others, related to time and location, coincide with how new ideas and advances in technology are shared. Sometimes we don't even agree on what is the appropriate question we should try to answer!

Although our views differ on what is ideal, and even on what are the appropriate standards for assessing measurement quality, social scientists generally *do* agree that the following five issues should be considered:

1. We agree on the need to be clear about the scope and purpose of our pursuits. The benchmarks for evaluating success differ depending on whether our intent is to describe, explain, or predict and whether we focus extensively on a single subject or case (e.g., person, family, organization, or culture) or more generally on patterns among many cases.
2. We agree on the need to make assurances for the ethical treatment of the people we study.
3. We agree on the need to be aware of potential sources of measurement error associated with our study design, data collection, and techniques of analysis.
4. We agree it is important to understand the extent to which our research is a reliable and valid measure of what we contend. Our measures are reliable if they are consistent with what others would have found in the same circumstances. If our measures also are consistent with those from different research circumstances, for example in studies of other behaviors or with alternate measurement strategies, then such replication helps us to be confident about the quality of our efforts. Sometimes we'd like the results of our study to extend beyond the people and behavior we observed. This focus on a wider applicability for our measures involves the issue of generalizability. When we're concerned about an accurate portrayal of reality, we use tools to assess validity. When we don't agree about the adequacy of the tools we use to assess validity, sometimes the source of our disagreements is different views on scientific objectivity.
5. We also agree that objectivity merits consideration, although we don't agree on the role of objectivity or our capabilities to be objective in our research. Some social scientists contend that our inquiries must be objective to have credibility. In a contrasting view of social science, or epistemology, objectivity is not possible and, according to some, not preferable. Given that we study people and are human ourselves, it is important that we recognize that life experiences necessarily shape the lens through which people see reality.

Besides a lack of consensus within the social sciences, other skeptics challenge our measures and methods. In

what some recently have labeled "the science wars," external critics contend that social scientists suffer "physics envy" and that human behavior is not amenable to scientific investigation. Social scientists have responded to "anti-science" sentiments from the very beginning, such as Emile Durkhiem's efforts in the 19th century to identify "social facts." As entertaining as some of the debates and mudslinging can be, they are unlikely to be resolved anytime soon, if ever. One reason that Lazarsfeld and Rosenberg contend that tolerance and appreciation for different methodological pathways make for better science is that no individual scientist can have expertise in all the available options. We recognize this now more than ever, as multidisciplinary teams and collaborations between scientists with diverse methodological expertise are commonplace, and even required by some sources of research funding.

Meanwhile, people who can be our research subjects continue to behave in ways that intrigue, new strategies are proffered to reduce social problems and make life better, and the tool kits or arsenals available to social scientists continue to grow. The entries in these volumes provide useful information about how to accomplish social measurement and standards or "rules of thumb." As you learn these standards, keep in mind the following advice from one of my favorite methodologists: "Avoid the fallacy fallacy. When a theorist or methodologist tells you you cannot do something, do it anyway. Breaking rules can be fun!" Hirschi (1973, pp. 171–2). In my view nothing could be more fun than contemporary social science, and I hope this encyclopedia will inspire even more social science inquiry!

In preparing this encyclopedia the goal has been to compile entries that cover the entire spectrum of measurement approaches, methods of data collection, and techniques of analysis used by social scientists in their efforts to understand all sorts of behaviors. The goal of this project was ambitious, and to the extent that the encyclopedia is successful there are many to people to thank. My first thank you goes to the members of the Executive Advisory Board and the Editorial Advisory Board who helped me to identify my own biased views about social science and hopefully to achieve greater tolerance and appreciation. These scientists helped identify the ideal measurement topics, locate the experts and convince them to be authors, review drafts of the articles, and make the difficult recommendations required by time and space considerations as the project came to a close. My second thank you goes to the many authors of these 356 entries. Collectively, these scholars represent well the methodological status of social science today. Third, I thank the many reviewers whose generous recommendations improved the final product. In particular I extend my personal thanks to colleagues at the University of Texas at Dallas, many of whom participated in large and small roles in this project, and all of whom have helped me to broaden my appreciation of social

measurement. Finally, I thank Scott Bentley, Kirsten Funk, Kristi Anderson, and their colleagues at Elsevier for the opportunity and their encouragement when the tasks seemed overwhelming. Scott's insights to the possibilities of a project such as this and the administrative prowess of both Kirsten and Kristi helped make this a reality.

Good science is a cumulative process, and we hope this project will be ongoing and always improving. Despite our best efforts to identify topics and authors, sometimes we

failed. If you have suggestions, criticisms, or information worth considering, I hope you will let me know.

Glossary

communality Variance of a variable accounted for by the factors.

factor Latent variable that determines to a considerable extent the values of the observed variables.

factor loading Weight indicating the direct influence of a factor on a variable.

factor structure Matrix of covariances between factors and variables. If the variables are standardized, then the factor structure matrix contains correlations rather than covariances.

oblique rotation Factor transformation designed to achieve a simple interpretation of the factors.

orthogonal rotation Factor transformation designed to achieve a simple interpretation of mutually uncorrelated factors.

uniqueness Amount of variable variance unrelated to factors.

Factor analysis is a multivariate statistical technique for finding theoretical concepts that underlie the association between observed variables. To this end, the factor model introduces latent variables, commonly referred to as factors, and posits that the observed variables are determined, except for random error, by these factors. Factor analysis is particularly well-suited to psychology, wherein concepts such as “intelligence” can be observed only indirectly—for instance, by noticing which test problems an individual is able to solve correctly.

Introduction

Spearman noted in 1904 that measures of performance for certain cognitive tasks are often positively correlated. If an individual performs well on, say, an intelligence-related task, he or she also tends to do well on similar tasks. To explain this phenomenon, Spearman introduced a general ability factor, commonly referred to as the g-factor, that he claimed determines performance of intelligence-related tasks to a considerable extent, albeit not completely. Thus, positive correlations between intelligence-related tasks were explained by Spearman in terms of the g-factor’s influence on each of these tasks. During the first half of the 20th century, factor analysis developed rapidly from a substantive theory on intelligence into a general statistical procedure. An early comprehensive account of factor analysis was given in 1947 by Thurstone.

The main idea of factor analysis is to “explain” correlations between observed variables in terms of a few unobservable variables, commonly called factors or latent variables. It will be convenient to refer to the observable and unobservable variables simply as variables and factors, respectively. More specifically, the model states that the factors determine the variables in such a way that when holding the factors constant, the residual variation of the variables is uncorrelated. If the number of factors needed to explain the correlations is “small,” compared to the number of variables, then the factor model is appealing because the associations between the variables can be explained in a parsimonious manner.

Factor analysis is used if latent variables are assumed to underlie the association among the variables, but the

conceptual nature of the factors is unclear before fitting the factor model to data. Because the purpose of factor analysis is to clarify the nature of the factors, one also speaks of exploratory factor analysis as opposed to confirmatory factor analysis, a closely related statistical technique that requires specific *a priori* assumptions about the factors and their relationships to the variables. Although in practice the factor model is almost always fitted to the sample correlation matrix, it is common to discuss the model in terms of the sample covariance matrix. This convention is followed here. Finally, note that factor analysis is different from principal component analysis. Although these two statistical techniques are frequently confused, they address different issues. While factor analysis explains observed correlations in terms of latent factors, principal component analysis is a data reduction technique that yields linear composites of the observed variables referred to as “components.”

The Factor Model

Consider p variables, each having zero expectation, that is, $E(x_i) = 0$, $i = 1, \dots, p$. The factor model states that the conditional expectation of each variable is a linear function of q factors, ξ_1, \dots, ξ_q . In other words, the factor model claims

$$E(x_i | \xi_1 \dots \xi_q) = \lambda_{i1}\xi_1 + \dots + \lambda_{iq}\xi_q,$$

for $i = 1, \dots, p$. The factor loadings, λ_{ij} , are regression coefficients that indicate the expected change in the i th variable that is related to a unit change in the j th factor, holding all other factors constant. Thus, the loadings measure the direct influence of a factor on the variables. Expressing the equations of all variables simultaneously in a single equation using matrix notation yields

$$E(\mathbf{x} | \boldsymbol{\xi}) = \mathbf{A}\boldsymbol{\xi}, \quad (1)$$

where \mathbf{x} is a $(p \times 1)$ vector of random variables that have zero mean, $\boldsymbol{\xi}$ is a $(q \times 1)$ vector of random factors, and $\mathbf{A} = (\lambda_{ij})$ is a $(p \times q)$ matrix of factor loadings.

In addition to Eq. (1), the factor model makes two further assumptions. First, as has been mentioned, the variables are assumed to be uncorrelated when controlling for the factors. If the conditional covariance matrix is denoted as $\boldsymbol{\Psi}$, that is, $\boldsymbol{\Psi} = \text{Var}(\mathbf{x} | \boldsymbol{\xi})$, then this assumption can be expressed as $\boldsymbol{\Psi} = \text{diag}(\psi_{11}, \dots, \psi_{pp})$. The ψ -parameters are referred to as uniquenesses. Second, the model assumes $E(\xi_j) = 0$ and $\text{Var}(\xi_j) = 1$, for $j = 1, \dots, q$. This assumption removes the arbitrariness in the scales of the factors and does not restrict the generality of the factor model.

Defining the residual vector as $\boldsymbol{\epsilon} = \mathbf{x} - E(\mathbf{x} | \boldsymbol{\xi})$, it is not difficult to see that $\boldsymbol{\Psi} = \text{Var}(\boldsymbol{\epsilon})$. Both specific factors and

measurement error may contribute to the residual term. However, because the factor model does not allow for the separation of these two sources of observed score variability, we do not distinguish between them.

From Eq. (1) and the preceding assumptions, it follows that the covariance matrix of the variables is

$$\boldsymbol{\Sigma} = \mathbf{A}\boldsymbol{\Phi}\mathbf{A}' + \boldsymbol{\Psi}, \quad (2)$$

where $\boldsymbol{\Phi} = (\phi_{ij})$ denotes the correlation matrix of the factors. Equation (2) shows that each variable's variance is the sum of two separate sources. One source encompasses the influences of specific factors and measurement error and is referred to as the variable's uniqueness, ψ_{ii} . The other source, commonly referred to as the variable's communality, h_i^2 , is the influence the factors have on determining the variable values. More specifically, the communality is defined as $h_i^2 = \text{Var}(E(x_i | \boldsymbol{\xi}))$ and is given in terms of the model parameters by the i th diagonal element of $\mathbf{A}\boldsymbol{\Phi}\mathbf{A}'$.

The covariance between factors and variables,

$$\text{Cov}(\mathbf{x}, \boldsymbol{\xi}) = \mathbf{A}\boldsymbol{\Phi}, \quad (3)$$

is called the factor structure. Specializing this expression to a variable–factor pair yields $\text{Cov}(x_i, \xi_j) = \lambda_{i1}\phi_{1j} + \dots + \lambda_{iq}\phi_{qj}$. The covariances of the factor structure matrix do not control for other factors. This means that even if a particular variable has a zero loading on, say, the first factor, it still can be correlated with the first factor because of indirect effects. Specifically, if the variable loads on a factor that is also correlated with the first factor, the variable will be correlated with the first factor despite its zero loading on this factor. Also note that for standardized variables, the factor structure matrix gives the correlations rather than the covariances between the factors and the variables.

An important special case occurs if the factors are uncorrelated, that is, $\boldsymbol{\Phi} = \mathbf{I}$. In this case, the factors are said to be orthogonal and several of the preceding equations simplify. First, the communality of the i th variable reduces to $h_i^2 = \lambda_{i1}^2 + \dots + \lambda_{iq}^2$. Second, the factor structure matrix [see Eq. (3)] is equal to the factor loading matrix, that is, $\text{Cov}(\mathbf{x}, \boldsymbol{\xi}) = \mathbf{A}$. Thus, if the factors are orthogonal, a zero loading will imply a zero covariance between the corresponding variable–factor pair. Again, note that for standardized variables, the λ parameters represent correlations rather than covariances between variables–factor pairs.

Estimating the Model Parameters

Before discussing approaches to estimating the factor loadings, it should be noted that factor loadings are not uniquely defined. If \mathbf{T} is a nonsingular $(q \times q)$ matrix such that $\text{diag}(\mathbf{T}\boldsymbol{\Phi}\mathbf{T}') = \mathbf{I}$, then $\boldsymbol{\xi}^* = \mathbf{T}\boldsymbol{\xi}$ will be an equally

legitimate set of factors with $\Lambda^* = \Lambda \mathbf{T}^{-1}$. This follows because the assumptions of the factor model are also fulfilled by the new factors ξ^* and the fact that the conditional expectation of the variables is invariant to this transformation. This is easily seen by noting that $E(\mathbf{x} | \xi^*) = \Lambda^* \xi^* = (\Lambda \mathbf{T}^{-1})(\mathbf{T} \xi) = \Lambda \xi = E(\mathbf{x} | \xi)$. When the factors are uncorrelated, the set of legitimate transformation matrices \mathbf{T} is limited to orthogonal matrices, which fulfill the condition $\mathbf{T} \mathbf{T}' = \mathbf{I}$. In order to obtain a solution for the factor loadings, it is desirable to remove this indeterminacy. This can be achieved if the factors are uncorrelated, that is, $\Phi = \mathbf{I}$, and if the so-called canonical constraint, which requires $\Lambda' \Psi^{-1} \Lambda$ to be diagonal, is satisfied.

Having imposed sufficient model restrictions to define the parameters uniquely, the degrees of freedom (df) can be determined. The degrees of freedom are equal to the difference between the $p(p+1)/2$ freely varying elements in the unconstrained population covariance matrix Σ and the number of unrestricted model parameters. The degrees of freedom characterize the extent to which the factor model offers a simple explanation of the correlations among the variables. A necessary condition for the identification of the model parameters is $df \geq 0$. Clearly, if the factors are uncorrelated, all model parameters are either loadings or uniquenesses and the total number of model parameters is $pq + p$. Because the canonical constraint introduces $q(q-1)/2$ restrictions on the model parameters, the degrees of freedom are

$$\begin{aligned} df &= p(p+1)/2 - [pq + p - q(q-1)/2] \\ &= (1/2)[(p-q)^2 - (p+q)]. \end{aligned} \quad (4)$$

Estimation procedures may yield negative estimates for the ψ parameters that are outside the permissible range. Such inadmissible solutions are commonly referred to as Heywood cases. Heywood cases occur quite frequently in practice. A simple strategy of dealing with negative uniquenesses is to set them equal to zero. However, this strategy implies an unrealistic model characteristic, namely, that the factors perfectly explain the variation of the variables having zero uniquenesses. Finally, note that methods for estimating the factor loadings assume that the number of factors is known.

Maximum-Likelihood Factor Analysis

When estimating the factor loadings by maximum-likelihood, a multivariate normal distribution is assumed to underlie the variables. The maximum-likelihood estimates of loadings and uniquenesses are obtained from minimizing the discrepancy function

$$F(\Lambda) = \log |\Sigma| + \text{trace}(\mathbf{S} \Sigma^{-1}), \quad (5)$$

where \mathbf{S} denotes the usual sample covariance matrix and $\Sigma = \Lambda \Lambda' + \Psi$. Note that the expression for Σ differs

from that in Eq. (2) because of the requirement $\Phi = \mathbf{I}$ discussed previously. Minimization of Eq. (5) with respect to the λ and ψ parameters requires iterative numerical methods.

If the assumptions underlying maximum-likelihood estimation are met, then this parameter estimation method has several desirable properties. First, it provides a likelihood-ratio statistic for testing the hypothesis that a particular number of factors is sufficient to describe the sample covariance matrix adequately. Second, standard errors for the loadings can be derived that allow testing of whether the loadings are different from zero. Third, the solution is scale-free in the sense that the results obtained from analyzing the correlation matrix can be obtained by rescaling the results obtained from analyzing the covariance matrix, and vice versa. A drawback of maximum-likelihood factor analysis is that the sample covariance matrix has to be of full rank.

Principal-Axis Factor Analysis

Principal-axis factoring starts by considering the matrix $\mathbf{S}_r = \mathbf{S} - \tilde{\Psi}$, where $\tilde{\Psi}$ contains initial estimates of the uniquenesses. One popular method of obtaining these initial estimates is to calculate $\tilde{\psi}_{ii} = s_{ii}(1 - R_i^2)$, where s_{ii} is the i th variable's variance and R_i^2 is the squared multiple correlation coefficient obtained from a regression of x_i on the remaining variables.

Because \mathbf{S}_r is symmetric, it is possible to write $\mathbf{S}_r = \mathbf{\Gamma} \mathbf{\Theta} \mathbf{\Gamma}'$, where the columns of $\mathbf{\Gamma}$ contain p eigenvectors of \mathbf{S}_r and $\mathbf{\Theta} = \text{diag}(\theta_1, \dots, \theta_p)$ contains the corresponding eigenvalues $\theta_j, j = 1, \dots, p$. Without loss of generality, the eigenvalues can be assumed ordered such that $\theta_1 \geq \theta_2 \geq \dots \geq \theta_p$. Note that some of these eigenvalues may be negative. Let the number of positive eigenvalues be greater or equal to q , then $\Lambda_q = \mathbf{\Gamma}_q \text{diag}(\theta_1^{1/2}, \dots, \theta_q^{1/2})$ can be defined, where $\mathbf{\Gamma}_q$ contains the first q columns of $\mathbf{\Gamma}$.

If one defines $\tilde{\Sigma} = \Lambda_q \Lambda_q'$, then it can be shown that this matrix minimizes the least-squares discrepancy function

$$F(\Lambda) = \text{trace}[(\mathbf{S}_r - \tilde{\Sigma})^2] \quad (6)$$

for fixed q . In other words, \mathbf{S}_r can be optimally approximated in the least-squares sense by $\Lambda_q \Lambda_q'$, and therefore \mathbf{S} is closely approximated by $\Lambda_q \Lambda_q' + \tilde{\Psi}$. It is possible to iteratively apply this procedure. Having estimated Λ_q using the procedure just explained, the initial estimate of $\tilde{\Psi}$ can be updated by calculating $\tilde{\Psi} = \text{diag}(\mathbf{S} - \Lambda_q \Lambda_q')$. An updated \mathbf{S}_r matrix can then be calculated that leads to a new estimates of Λ_q . The iteration is continued in this manner until the change in the factor loadings across successive iterations becomes negligible. Minimizing Eq. (6) has been recommended as more likely to find real but small factors when

compared to the number of factors extracted from minimizing the maximum-likelihood discrepancy function [see Eq. (5)].

Determining the Number of Factors

Approaches to estimating the factor loadings require the number of factors to be known. However, this is hardly ever the case in practice. Therefore, starting with a one-factor model, models are fitted to the data, increasing the number of factors sequentially by one.

If the factor model has been fitted by maximum likelihood and the variables follow a multivariate normal distribution, a likelihood-ratio test can be used to test whether a specific number of factors is sufficient to explain the sample covariances. The null hypothesis states that at most q factors underlie the sample covariances. If H_0 is true, the test statistic follows asymptotically a chi-squared distribution, with degrees of freedom given by Eq. (4). A drawback of the likelihood-ratio test is that the number of significant factors will be overestimated if the factor model is only approximately true, especially when sample size is large. In addition, if several models are estimated by varying the number of factors, the test procedure is open to criticism because of an inflated type-one error rate due to multiple testing. Therefore, it is useful to consider two other commonly used rules of thumb for deciding on the number of factors that do not require specific distributional assumptions. However, both rules apply only if the sample correlation matrix \mathbf{R} rather than the sample covariance matrix \mathbf{S} is used to fit the factor model.

The first rule is based on the eigenvalues of \mathbf{R} . Because only a few of these eigenvalues will be larger than 1.0, this rule states that the number of factors should equal the number of eigenvalues greater than 1.0. The second rule for choosing the number of factors is a visual plotting procedure called the scree test, which plots the ordered eigenvalues against their rank. Ideally, the decreasing trend in the eigenvalues exhibited by this plot has a clifflike shape. Such a shape results if only the first few eigenvalues are “large” and the remaining eigenvalues exhibit a linear decreasing trend, representing the “scree.” It has been recommended to retain as many factors as there are eigenvalues too large to be considered part of the scree. Although there is no mathematical rationale behind this procedure, the validity of the scree test has become accepted in standard factor analysis books. A drawback of the scree test is that it may be difficult sometimes to determine by visual inspection whether a particular eigenvalue should be considered large or small. To remedy the subjectivity involved in the scree

test, there is a statistical test for the hypothesis, that the decrease in a set of eigenvalues follows a linear trend. Finally, note that the criteria discussed in this section may not agree when applied to a particular data set. In these cases, researchers may want to decide on the number of factors by taking substantive knowledge into consideration.

Rotating Factors to Simple Structure

Because the estimated factor loadings are based on arbitrary constraints used to define uniquely the model parameters, the initial solution may not be ideal for interpretation. Recall that any factor transformation $\xi^* = \mathbf{T}\xi$ for which $\text{diag}(\mathbf{T}\Phi\mathbf{T}') = \mathbf{I}$ is an equally legitimate solution to Eq. (1). To simplify interpretation, it is desirable to rotate the factor loading matrix to simple structure, which has been defined in terms of five criteria: (1) each row of $\mathbf{\Lambda}$ should have at least one zero; (2) each of the q columns of $\mathbf{\Lambda}$ should have at least q zeros; (3) for every pair of columns of $\mathbf{\Lambda}$, there should be several variables with a zero loading in one column but not in the other; (4) for every pair of columns of $\mathbf{\Lambda}$, there should be a considerable proportion of loadings that are zero in both columns if $q \geq 4$; and (5) for every pair of columns of $\mathbf{\Lambda}$, only few variables should have nonzero loadings in both columns. Rotation techniques differ according to their emphasis on particular simple structure criteria.

Generally, a distinction is made between orthogonal and oblique rotation techniques, which yield uncorrelated or correlated factors, respectively. If the substantive concepts identified by the factors are related, correlated factors are appealing because they allow for a more realistic representation of the concepts, as compared to orthogonal factors.

One of the most popular orthogonal rotation methods is the varimax approach. This approach aims at finding a loading pattern such that the variables have either large (positive or negative) loadings or loadings that are close to zero. The varimax approach tries to accomplish this loading pattern by maximizing the variance of the squared loadings for each factor. Another popular orthogonal rotation techniques is the quartimax rotation, which maximizes the variance of the squared factor loadings in each row.

One of the most common oblique rotation techniques is the promax approach. This approach improves the loading pattern obtained from an orthogonal rotation in the sense of further increasing large loadings and further decreasing small loadings. Varimax rotation is commonly used as prerotation to promax. The promax approach accomplishes this goal in two steps. First a “target” matrix

is obtained from the normalized loading matrix by replacing each factor loading by its k th power. For even powers, the signs of the loading matrix elements carry over to the corresponding target matrix elements. Common values for k are 3 and 4. Second, the orthogonal factors are rotated such that the variable loadings are, in the least-squares sense, as close as possible to the corresponding elements of the target matrix.

Predicting the Factor Scores

Because the factor model assumes that the variables are determined to a considerable extent by a linear combination of the factors $\xi_{i1}, \dots, \xi_{iq}$, it is often of interest to determine the factor scores for each individual. Two approaches to predicting factor scores from the variable raw scores are discussed here. Both approaches assume variables and factors to be jointly normally distributed.

The so-called regression factor scores are obtained as

$$\hat{\xi} = \Phi \Lambda' \Sigma^{-1} \mathbf{x}.$$

It can be shown that this predictor minimizes the average squared prediction error, $E\{\sum_{j=1}^q (\hat{\xi}_j - \xi_j)^2\}$, among all factor score predictors that are linear combinations of the variables.

The Bartlett factor score predictor is given by

$$\hat{\xi} = (\Lambda' \Psi^{-1} \Lambda)^{-1} \Lambda' \Psi^{-1} \mathbf{x}.$$

This expression also minimizes the average squared prediction error among all factor score predictors that are linear combinations of the variables. In addition, the Bartlett factor score predictor is conditionally unbiased, that is, $E(\hat{\xi} | \xi) = \xi$. Notice that when calculating the factor scores, the matrices Λ and Ψ are replaced by their estimates. In these cases, the optimum property

under which the predictors have been derived may not apply. The formula for the Bartlett factor scores can be expressed equivalently when Ψ is replaced with Σ . An advantage of this formulation is that the factor scores can be calculated even if Ψ is singular, which may occur if uniquenesses are zero (Heywood case).

The use of factor scores is problematic because the factor loadings and the factor intercorrelations cannot be defined uniquely. The predicted factor scores will depend on the selected rotation procedure; therefore, factor scores resulting from different rotation procedures may rank order individuals differently. In addition, factor scores are problematic to use as independent variables in regression models because their values differ from the true values, which typically leads to bias in the regression coefficients.

Example

Generally, the results from a factor analysis of a correlation matrix and the corresponding covariance matrix are not identical. When analyzing a covariance matrix, variables having large variance will influence the results of the analysis more than will variables having small variance. Because the variances of the variables are intrinsically linked to the measurement units, it is preferable to analyze standardized variables, which is equivalent to fitting the factor model based on the correlation matrix, if the variables have been measured using different units.

Factor analysis can be illustrated using the artificial data set given in Table I. The data set contains standardized performance scores of 10 individuals obtained from an algebra problem, a trigonometry problem, a logic puzzle, a crossword puzzle, a word recognition task, and a word completion task. The correlation matrix of

Table I Standardized Raw Scores of Six Performance Measures^a

Observation	x_1	x_2	x_3	x_4	x_5	x_6
1	-0.697	-0.700	-1.268	-2.245	-1.973	-1.674
2	-1.787	-1.538	-2.018	0.486	-0.163	-0.065
3	0.206	-0.913	0.079	0.801	0.964	1.043
4	-0.191	-0.430	1.074	0.002	-0.071	-0.159
5	-0.606	-0.225	0.296	-0.602	-0.990	-1.174
6	0.171	-0.417	-0.620	-0.519	0.694	0.648
7	1.460	1.038	0.532	1.261	-0.364	0.848
8	-0.639	0.888	0.306	-0.372	-0.305	1.101
9	0.779	1.595	0.775	0.499	1.215	-1.055
10	1.304	0.702	0.844	0.688	0.992	0.488

^aThe performance measures (x_1 – x_6) are scores obtained on six tests: an algebra problem, a trigonometry problem, a logic puzzle, a crossword puzzle, a word recognition task, and a word completion task.

the six performance measures calculated from the raw data of Table I is

$$\mathbf{R} = \begin{pmatrix} 1.0 & 0.7 & 0.7 & 0.5 & 0.5 & 0.3 \\ 0.7 & 1.0 & 0.7 & 0.3 & 0.3 & 0.1 \\ 0.7 & 0.7 & 1.0 & 0.4 & 0.4 & 0.2 \\ 0.5 & 0.3 & 0.4 & 1.0 & 0.7 & 0.6 \\ 0.5 & 0.3 & 0.4 & 0.7 & 1.0 & 0.5 \\ 0.3 & 0.1 & 0.2 & 0.6 & 0.5 & 1.0 \end{pmatrix}.$$

It is hoped that subjecting this matrix to factor analysis will explain the correlations between the performance scores in terms of a small number of factors having easily interpretable relations to the tasks. First, the number of factors has to be determined. The eigenvalues of the sample correlation matrix are 3.34, 1.35, 0.47, 0.30, 0.28, and 0.26. Clearly, if the criterion to retain as many factors as there are eigenvalues greater than 1.0 is employed, two factors are retained. The scree plot in Fig. 1 confirms this conclusion. Clearly, the “small” eigenvalues appear to decrease linearly.

Finally, because the factor model has been fitted by maximum likelihood, the likelihood-ratio test can be used to evaluate the hypothesis that two factors are sufficient to explain the sample correlations. The test statistic yields a value of 0.0334 that can be compared against a suitable quantile of the chi-square distribution based on $df = 4$. If the nominal type-one error rate is set to 0.05, this test does not provide evidence against the null hypothesis. As a result, for this artificial data set, all three criteria for determining the number of factors agree.

Figure 1 Scree plot depicting the ordered eigenvalues plotted against their rank. “Small” eigenvalues follow a linear decreasing trend.

Table II Maximum-Likelihood Estimates of Factor Loadings before Rotation and after Varimax and Promax Rotation

Variable	Rotation method					
	Unrotated		Varimax		Promax	
	ξ_1	ξ_2	ξ_1	ξ_2	ξ_1	ξ_2
x_1	0.828	-0.226	0.781	0.356	0.758	0.184
x_2	0.711	-0.489	0.860	0.079	0.920	-0.141
x_3	0.754	-0.335	0.794	0.225	0.807	0.037
x_4	0.746	0.486	0.263	0.851	0.055	0.864
x_5	0.693	0.373	0.294	0.730	0.123	0.722
x_6	0.482	0.485	0.061	0.681	-0.120	0.731

Next the focus is on the interpretation of the factors. Table II contains the factor loadings for the unrotated factors, the factor loadings after varimax rotation, and the factor loadings after promax rotation (the target matrix is created using $k = 3$ and varimax rotation). Because the maximum-likelihood estimates of the loadings on the unrotated factors satisfy the canonical constraint, the unrotated loadings are typically not of substantive interest. However, note that maximum-likelihood factor analysis together with the constraint $\mathbf{\Lambda}'\mathbf{\Psi}^{-1}\mathbf{\Lambda}$ is equivalent to Rao’s canonical factor analysis. Because the orthogonal varimax rotation and the oblique promax rotation attempt to provide loadings that fulfill Thurstone’s simple structure criteria, these loadings are more useful for interpretation.

First, consider the factor loadings after varimax rotation. Because varimax is an orthogonal rotation, the loadings can be interpreted as correlations between the variables and the factors. Based on the pattern of these loadings, each of the six variables can be identified with one and only one of the factors. Variables x_1 , x_2 , and x_3 are considerably influenced by the first factor whereas variables x_4 , x_5 , and x_6 are mainly determined by the second factor. Because the first three variables involve cognitive processing of formal and abstract material, it may be desirable to label the first factor as “formal ability” or “mathematical ability.” Similarly, because the last three variables, which involve cognitive processing of verbal material, load highly on the second factor, it may be convenient to label the second factor “verbal ability.”

Based on the loadings from the oblique promax rotation, the conclusions about the direct influence of the factors on the variables are essentially the same as before. Overall, the comparison between the loadings from the orthogonal and the oblique rotation shows that the relationships between the factors and the variables have become clearer by allowing for correlated factors. Based on the promax rotation, the correlation between the factors is estimated to be moderately high—specifically, $\phi_{12} = 0.46$.

It is also interesting to consider the factor structure matrix, which for correlated factors gives the correlations between the variables and the factors. Using the factor

Figure 2 Loadings of variables on unrotated and rotated axes. The left-hand panel depicts the loadings with respect to the unrotated and varimax-rotated factors. The right-hand panel depicts the loadings with the respect to the unrotated and promax-rotated axes.

loadings from the promax rotation, the factor structure matrix is

$$\text{Corr}(\mathbf{x}, \boldsymbol{\xi}) = \begin{pmatrix} 0.843 & 0.534 \\ 0.855 & 0.285 \\ 0.824 & 0.411 \\ 0.455 & 0.889 \\ 0.457 & 0.779 \\ 0.218 & 0.676 \end{pmatrix}.$$

This matrix shows that because of the factor inter-correlation, a small factor loading does not necessarily imply a small correlation between the corresponding variable–factor pair. In fact, the correlations in the factor structure matrix that correspond to small factor loadings have a moderately high value.

For the present example, factor rotation can be illustrated graphically. The left-hand panel of Fig. 2 depicts the loadings with respect to both the unrotated factors (solid lines) and the factors after varimax rotation (dashed lines). The right-hand panel of Fig. 2 depicts the loadings with respect to both the unrotated factors (solid lines) and the factors after promax rotation (dashed lines).

Finally, both the regression factor scores and the Bartlett factor scores are given in Table III. These scores are based on the results of the promax rotation. Because the factor scores are centered, positive and negative values can be interpreted as being above and below average, respectively. From Table III, the first individual appears to be considerably below average in terms of both math and verbal abilities. The second individual is considerably below average for math ability but about average for verbal ability. The factor scores of the other individuals

Table III Regression and Bartlett Factor Scores Calculated from the Result of a Maximum-Likelihood Factor Analysis after Promax Rotation

Observation	Factor score			
	Regression		Bartlett	
	ξ_1	ξ_2	ξ_1	ξ_2
1	−1.008	−2.122	−0.994	−2.463
2	−1.764	0.093	−2.076	0.300
3	−0.230	0.968	−0.356	1.197
4	0.070	−0.014	0.083	−0.024
5	−0.244	−0.846	−0.211	−0.998
6	−0.296	0.036	−0.351	0.075
7	1.065	0.862	1.173	0.931
8	0.187	−0.199	0.237	−0.261
9	1.214	0.389	1.389	0.342
10	1.007	0.833	1.107	0.902

may be interpreted similarly. Although there are small discrepancies between the regression factor scores and the Bartlett factor scores, overall they appear to agree well for this data set.

Glossary

Bayesian inference A use of Bayes' theorem relating conditional and unconditional probabilities, by which it has sometimes been hoped to interrelate objective and subjective probabilities.

falsification Any method by which scientific claims are evaluated by empirical disconfirmation.

induction Any method for confirming general scientific laws or theories by appealing to the accumulation of specific experimental observations.

methodological pluralism The position according to which diverse methods, perhaps having different ontological implications, may nevertheless be legitimate means of discovering scientific truths.

positivism A philosophy of science according to which scientific observation is independent of theoretical commitments and science does and should rest on a secure empirical foundation.

Quine–Duhem thesis The position according to which the meaning or truth of statements cannot be determined individually, but only holistically.

scientific method Any means by which scientific truths are reliably obtained and scientific claims are evaluated.

underdetermination The condition in which two or more mutually inconsistent theories can equally account for the same data and for which evidence alone does not determine theory selection.

Falsification originated in the problem of determining scientific truth. Answers based on induction and on the confirmation of hypotheses were discovered to have theoretical and practical problems. Falsification was proposed as an alternative answer, in terms of which science

can rest on a secure foundation, provided that its hypotheses and theories are required to be subject to possible empirical falsification. Contemporary views of falsification vary greatly. In the philosophy of science, it is seen chiefly in logical and historical terms. In introductory social science texts on methodology, it is often seen as a way to reduce scientists' self-imposed biases that reflect theoretical preferences. Accordingly, in texts on rigorous, quantitative methodology, falsification tends to be praised either explicitly or implicitly as an essential part of the scientific method. Alternatively, in texts on qualitative research methods, it is sometimes described as a largely unhelpful or even counterproductive method. In social science practice, there is often an appeal to informal falsification, along with parsimony, as key evaluative criteria by which theories and empirical claims about truth can be evaluated. In theories of choice, decision making, and rational judgment, humans are seen as hypothesis-testing organisms who, in some contexts, may use an intuitive form of falsification. In mathematical statistics, many alternatives have been developed in response to the somewhat counterintuitive, negative logic of falsification. Similarly, the philosophical context from which falsification is viewed has broadened, so that to some scholars, positivism, within which falsification developed, is often seen as only a historical phase in the development of the philosophy of science. To other scholars, the scientific method is seen as successfully applying to the physical sciences but not to the social sciences. Most radically, some scholars see the scientific method within which falsification is defined as an unworkable method and in any case as a political tool. This constructionist and historicist view is compatible with the increasing use of narratives and other qualitative methods in sociological,

anthropological, and psychological research methods. How the tension between this approach and the traditional scientific method will be resolved remains to be seen.

Introduction and Overview

Falsification is often viewed as central to the scientific method, essential for correct experimental design, and thus required for scientific progress. It is a view strongly associated with Karl Popper's argument that a genuine scientific claim must be subject to a critical empirical test. According to this view, science ideally proceeds by formulating hypotheses that are subject to empirical testing in such a way that the results could, in principle, show the hypotheses to be false. The critical empirical test should have two conceivable outcomes, one that is compatible with the hypothesis, and one that disconfirms it. Hypotheses that are not falsifiable in principle may be seen, according to this view, as having some potential heuristic value, but having no factual scientific status. Such unfalsifiable hypotheses belong merely to prescientific or pseudoscientific endeavors. From this perspective, falsification is designed as a tool to ensure that scientific claims are grounded in empirical observation, rather than in entrenched theoretical or ideological commitments. Falsification is an attempt to overcome various methodological problems in earlier views of science that were based in induction. These problems include worries about the effectiveness of induction, deriving from the underdetermination of theory by confirming evidence. Falsification, however, faces its own set of problems. Among these is that falsification does not accurately describe the historical practice of scientific discovery or justification. Neither can it account for how evidence can, in practice, falsify any hypothesis at all, given that any hypothesis can always be saved by ad hoc hypotheses, or even by the outright rejection of seemingly falsifying evidence. Perhaps a more sophisticated version of falsification can avoid some or all of these problems; on purely logical grounds, however, falsification seems no better than induction as a means for promoting scientific progress.

In the social sciences, falsification has both defenders and detractors. Proponents accept falsification as an essential part of the scientific method. This is sometimes explicitly stated in introductory social science texts, and it is often implicit in experimental design and in the context of hypothesis testing in inferential statistics, where "negative logic" may be used to test a null hypothesis according to which a variable is hypothesized to have no effect. Opponents, on the other hand, point to the methodological and conceptual problems mentioned previously. These problems with falsification have

motivated the development of many alternative methodologies, some of them explicitly designed to preserve some of the logic of induction. In addition, some detractors argue that applying falsification to the social sciences is fundamentally illegitimate because it relies more on the quantitative methods and logic of the physical sciences, whereas its requirements are not met by the social sciences that do or should rely on qualitative and interpretive methods. Despite these criticisms, falsification retains a substantial presence in social science method and theory. This persistence of falsification in the social sciences raises a number of questions regarding the sociology of science as well as the possibility of a legitimate methodological pluralism in the social sciences.

Origins of Falsification

Induction and Scientific Method

Falsification originated in part as a response to various problems raised by earlier views of scientific methods based on induction. Induction has the intuitively desirable property that data that agree with a scientific hypothesis support or confirm that hypothesis. Few claims about scientific method seem more natural to a beginning science student. For example, suppose it is predicted that it will rain if the temperature falls below the dew point. To many students, it seems reasonable that there is confirmation of the prediction when the temperature falls below the dew point and it indeed starts to rain. From the perspective of induction, science progresses by the formulation of a hypothesis and the collection of sufficient empirical data that agree with the hypothesis. When accumulated evidence consistent with the hypothesis is sufficient, the hypothesis is confirmed. Although this account is oversimplified, insofar as induction exists in sophisticated forms, the goal of induction may be simply stated as the confirmation of scientific claims by the accumulation of data that agree with those claims.

Problems with Induction

Both theoretical and practical problems have been identified with induction. Consider the problem that arises if scientific method were based on induction: A universal empirical claim such as "All crows are black," or "Rate of information processing is a linear function of uncertainty," could never be conclusively verified, because it is unclear what finite amount of evidence could ever confirm its truth. Similarly, a probabilistic empirical claim faces the same problem. No finite amount of evidence could conclusively confirm the objective accuracy of a claim such as, "Most crows are black," or "Rate of information processing varies randomly but is on the

average a linear function of uncertainty.” In social science practice, of course, statements such as these are made in the context of additional assumptions that specify experimental and observational requirements. Nevertheless, the problem remains the same. But more damaging is that induction in general requires inferences from a sample of evidence. As Hume observed in 1739, the only reason to accept an inductive generalization as reliable is based on accepting a principle of reasoning—the future will be like the past, similar causes have similar effects, etc.—which is inherently either not subject to empirical confirmation or employs an inductive method to justify itself. The justification for induction therefore is subject to vicious circularity. Thus, if science rests on induction, it would appear that science involves a fundamental irrationality. Even if this skepticism about induction could somehow be satisfactorily overcome, there would remain the problem of underdetermination. Evidence underdetermines hypotheses in the sense that hypotheses or theories established by an accumulated amount of inductive support, aside from not being conclusively verified, are not uniquely confirmed. For any finite set of data, there is no unique hypothesis that is consistent with that data. It is always possible that two or more theories or hypotheses, each logically inconsistent with the others, will be equally consistent with the supporting data. That is to say, inductive support by data, by itself, never logically suffices to permit a scientist to choose between competing theories that are equally consistent with the data. Other criteria, including parsimony, explanatory power, esthetic qualities, perceived heuristic power, perceived social utility, and political and social values, are needed to supplement an inductive method of choosing between theories. But these additional evaluative criteria are obviously based on exactly the kinds of arbitrary, personal, subjective, potentially irrational human values science conventionally hopes to avoid.

Falsification as a Solution to the Problems of Induction

Falsification aims to overcome these problems with induction. According to falsification, the hallmark of scientific methodology is not that it uses observation or empirical evidence to verify or confirm its hypotheses. After all, many “nonscientific” practices, e.g., astrology, also employ this strategy. Rather, according to falsificationists, what makes science unique is that its claims are open to empirical falsification. What makes a generalization such as “All crows are black” genuinely scientific is not that there is a huge amount of observational evidence in its support, but that we know what type of evidence would count decisively against it; namely, the observation of only one nonblack crow would falsify it. Although such

universal claims may never be conclusively verified, they can, in principle, be conclusively falsified. According to this view then, empirical evidence should be used to test scientific hypotheses, not to confirm them. More importantly, falsification is possible without the use of induction, thus avoiding the skeptical problems just described, and to some extent the problems associated with the underdetermination of theory by evidence. In this way, falsification is seen as an improvement over induction. Accordingly, falsification has become a widely accepted feature of accepted scientific method.

Problems with Falsification

Falsification, however, has its own serious logical and methodological problems. First, falsification as described by Popper does not appear to describe accurately historical scientific practice, either of scientific discovery or theory justification. The history of science reveals cases when observational data seemingly incompatible with a hypothesis did not lead to the abandonment of that hypothesis, and for good reason. Copernican theory, for example, initially failed to predict the trajectories of falling terrestrial bodies or why objects do not fly off the surface of the spinning Earth. (Early critics argued, for example, that if Earth spins, as Copernican theory claims, then objects dropped from a tower should fall some distance from the tower base, but this is not what is observed.) Such potentially falsifying observations did not, however, lead to the rejection of Copernican theory. Contemporary social science reveals many other such examples (see later). Second, it is not obvious either in principle or in practice how to determine what counts as a falsifying observation for a specified hypothesis. In the philosophy of science, this problem is described by the Quine–Duhem thesis, according to which hypotheses are not tested in isolation from background theory. That is to say, hypotheses are always tested in clusters consisting of the explicitly tested hypothesis and a complex background theory, which in turn consists of definitions, concepts, conventional methods, instrumentation, and so on. The result of this type of holistic view of hypothesis testing is that an instance of falsifying evidence does not necessarily falsify the hypothesis explicitly being tested. Falsifying evidence, or evidence seemingly incompatible with the tested hypothesis, can only demonstrate that the cluster of claims (the hypothesis plus background theory, etc.) used in the experiment is, at worst, inconsistent. The evidence does not indicate which particular claim to discard. Thus, it is relatively easy to save a hypothesis by rejecting another claim in a background theory, or to propose auxiliary hypotheses not in the original set that would explain the inconsistency. Thus, deciding when to abandon a hypothesis, or when to choose one theory over another, is not merely a matter of seeing falsifying evidence.

Instead, other criteria are needed. Some candidates include considerations of parsimony (e.g., Occam's razor), consistency with already accepted theory, productivity, and predictive power, each of which has its own methodological problems. More insidious problems arise for theory selection if scientific method is viewed from a historicist or sociological view, according to which science involves metatheoretical, arbitrary, possibly irrational, and ideological or political features. From this view, falsification does not provide a methodology from which to escape these idiosyncratic features of scientific research methodology.

Falsification in Contemporary Social Science Research

The Persistence of Falsification

Despite the problems with falsification, it retains a prominent position in social science. One reason why falsification, in one form or another, continues to be used may be that it so effectively captures a widespread view of science: Virtually everyone seems to agree that, in some sense, empirical scientific claims should be subject to refutation by empirical observation. In theory evaluation, in research methods, and especially in statistical methods, falsification is often held up as an essential component of scientific method. Falsification remains prominent even in cases in which it is the object of criticism, in part for reasons already described and in part because some assert that it does not apply constructively to qualitative and interpretive methods that are increasingly employed in the social sciences. The proper place for falsification in social science research is therefore still a matter of some debate.

Diverse Forms of Usage

There are many ways in which falsification is currently used, among which are the following five. First, to gain some small empirical perspective on the extent to which social science texts agree that falsification has a useful role, the present authors informally reviewed various introductory texts on scientific method in psychology and sociology (including statistical methodology). Falsification appears in several guises. (Excluded from consideration are historically related meanings, such as when one scientist criticizes another for having falsified or misrepresented something.) According to most of the introductory texts reviewed, most prominently in psychology texts, science involves a method that relies on observation, empirical data, and hypothesis testing. Some of these texts refer to a self-correcting process of peer review in which, sooner or later, false claims will be laid to rest. Some

texts explicitly state that science does not address basic moral or religious issues because such issues involve claims that are not testable or falsifiable. Sociology texts were found somewhat more often than psychology texts to advocate various qualitative methods not involving rigorous hypothesis testing or falsification. Second, statistical methods often explicitly rely on falsification when, for example, the sampling distribution of a statistic of theoretical interest is derived to permit a null hypothesis to be tested. Such a test is motivated by a commitment to falsification, namely, that empirical data will show the hypothesis is falsified, i.e., is unacceptably improbable. If the null hypothesis is falsified in this sense, it is widely believed that scientific progress has been made. Third, falsification appears in its most basic form when a scientist concludes (perhaps most often in the case involving a theory contrary to the scientist's own theoretical predisposition) that the outcome of a single experiment falsifies an opponent's theoretical position. In accordance with the problems with falsification described previously, the theorist whose theoretical position Nevin ostensibly falsified was moved only to generalize and strengthen it, not to reject it. Fourth, on a grander scale, falsification appears in the idea of a "critical experiment" or "critical test." This idea was central to classic contests in the 1930s and 1940s between behavioral and Gestalt learning theorists. Hull and Tolman conducted numerous experiments, each designed to show that the competing theory was wrong. Again, in accordance with one of the problems with falsification described previously, neither side seemed much fazed by this series of critical tests wherein each side successively claimed their opponent's position had been falsified. More recently, the "cognitive revolution" is often said to have shown a basic inadequacy of behaviorism, and to have led to the death of behaviorism. Although cognitive psychologists appear not to claim explicitly that behaviorism was "falsified," the practical consequences seem similar: Behaviorism is declared dead, presumably on the basis of empirical results. As in the case of Hull and Tolman, many behaviorists continue to live happily, however, with their commitment to behaviorism, and care little that cognitive psychologists believe behaviorism is dead. Fifth, falsification as part of the logic of hypothesis testing appears in theories of human and nonhuman animal naturalistic decision making. That is, humans and animals have been studied as intuitive statisticians, especially in terms of the rationality and optimality of their decisions.

Alternative Methods

Not all social scientists are willing to accept falsification as an essential part of scientific method, for reasons previously described. Others reject falsification and associated views about rigorous hypothesis testing

because they believe those views derive from methods appropriate to the physical sciences, but not necessarily to the social sciences. These scientists believe that the subject matter of the physical sciences allows for falsification only because of the quantitative and observational methods available to them. These methods, they argue, are not available to social scientists, because human behavior can be adequately understood only by using hermeneutic methods. They therefore worry that transferring the commitments of falsification to the social sciences may be illegitimate and ultimately damaging to the social sciences. These and other concerns have motivated the development of alternative methods and design criteria that avoid some of the problems raised by falsification. Some of these alternative methods are designed to restore a more confirmatory and inductionist approach to statistical analyses. These methods include techniques such as confidence intervals and other forms of Bayesian inference, and the development and evaluation of mathematical and computer simulation theories, some of which have been developed without appeal to falsification. In addition, case studies, narratives, and other qualitative methods are often not committed to falsification or hypothesis testing. Falsificationists tend to worry that some of these alternative methods merely raise again the problems falsification was designed to avoid.

The Broader Impact of Falsification

Philosophy and Sociology of Science

Falsification is often seen as coming out of a positivist view of science, according to which progress is real and cumulative, and which employs methods that are empirical and objective, and which has a self-correcting process in the form of peer review. The critique of falsificationism in the philosophy of science has focused much-needed attention on metatheoretical issues in the practice of science, rather than on idealized logical reconstructions of scientific method. The end result is a richer appreciation for the historical and sociological features of scientific theorizing. Although falsificationism is rejected by philosophers of science as an adequate account of scientific method, it motivates important questions in the sociology and rationality of science.

Falsification from the Perspective of Evolutionary Theory

Falsification has also raised questions about the extent to which hypothesis testing is a natural or default form of decision making. If it is not, then it is possible that humans, including scientists, may find it difficult to behave

in accordance with the rational logic of scientific hypothesis testing. For example, Tversky and Kahneman have argued, especially in terms of base-rate neglect, that human categorical judgment displays large-scale irrationality. In another series of experiments to determine whether humans are naturally Popperian falsificationists, Wason presented subjects with a selection task aimed at testing an abstract rule. The result was that participants demonstrated a strong bias toward selecting potentially confirming evidence, and not equally available potentially disconfirming evidence. However, others have argued that rationality in these types of experiments must be interpreted in terms of cognitive processes evolution has provided, not in terms of the logic of falsificationist hypothesis testing. Thus, Tooby and Cosmides showed that participants in the Wason selection task actually did use something like falsificationist logic when the rule to be tested was placed in a more naturalistic setting, involving detecting cheaters in a social setting, not as a form of abstract rule testing. These types of experiments are provocative in what they can tell us about the standards of scientific methodology and research design.

Methodological Pluralism

The acceptance of falsification has been so pervasive in some circles that it has caused concern among researchers, who have felt its weaknesses have been underestimated and that domination by a single method is unhealthy. Alternative methods less committed to falsification and more in line with the tradition of induction seem to be finding growing acceptance in some parts of social science. The increasing use of narrative and other qualitative methods in sociological, anthropological, and psychological research raises controversial questions about the feasibility and appropriateness of methodological pluralism. Legitimate scientific method may not be a unified system relying heavily on falsification in the context of hypothesis testing, but may involve a great diversity of methods that may or may not be consistent with one another. How the tension between these competing approaches and the traditional view of scientific method will be resolved remains to be seen.

Acknowledgment

The authors thank Dr. Frank Drews for helpful references to naturalistic decision making as hypothesis testing.

Federalism: Local, State, Federal, and International Data Sources

Bertram Johnson

Middlebury College, Middlebury, Vermont, USA

Glossary

federalism A system of government in which national and local units possess autonomous domains of decision making.

fiscal federalism The division of responsibility for public services, taxation, and debt across multilevel jurisdictions.

general-purpose government A government, such as a state, municipal, county, or township government, that performs a variety of functions; in contrast to school districts or special districts, which perform only one or a few specific roles.

obligation In U.S. budgeting terms, a transaction that may either be paid in the present period or require payment in a future period.

State, federal, and international data sources comprise a variety of data that may be employed to better understand the relationships between autonomous regions and central governments, as well as the diversity among regions, in fiscal, political, and cultural terms.

Introduction

In the *Federalist Papers*, James Madison characterized the U.S. constitution as a mixture of federal and national elements. For Madison, “federal” meant “decentralized,” but more recently, students of intergovernmental relations have used the word “federalism” to refer to a system of government in which national and local units divide sovereignty, each level possessing its own decision-making domain. There are many such nations in the world today, including Argentina, Australia, Austria, Brazil, Canada, Germany, India, Malaysia, Mexico,

Nigeria, Russia, Spain, Switzerland, and the United States. The European Union and even China have also been analyzed as federal systems.

Divided sovereignty naturally raises a number of important social science research questions. Because federalism is defined in terms of relationships between governments, and because governments tend to keep track of their activities, data on the consequences of federalism for public finance are abundant, both for the United States and for other countries. Records concerning the electoral implications of federal systems are less common. Finally, information on federalism’s effect on public opinion and political culture is rare, and scholars have only begun to develop useful resources in this area.

There are innumerable sources of data, many produced at a local level, thus a comprehensive listing of all empirical information available concerning federalism is not possible. For example, numerous U.S. state comptrollers’ offices maintain publicly accessible depositories of budgetary data, but the availability of such data varies widely, depending on the jurisdiction. Nevertheless, several major U.S. and international data sources concerning fiscal federalism are reviewed here, with the focus being on the electoral implications of federalism and regional variations in individual behavior.

U.S. Fiscal Federalism Data

Much of what has been written on federalism in the United States concerns so-called fiscal federalism, i.e., the division of responsibilities for public service provision, taxation, and debt across multilevel jurisdictions. Data

available for the study of fiscal federalism may be divided into two components: data on national funds distributed to local levels and data concerning state and local public finance.

Data on U.S. Federal Funds Distributed Locally

“All politics is local,” former House Speaker Tip O’Neill famously pronounced, and indeed, in the United States, voters may judge their representatives and senators by how much national money they can deliver to their districts. Data on federal program funds distributed to localities are organized according to protocols developed by the Catalog of Federal Domestic Assistance (CFDA). Once a year (in June), the General Services Administration (GSA) issues the CFDA paper, but the online version is updated in December as well. It was first published in 1965 by the Office of Economic Opportunity; it was moved to the Bureau of the Budget (later the Office of Management and Budget) in 1971 and was transferred to the GSA in 1984.

The CFDA is comprehensive, describing federal domestic assistance programs available to: state and local governments (including the District of Columbia and federally recognized Indian tribal governments); territories (and possessions) of the United States; domestic public, quasi-public, and private profit and nonprofit organizations and institutions; specialized groups; and individuals. For each program, the CFDA provides the authorization history, eligibility requirements, and application guidelines. Each program is also assigned a five-digit program identification number.

Federal Assistance Awards Data System

The Federal Assistance Awards Data System (FAADS) is a quarterly report, organized and published by the U.S. Bureau of the Census, describing financial assistance awards of federal agencies to local individuals and local governments, either representing direct payments, guaranteed loans, direct loans, or insurance program expenditures. The FAADS has existed since 1982; records dating back to 1996 are available online (via www.census.gov). These data are listed by CFDA program number, and are disaggregated down to the county level. Scholars should be aware that the data represent federal agency obligations—that is, transactions that either may be paid or will require payment in a future period, rather than actual expenditures. For this reason, the Census Bureau advises caution when interpreting such data.

Federal Aid to the States

The Census Bureau’s annual Federal Aid to the States publication reports actual expenditures made by federal

agencies to state and local government entities only during a given fiscal year. These data are presented at a higher level of aggregation compared to the FAADS data, but are useful for those who are interested in annual federal grant aid to governments, rather than to individuals or private organizations.

Consolidated Federal Funds Report

The Consolidated Federal Funds Report (CFFR) is published annually by the U.S. Census Bureau and includes data (based on CFDA classifications, with records from 1993 to present available online) on distribution of federal funds to local areas at least down to the county level (sometimes down to the city level). This publication combines data from the FAADS, the Federal Aid to the States report, and several other (relatively minor) sources. An online query system at the Census Bureau web site allows users to search for data by geographic area and by agency (and subagency if applicable). This search produces summary tables with program names, program codes, and annual dollar figures. Consolidated data files are also available for download in comma-delimited format.

Data on State and Local Government Finances and Employment

The major source on state and local government finances and employment is the U.S. Census of Governments, which is undertaken in full every 5 years, most recently in 2002. All Census of Governments data are available from the U.S. Census Bureau (www.census.gov), along with extensive explanatory documentation.

Each year, the Census Bureau conducts annual finance and employment surveys of between 10,000 and 14,000 local governments. In Census of Governments years, this survey expands to data collection on all 87,525 state and local governments in the United States. The result of this undertaking is as exhaustive picture of state and local governance in the United States, organized in three data files (government organization, public employment, and government finances), with corresponding summary reports.

Government Organization

This section of the census describes the number of state and local governments, classifies each of them according to type, and indicates the services they provide. Important here is the distinction between general-purpose local governments, such as counties, municipalities, and township governments, which provide a variety of services to residents, and school districts or special districts, which may overlap general-purpose governments and typically perform only one or a few functions.

Public Employment

Here the census includes statistics on employment and payrolls at several different levels of aggregation: nationally by function, by states, and by county area. It also contains detailed data on “major local governments,” which includes all counties, general-purpose governments of greater than 25,000 population, and school districts of over 7500 students.

Government Finances

Of most interest for those studying intergovernmental public finance, this section of the census details all revenue, expenditure, debt, and financial assets of governments for the fiscal year. Within these broad categories, data are further broken down into very specific classifications. A scholar interested in transportation expenditures, for example, encounters spending data for highways, air transportation, parking facilities, sea and inland port facilities, and transit subsidies.

U.S. Electoral Data

Data on state and local elections and/or the relationships between national elections and intergovernmental aid are less substantial, compared to public finance data. Nevertheless, in recent years, a number of excellent data collection efforts have expanded the list of available data in this area considerably.

Data on State Elections

Several major data sets exist for the study of U.S. state-level elections. First, the Inter-University Consortium for Political and Social Research and scholar Christian Collet have collected state legislative race data at the district, county, candidate, and constituency level from 1968 to 1989, and in the 1993/1994 cycle. Second, Gary King and colleagues have collected and organized precinct-level data on election returns for races from state legislative to presidential from 1984 to 1990. This unusually low level of aggregation, coupled with included demographic and socioeconomic information, make this data set particularly useful for studies examining the microconsequences of macropolitical phenomena. Finally, the Federal Elections Project, directed by David Lublin of American University and D. Stephen Voss of the University of Kentucky, aims to link electoral data at the precinct level with 2000 Census demographic data. Although this data set is primarily concerned with federal elections, it also contains data on the 11 governors’ races that were held in 2000.

Data on Elections and Intergovernmental Processes

Kenneth Bickers and Robert Stein have developed a useful tool for analyzing how elections to the U.S.

Congress affect the distribution of federal grant aid to local areas. They aggregate FAADS data on intergovernmental grant awards to the congressional district level. At present, they have created data sets for each year from 1983 to 1997. In their own work, Bickers and Stein use these data to test theories of distributive policymaking. The records of the National Election Studies’ Senate Election Study, conducted each election year from 1988 to 1992, contain state data samples that researchers may use to examine state electoral phenomena. This data set has been most productive in comparing gubernatorial elections to senate elections.

U.S. Public Opinion, Culture, and Policy

At least since the publication of Daniel Elazar’s influential book, *Federalism: A View from the States*, students of federalism have been concerned with the diversity of culture and public opinion that federalism may play a role in preserving. The recent major work in this area has been Erikson, Wright, and McIver’s ongoing state public opinion and policy project, which evaluates the relationship between local preferences and government policy decisions. At this writing, they have updated their publicly available state-level ideology estimates, based on aggregated CBS News/*New York Times* polls, to cover the years 1977 to 1999.

In 2000, Harvard University’s Saguaro Seminar and affiliated organizations conducted the Social Capital Benchmark Survey nationally, as well as in 41 distinct U.S. communities. Survey questions included queries about individual levels of participation in group activities, attitudes toward politics, and community involvement. The investigators, led by Harvard’s Robert Putnam, hope to use the survey as a baseline measure, for future comparison, of civic engagement in the communities studied.

Finally, the number of American state-level policy data sources, which are often used to measure the links between public opinion and public policy, continues to grow. Many of these data sets are available at the Florida State University (FSU) State Politics and Policy Data Archives, maintained by FSU’s Charles Barrilleaux.

International Data Sources

International sources of data on federalism are more widely scattered than are data on the United States, so it is difficult to evaluate all of them here. As in the United States, in general, data on fiscal federalism is easier to come by than are data on electoral behavior or public opinion.

Fiscal Federalism

Studies of fiscal federalism in individual nations may rely on data from national finance or statistics agencies, or on data collected or analyzed by several private research organizations, such as Argentina's Fundación de Investigaciones Económicas Latinoamericanas (www.fiel.org), or the Center for Monitoring Indian Economy (www.cmie.com). Many single-nation and multinational analyses of fiscal federalism must rely on World Bank and International Monetary Fund figures, however. The World Bank has published studies of fiscal federalism in individual countries, in addition to managing a significant educational and research program on fiscal decentralization. The International Monetary Fund (IMF) maintains its comprehensive *Government Finance Statistics Yearbook*, which includes annual figures on region and local government taxes and spending; in 1997, IMF published *Fiscal Federalism in Theory and Practice*, which contains information on intergovernmental grants and borrowing.

Politics and Elections

Basic data on politics and elections in federal states are available from state agencies, or from a comprehensive reference such as the *Europa World Yearbook*. A newer arrival, the Forum of Federations, a nongovernmental organization founded in 1998 and based in Ottawa, Canada, shows promise of being an excellent resource on the political aspects of federalism (www.forumoffederations.org). In addition to serving as a depository for scholarly articles, opinion pieces, and other materials on federal states, the fund's web site includes links to affiliates in a number of countries.

Public Opinion and Culture

Only in the past several decades have public opinion surveys been widely used in many federal countries, and, as in the United States, when these surveys have been conducted, they are rarely designed to enable studies of within-country regional variation. There are several notable exceptions, however, which suggest that the amount of data in this area will steadily improve. The unprecedented international World Values Survey, which measures basic values and belief systems, completed a fourth wave of research in 2001. Components of this study allow local comparisons, such as the separate surveys from four regions in Spain and from the Moscow region in Russia, in addition to the standard national surveys for those countries.

Field Experimentation

Donald P. Green

Yale University, New Haven, Connecticut, USA

Alan S. Gerber

Yale University, New Haven, Connecticut, USA

Glossary

dependent variable The outcome variable to be explained.

external validity The extent to which the results from a given study inform the understanding of cause and effect in other settings or populations.

independent variable The explanatory or treatment variable.

instrumental variables regression A statistical technique designed to correct for the contamination or mismeasurement of an independent variable. The technique involves predicting this independent variable with one or more variables that are uncorrelated with unmodeled causes of the dependent variable.

random assignment A method of distributing experimental subjects to treatment and control groups such that every observation has an equal probability of receiving the treatment.

spurious correlation A correlation between two variables that occurs, not because one variable causes the other but rather because both variables are correlated with a third variable.

Field experiments are randomized interventions that take place in naturalistic settings. Well-executed field experiments combine the strengths of randomized designs with the external validity of field studies. When ethically and practically feasible, field experimentation represents the strongest basis for sound causal inference.

Introduction

Field experiments, as distinct from laboratory experiments, are studies conducted in natural social settings,

such as schools, voting wards, or police precincts. In contrast to ethnographic or descriptive research, field experiments are principally designed to establish causal relationships. When well executed, this type of inquiry represents the conjunction of four methodological precepts: intervention, controlled comparison, randomization, and verisimilitude.

Intervention

Unlike passive observation, which tracks putative causes and effects as they unfold over time or turn up in different places, intervention-based research seeks to identify causal patterns by disrupting the normal flow of social activity, for example, through the introduction of a new policy, dissemination of information, or creation of new social arrangements.

Controlled Comparison

Intervention research has a long intellectual history, but the scientific value of intervention research depends on the procedures used to determine when and where to intervene. Although massive interventions such as the creation of the Soviet Union are sometimes dubbed experiments in the colloquial sense, a basic requirement of any experiment is the use of a control group against which changes in the treatment group are to be gauged. Control groups may be formed in a number of ways. We may compare different sets of observations to one another, track a single set of observations over time, or follow multiple groups over time. But to draw meaningful

comparisons between treatment and control groups, they must be formed in ways that make them equally likely to respond to a particular intervention and they must be exposed to similar influences other than the intervention.

Randomization

The comparability of treatment and control groups is ensured by random assignment. The assignment of observations is said to be random when each observation has the same *ex ante* probability of winding up in the treatment or control groups. The integrity of randomization is best ensured through a set of assignment procedures, whether it be flipping coins or consulting a sequence of random numbers. Note that randomization procedures may be under the control of the experimenter or some other agency or institution in charge of a lottery (e.g., the random assignment of judges to court cases).

Other approaches, such as assigning observations to treatment groups on an alternating basis, might be termed near-randomization, because we cannot be certain that the treatment and control groups differ by chance alone. Still less secure are attempts to simulate random assignment after the fact by matching treatment and control observations as closely as possible in terms of other observable characteristics. This approach, the logic of which undergirds the overwhelming majority of social science research, is known as quasi-experimentation.

The advantage of randomization is that it guarantees that treatment and control groups differ solely by chance prior to an intervention. Moreover, randomization guarantees that chance differences will disappear as the number of observations increases, so that remaining differences reflect the intervention's influence on the treatment group. No such guarantees govern near-random or quasi-experimental research. The first to recognize the full significance of this point was R. A. Fisher, who in 1926 argued vigorously on the advantages of assigning the units of observation at random to treatment and control conditions, as reported by Box:

As Fisher put it in correspondence, the experimenter games with the devil; he must be prepared by his layout to accommodate whatever pattern of soil fertilities the devil may have chosen in advance. A systematic arrangement is prepared to deal only with a certain sort of devilish plan. But the devil may have chosen any plan, even the one for which the systematic arrangement is appropriate. To play this game with the greatest chance of success, the experimenter cannot afford to exclude the possibility of any possible arrangement of soil fertilities, and his best strategy is to equalize the chance that any treatment shall fall on any plot by determining it by chance himself.

Verisimilitude

Finally, field experimentation reflects the notion that research best occurs in settings that most closely approximate the domain in which knowledge is to be applied. The term field harkens to the agricultural origins of modern experimentation. Near-experiments in agriculture date back to the eighteenth century and grew increasingly sophisticated by the late nineteenth century. The path-breaking work of R. A. Fisher in the 1920s, which laid the foundation for randomized experimentation, grew out of and was first applied to agricultural research. That research program had the down-to-earth objective of raising crop yields and lowering production costs on English farms. In a similar vein, many field experiments in social science are conceived as an attempt to evaluate specific programs or pilot projects. Often, however, they inform larger theoretical debates about behavioral responses to incentives, coercion, information, and moral suasion.

Recent Examples of Field Experiments in Social Science

Since their introduction into social science in the 1940s, randomized field experiments have been conducted in a variety of disciplines, particularly those that take a special interest in the behavior of institutionalized populations, students, prisoners, soldiers, recipients of public assistance, and the like. The basic features of field experiments are illustrated by the following selected examples.

1. The Moving to Opportunity experiment conducted by the U.S. Department of Housing and Urban Development randomly assigned 638 applicant families living in high-poverty neighborhoods to a control group or to one of two housing subsidy programs designed to facilitate residential relocation to neighborhoods with lower poverty rates. In 2001, Ludwig, Duncan, and Hirschefeld examined the arrest rates of teenage children in the three experimental groups over a 4-year posttreatment period.

2. Dartmouth College freshmen are randomly assigned dorms and roommates. This procedure sets the stage for an investigation on the effects of interpersonal influence. In 2001, Sacerdote examined the extent to which a student's grade point average, choice of major, and decision to join a fraternity was influenced by roommate characteristics.

3. The Tennessee Student/Teacher Achievement Ratio experiment randomly assigned 11,600 students in 80 schools to large or small classrooms from kindergarten through third grade. Students were given a battery of standardized tests at the end of each year, enabling researchers to gauge the short- and long-term effects of class size on academic performance. Krueger, in a 1999 report,

provides a careful analysis of the data that takes into account the practical problems that arose during the course of the study.

Advantages of Field Experimentation

Field experimentation may be viewed as a response to the limitations of both laboratory experimentation and observational research. In this section, we briefly summarize these limitations and the advantages of field experimentation.

Advantages over Laboratory Experiments

Inferences drawn from social science laboratory experiments confront somewhat different problems of inference. Such experiments create artificial environments designed to simulate the effects of market regulation, legislative voting rules, television consumption, and many other social institutions and processes. Randomization enables the researcher to draw secure inferences about cause and effect, but the question is whether laboratory results say anything about the operation of cause and effect outside the lab. The issue of external validity, or generalizing beyond the confines of a given study, surrounds all research, but it has special force in the case of laboratory studies. The social environment of the laboratory is often unusual, at very least because the participants typically realize that they are under observation in a university setting. The experimental manipulations are often contrived, and the participants tend to be college undergraduates. Whether these features of laboratory experiments threaten the external validity of their results is always unclear. Even under the best conditions, in which sampling and obtrusive measurement are not an issue, the simulated environment of the lab raises questions about generalizability to natural settings.

These concerns are especially pronounced when the aim is to evaluate the effects of a particular policy or program. A reading-enrichment program, for example, may work well in a laboratory setting; but if the aim is to gauge whether it will work in school settings, the experiment must take into account the manner in which schools are likely to administer the program. In contrast, a field experiment in one school will not settle the question of how the program fares on average across the population of schools, but the interpretation of the data requires a smaller inferential leap.

Another practical advantage of field experiments concerns the tracking of behavioral outcomes over time. For example, studies of how exposure to televised political advertisements affects voter preference go to great

lengths to have subjects view television in a relaxed environment akin to their own homes, yet the evaluation of these exposure effects consists of a survey administered shortly afterward. It is difficult to know how to translate these survey responses into the terms that matter politically, namely, votes on election day. The advantage of randomizing media markets in which political advertisements are aired is that we can link the treatment to election results. Similar arguments could be made about laboratory versus field studies of whether policing deters crime or pre-school programs augment high school graduation rates.

Advantages over Nonexperimental Research

In nonexperimental research, causal inference is fraught with uncertainty. Lacking a procedure such as random assignment to ensure comparability of treatment and control groups, the researcher is forced to fall back on theoretical stipulations. For example, researchers who argue that active participation in civic organizations encourages the belief that most other people are trustworthy stipulate that beliefs follow from actions when interpreting the correlation between the two in survey data. This correlation, however, is also consistent with the hypothesis that trust encourages participation or that trust and participation bear no causal relationship to one another but happen to share similar causes. Unless the researchers manipulate political participation through some randomized mechanism, they cannot rule out the possibility that the putative relationship between participation and trust is spurious.

A variety of statistical analyses can be used to buttress causal claims based on observational data. Each technique aims to simulate the conditions of an experiment and does so by introducing certain theoretical assumptions. One approach involves the use of multivariate analysis in order to eliminate pretreatment differences between treatment and control groups. Multivariate regression, for example, eliminates the covariance between the treatment variable and other observable factors that are thought to influence the dependent variable. This approach works as long as no unobserved or imperfectly measured factors remain correlated with both the treatment and the outcome variable. Unfortunately, this assumption cannot be tested directly except by means of an experiment.

Another approach involves the use of instrumental variables regression. Here the researcher posits an instrumental variable that predicts the treatment, yet is uncorrelated with unmodeled causes of the outcome variable. Note that the randomization procedures used in experimentation are designed to generate just such an instrumental variable—a sequence of random numbers

that predict nothing other than who gets the treatment. In nonexperimental work, the selection of an appropriate instrumental variable is a matter of speculation. Sometimes the proposed instruments are quite compelling. Whether a child's birthday falls immediately before or after the cut-off date for acceptance into kindergarten predicts educational attainment but seems unlikely to affect wage rates, and whether municipal government faces an election year predicts how much money is budgeted for police but seems unlikely to affect crime rates. More often, however, instrumental variables regression languishes for lack of plausible instruments.

The advantages of field experimentation go beyond random assignment. Because the experimenter is often in direct control of how a treatment is administered, there is less measurement uncertainty than is often the case with nonexperimental research, much of which relies on surveys. Asking a sample of survey respondents to report whether they have participated in a job-training program, read the newspaper, or attended the meeting of a civic organization often invites misreports and fails to garner detailed information about the specific content of these stimuli.

Finally, field experimentation can be used to create circumstances that are rare yet informative. Consider the case in which a researcher seeks to study the effects of marginal tax rates on a region's labor supply but tax rates historically vary little around a long-term average. With limited variance in the independent variable, the researcher cannot estimate the effects of tax rates with precision (putting aside the usual uncertainties associated with drawing causal inferences from nonexperimental correlations). An income tax field experiment has the advantage of creating new observations so that widely varying tax rates may be compared, permitting more precise estimates of the effects of tax rates. This experimental approach has the further advantage of enabling researchers to examine whether their modeling assumptions, hold outside the confines of historical data.

Field Experimentation in Practice

To appreciate the relative merits of experimental and nonexperimental research in practice, it is instructive to examine a research literature that features both types of investigation. One such literature concerns voter mobilization. This line of research dates back to Harold Gosnell's efforts in the mid-1920s to register voters and impel them to vote by mailing them leaflets. The handful of experiments following Gosnell have been overshadowed by a plethora of nonexperimental studies that use survey data to gauge whether citizens recall having been contacted by political campaigns. In a typical statistical analysis, reported campaign contact

predicts voter turnout, controlling for background variables such as partisanship, interest in politics, and demographic characteristics.

This approach has certain inherent drawbacks. First, the researcher must take the respondent's word that reported contacts actually occurred. In addition, the vague way in which campaign contacts are defined and measured raises further concerns. Little attempt is made to distinguish between personal and phone contacts or between single and multiple contacts. Serious though these measurement concerns may be, they are in some sense eclipsed by even more serious doubts about spuriousness. If parties direct their appeals disproportionately to committed partisans and frequent voters, those most likely to vote will be the ones most likely to receive political contact, and the apparent link between contact and turnout may be spurious.

In principle, these problems may be corrected statistically. For example, we may use instrumental variables regression to offset biases associated with endogeneity and misreporting. None of the aforementioned studies uses instrumental variables regression. This gap in the literature is not hard to understand. Valid instrumental variables are difficult to think of, let alone find in existing surveys. In this case, we must find a variable that predicts campaign contact but remains uncorrelated with unmodeled determinants of voting. We might look for natural experiments in which exogenous events, such as unexpected policy changes or technological innovations, altered campaign contact. Even then, the validity of the instrumental variable would remain a matter of speculation. Only randomization provides a procedure for generating valid instrumental variables.

A more common but nonetheless problematic strategy for avoiding bias is to formulate an exhaustive model of voting, hoping that the control variables in the model eliminate any correlation between campaign contacts and the disturbance term. Unlike the instrumental variable approach, this methodological tack fails to address biases arising from mismeasurement. Given the seriousness of the measurement problem in most survey-based studies, this defect may altogether invalidate the results. Holding measurement concerns in abeyance, this statistical approach nonetheless requires a leap of faith. How can we tell whether a given set of control variables performs its appointed task?

In the case of voter mobilization, it would be very difficult to predict *ex ante* whether experimental and nonexperimental results will coincide. Random errors in survey measures of campaign contacts might lead to an underestimate of their effects; on the other hand, if voters are more likely than nonvoters to report campaign contact when none occurred, regression analysis might overestimate the effects of mobilization. If parties and candidates target likely voters, the effects will also be

overestimated. Under these conditions, the sign and magnitude of the biases in nonexperimental research are knotty functions of variances and covariances of observed and unobserved determinants of the vote. Even if by some accident of fate the positive biases were to offset the negative, our ability to compare experimental and nonexperimental findings is hampered by the fact that most surveys fail to gauge the precise nature and frequency of campaign contact.

As it turns out, experimental studies have found that the effectiveness of mobilization varies markedly depending on whether voters are contacted by phone, mail, or face-to-face. In 2000, Gerber and Green conducted a randomized field experiment using a population of 30,000 registered voters in New Haven. Their results indicated that personal canvassing boosts turnout by approximately 9 percentage points, whereas phone calls have no discernible effect. Both experimental and nonexperimental studies find statistically significant effects of campaign activities on voter turnout. Experimental studies, however, speak to the issue of causality with far greater clarity and nuance because the researchers have control over the content of the campaign stimulus and can rule out threats to valid inference.

Drawbacks

Performing randomized experiments in real-world settings presents a number of practical challenges, the magnitude of which in part explains the relative paucity of this form of research in social science.

Limited Access to Manipulations

Social scientists seldom have the opportunity to assign resources, institutions, or experiences at random. Despite Campbell's 1969 plea for an "experimenting society" in which innovations are routinely attempted and subjected to rigorous scientific evaluation, the fact remains that such randomized interventions are rare. A failure to appreciate the special advantages of randomization combines with a reluctance on the part of administrators to be seen to act randomly, preventing experimentation from becoming one of the ordinary data-gathering tasks used in evaluation.

Resource Limitations

Field experiments are often expensive. Even relatively inexpensive field experiments that require a change in administrative behavior (e.g., mandatory arrests in domestic violence cases) rather than the allocation of additional resources still require more funding and effort than the typical observational study.

Implementation Failure

Assigning subjects at random to treatment and control groups is no guarantee that subjects will actually receive the treatment on a purely random basis. Sometimes those who administer or participate in experiments subvert randomization in various ways. A classic instance of implementation failure may be found in the Lanarkshire milk study, one of the first randomized experiments ever conducted. Thousands of children in Lanarkshire schools were randomly assigned during the 1920s to dietary supplements of pasteurized milk, raw milk, or nothing. Their physical development was tracked over several years. Out of concern for the well-being of their students, teachers reassigned some of the smallest and most needy children from the control group into one of the milk-drinking conditions, thereby undermining the randomness of the treatment. Similar problems arise in social experiments in which administrators steer certain subjects into the treatment group or when subjects themselves insist on being reassigned.

Sampling

The central aim of field experimentation is to estimate the average treatment effect in a given population. For example, a study may seek to estimate the average extent to which preparatory classes improve performance on college entrance examinations. Although it is conceivable that all students react in the same way to such classes, it may be that certain types of students benefit more than others. If effects vary, and the aim is to estimate the average treatment effect, we must either draw a representative sample of students or narrow our focus (and conclusions) to students of a particular type.

The issue of sampling and generalizability arises in several ways. First, the challenges of orchestrating field experiments means that they tend to occur in a small number of sites that are chosen for reasons of logistics rather than representativeness. Second, within a given experiment, the numbers of observations may be attenuated by subjects' refusal to participate or decision to drop out of the study. Noncompliance and attrition are remediable problems as long as the decision to participate is unrelated to the strength of the treatment effect. The statistical correction is to perform an instrumental variables regression in which the independent variable is whether a subject was actually treated and the instrumental variable is whether a subject was originally assigned to the treatment group.

The situation becomes more complex if participation and responsiveness to the experimental treatment interact. In this case, the study's conclusions apply only to the types of people who actually participate in an experiment. The way to address this concern empirically is to replicate the experiment under conditions that lead to

varying participation rates in order to see whether the results vary. In general, replication is the appropriate response to concerns about drawing conclusions based on studies of particular times, places, and people.

Conclusion

The results from large-scale field experiments command unusual attention in both academic circles and the public at large. Although every experiment has its limitations, field experiments are widely regarded as exceptionally authoritative. By combining the power of randomization with the external validity of field research, these studies have the potential to eclipse or significantly bolster findings derived from laboratory experiments or nonexperimental research.

Further contributing to the strength of field experimentation is the transparent manner in which the data are analyzed. In contrast to nonexperimental data analysis, in which the results often vary markedly depending on the model the researcher imposes on the data and in which researchers often fit a great many models in an effort to find the right one, experimental data analysis tends to be quite robust. Simple comparisons between control and treatment groups often suffice to give an unbiased account of the treatment effect, and additional analysis merely estimates the causal parameters with greater precision. This is not to say that experimental research is free from data mining, but the transformation of raw data into statistical results involves less discretion and therefore fewer moral hazards.

Field Relations

David A. Snow

University of California, Irvine, California, USA

Calvin Morrill

University of California, Irvine, California, USA

Glossary

derived dimension of roles The highly variable, situationally specific behaviors and orientations associated with the role, and through which actual relations are negotiated and maintained.

fieldwork relations The set of researcher/informant relationships established between the fieldworkers and those members of the scene or setting who function as hosts and objects of the research.

fieldwork roles The various negotiated positions or vantage points that situate the fieldworker in relation to the phenomenon of interest, or in relation to some set of members of the group or setting studied.

rappport/trust A property of a relationship, referring to the point in the development of fieldwork relationships at which the informant feels reasonably comfortable in functioning as a behavioral and orientational guide to the setting/group/social world being studied, thus divulging what s/he knows and does not know, and the corresponding confidence the fieldworker has in his/her informants and the information elicited from them.

structural dimension of roles The generic, skeletal boundaries of a role (such as the role of a fieldworker), but without explicitly defining the various behaviors and orientations associated with the actual performance of the role.

Field relations encompass the set of relationships established, in the scene or setting being studied, between the researcher and those informants who function as the hosts and objects of the research. Because of the importance of field relations to successful field research, such

relationships have received considerable attention among field researchers, particularly ethnographers, in their research reports and texts. Examination of the literature detailing these experiences suggests five sets of factors that can affect the development and maintenance of field relations: fieldwork roles, setting or group attributes and characteristics, researcher attributes and characteristics, strategies to facilitate trust or rapport, and strategies to modify relational involvement.

Introduction

Of the various issues that qualitative field researchers must consider and negotiate during the course of their fieldwork, few are as fundamental to the success of a project as the kinds of field relations established with members of a research setting. Indeed, it is arguable that nothing is more determinative of what a field researcher sees and hears, and thus learns about aspects of a social context, than the numbers and types of field relationships developed with informants. This is so for two reasons: first, intimate, up-close access to the happenings, events, and routines that constitute any particular social setting is contingent on establishing relationships in that setting with one or more members who function as “guides” to the organization and perspectives associated with those happenings, events, and routines. Second, different kinds of relationships with different individuals variously situated within the setting are likely to yield different perspectives and understandings. Ethnographic knowledge of any particular family, for example, is likely to vary somewhat, depending on whether the family is accessed

and explored from the perspective or vantage point of the mother, or the father, or each of the children, or perhaps even the neighbors.

This intimate connection between field relations and what is seen or heard, and thus learned, has long been acknowledged, both directly and indirectly, by practitioners and observers of ethnographic fieldwork, although not always in the same terminology. For example, using the language of roles, which are relational entities, McCall and Simmons argue that the role the field researcher claims or is assigned “is perhaps the single most important determinant of what he (or she) will be able to learn.” Rosaldo makes a similar point with the terminology of “position” and “angles of vision,” noting that what the fieldworker sees and what is made of it depends in large measure on how he or she is positioned in relation to those being studied. And Emerson and Pollner emphasize “embodied presence in the daily lives of those who host the research” as “the *sin qua non* of ethnography,” thus accenting the importance of field relations by emphasizing that “the ethnographer constructs the field not simply through gaze and representation but also, and more fundamentally, by negotiating interactional presence to local events and scenes that can then be made subject to disciplinary gaze and textual representation.” In each instance, the implication is that what is seen and heard in the context of fieldwork, and thus what ultimately constitutes the basis for the data log or field notes, is contingent on the kinds of field relationships negotiated between field researchers and those who are both their research hosts and objects of study.

Fieldwork Roles and Field Relations

Traditionally, the concept of fieldwork roles has been the primary conceptual vehicle through which field relations have been discussed and analyzed. The logic or cornerstone rationale for approaching field relations via the concept of roles resides in the fact that roles are relational entities, the essence of which derives from the set of other roles with which they are intertwined, and thus they function as avenues or barriers to other roles and their information bases and standpoints. Accordingly, the claim that the fieldwork role is the primary determinant of what the researcher will learn rests on the presumption that the role determines where, what, and with whom the fieldworker can go, do, and interact, what the fieldworker can ask and observe, and what the fieldworker will be told.

Not all field researchers find the concept of fieldwork roles particularly useful, because of the overly structural, rational, deterministic, and impersonal baggage often

associated with the idea of roles. However, these troublesome accouterments can be bypassed if roles are understood more flexibly as having two components: the structural dimension, which delimits the skeletal or generic boundaries of roles, and the derived dimension, which denotes the more situationally specific, negotiated, and thus emergent aspects of roles. Although not always framed in terms of these two dimensions of roles, much of the discussion of fieldwork roles can be usefully understood in terms of these components. For example, Raymond Gold's now classic distinction concerning the observational roles of the complete observer, the observer-as-participant; the participant-as-observer, and the complete participant, Herbert Gans' similar distinction concerning the total participant, the researcher-participant, and the total researcher; and John and Lyn Lofland's even more parsimonious distinction between known (overt) and unknown (covert) investigators all identify two or more ideal-typical fieldwork roles, with each implying different kinds of field relations and informational yield.

Although these typologies of fieldwork roles are useful insofar as they sensitize researchers to possible variations in the degree of participation/membership and openness with respect to research identity and interests, and the advantages and disadvantages associated with such variations, such typologies are not very helpful with respect to actually negotiating and maintaining field relationships. Moreover, they gloss over the multitude of ways in which it is possible to be a participant-observer within a setting, or a member of a group, whether known or unknown. For example, Adler and Adler's examination of a large number of ethnographic field studies in which the researcher was a member of the setting or group revealed that membership roles can vary considerably, ranging from peripheral through active to complete membership roles, with each entailing different kinds of relationships with members and commitments to the group or setting. In the case of peripheral membership roles, for example, the researcher participates in some of the activities associated with the group or setting being studied, but refrains from engaging in its central activities, as illustrated in Ruth Horowitz's study of Chicano youth gangs in Chicago. Though she hung out with members in some places and at some times, she avoided participation in their more dangerous and sexual activities, thus foregoing the kinds of knowledge that derive from relationships and experiences forged in certain group-specific contexts. In the active membership role, by contrast, the researcher participates in the group's core activities, but without fully embracing the group's values and goals, as illustrated by Burke Rochford's study of the Hare Krishna movement in the United States in the 1980s. And exhibiting both thoroughgoing engagement in a group's activities and embracing its goals and

values is the complete membership role, as reflected in Barrie Thorne's study of the draft resistance movement of the 1960s.

Each of the varieties of membership roles points to the interactionally negotiated and derived character of fieldwork roles and their associated field relations, and show that the broad, generic fieldwork roles of participant-observer, known investigator, or member are at best skeletal shells that have to be filled in and modified throughout the research process. Thus, the concept of fieldwork roles constitutes a useful conceptual tool for getting a handle on field relations, but only insofar as fieldwork roles are understood as relational entities that position researchers in relation to some set of members and activities within the research setting, and as interactionally negotiated rather than merely structurally given.

Setting or Group Attributes/ Characteristics and Field Relations

One of the reasons why field-role relationships are negotiated relates to the kinds of relationships that evolve during the course of fieldwork—they are not simply a matter of the researcher's own choosing. Whatever the objectives and interests of the field researcher, they have to be melded with various characteristics of the group or setting, which constitutes constraints on the kinds of role relationships that can be developed. Settings that are public or private, or groups that conduct their business in one context rather than another, call for somewhat different kinds of fieldwork roles and relations. In public settings, such as parks and malls, researchers typically have greater latitude with respect to access and movement, whereas in quasi-private and private places, such as offices and homes, access and movement are contingent on negotiating an invitation and a more concrete role relationship. Because of such differences, the issue of whether to be overt or covert, or open or closed about research identity and interests, is less complicated interactionally and ethically in public contexts than it is in private ones. To study lifestyle of the street homeless, for example, it is not necessary to knock on doors and negotiate with formal gatekeepers, as might be required in order to study corporate elites.

Similarly, whether a group is inclusive or exclusive in terms of membership criteria affects the kinds of relationships that need to be and can be developed. Studying exclusive religious movements that require the researcher to drop out and join one of its communes

mandates nothing less than an active membership role, whereas research on inclusive religious groups that do not require such encompassing commitment allows for greater flexibility in terms of the kind of research role that might be negotiated. Whether the activities associated with the setting or group studied are legal or illegal has significant implications for the kind of role relationships that should be negotiated as well.

Researcher Attributes/ Characteristics and Field Relations

Also significantly affecting the kinds of fieldwork roles and relations that can be negotiated are the researcher's social attributes (gender, age, race, and ethnicity) and personal characteristics and experiences, including biography, personality, and perspectives. Such personal and social characteristics can be relevant to all social research, but they are especially significant in the case of fieldwork, and particularly ethnographic fieldwork, because it is the most embodied of all social research in the sense that the fieldworker is the primary research instrument. Because of this characteristic of fieldwork, the social attributes of the researcher are likely to be especially relevant to those studied, not only closing or opening doors, but also influencing the character of the relationships that evolve.

Given that we live in a gendered social world, with gender figuring in the organization of relationships in most social settings and scenes, the gender of the researcher is likely to be an especially significant factor in accessing and negotiating relationships in most settings and groups. Not surprisingly, the settings and activities that are most gendered, in the sense of being associated primarily with women or men, tend to get studied primarily by the matched gender, or used accordingly as research sites. Public restrooms, for example, can be particularly good sites for developing fleeting relationships that yield information about activities and interests that extend beyond the restroom, but both experience and research show that access and the possibility of developing such fleeting relationships is highly gendered. In other words, women fieldworkers traditionally have been more likely to study topics and issues stereotypically associated with women, such as child care, emotion work, and veiling, whereas male fieldworkers have been more likely to focus on topics and issues more stereotypically associated with men, such as hunting, police work, and drinking. But just as gender barriers and logics have changed, so have there been changes in the link between gender and research; women, in particular, have negotiated sexually

ambiguous roles and relationships. Prominent examples of this loosening of the connection between gender and research foci include Arlene Kaplan Daniels' study of military psychiatrists and Jennifer Hunt's field research among police patrol officers. In both cases, however, the derived research roles were impacted by gender considerations, i.e., Daniels was regarded as an "amusing and ornamental mascot, treated with friendly affection but little respect," and Hunt was treated as an "honorary male."

Age is another factor that can influence access to and the development of functional field relations. Certainly this makes sense, especially in fieldwork with children, but it is often difficult to distinguish the effects of age from those of other social attributes. As well, the research experiences of various fieldworkers suggest that variation in the ages of those studied and in the age of the researcher can often facilitate relational access and informational flow, as when the dependent elderly are interviewed by younger fieldworkers.

The attributes of race and ethnicity can also affect the prospect of developing viable fieldwork relationships. As with any attribute, however, their salience in negotiating functional research relationships varies with what is being studied and the context in which it is studied. If the object of research is an exclusionary group in which membership is based on race or ethnicity, then the prospect of negotiating a viable research relationship is contingent on sharing the same race or ethnicity. But if the research is conducted in more public or quasi-public contexts, such as street corners, sidewalks, parks, and neighborhood bars or eating establishments, a number of prominent studies indicate that viable research relationships between fieldworkers and the objects of their research can evolve independently of racial or ethnic homogeneity. Examples include William F. Whyte's field research among Italian cornerboys, Elliot Liebow's field study of Blacks hanging around Tally's corner, and Mitchell Duneier's research among Black book peddlers in New York's Greenwich Village.

Though the researcher's various social attributes can affect the kind of fieldwork roles and relationships that can develop, attribute heterogeneity or dissimilarity does not preclude the possibility of negotiating viable field researcher relationships. In other words, it is not always a necessary condition for researchers to be "insiders" in the sense of sharing the same attributes (gender, age, race, and ethnicity) and orientations or perspectives of the objects of study. Obviously, there are both advantages and disadvantages to being an "insider" and "outsider"; for example, initial access is easier for the insider but subsequent access to certain kinds of information may be less complicated for the outsider to negotiate. The point, then, is that though researcher attributes are indeed important, attribute heterogeneity can be successfully negotiated and managed in many

contexts with heightened sensitivity to its limitations and advantages.

Strategies to Facilitate Relational Access and the Development of Rapport/Trust

Although the character of fieldwork roles and the development of corresponding field relations are constrained by both group and researcher attributes and characteristics, they are rarely determinative of the kinds of fieldwork roles and relations that evolve. If they were, then there would be little substance to the repeated claim that both fieldwork roles and relations are interactionally derived or negotiated. Part of what gets negotiated are these very constraints, because the fieldworker attempts to find a role or vantage point within the group or setting, or in relation to some set of members, that optimizes what is likely to be learned per the objectives of the study. Thus, for most field studies, the fieldworker is likely to have some elbow-room or latitude for negotiating functionally viable fieldwork roles and relationships. Primary field research monographs and secondary works synthesizing these original works are filled with accounts of an array of strategies that have been used to facilitate relational access and informant rapport or trust.

Perhaps the most basic and frequently mentioned strategy involves framing the research in terms of an exchange relationship, such that both parties are beneficiaries of the research project. Simply put, the fieldworker provides context-, group-, or member-appropriate favors or assistance in exchange for relational access and information. Often key to the development of such an exchange relationship is the negotiation of a role relationship that lends itself to exchange. The "buddy researcher" is an example of such a role. Based on a blending of the roles of researcher and friend, it has been used repeatedly to develop rapport and facilitate information flow in studies of street corner men, hoboes and tramps, and contemporary homeless individuals.

A related strategy is the negotiated creation of auxiliary derived roles. Formulations include the derivation of the role of the "controlled skeptic," in which the researcher engages in group-specific behaviors and rituals but does not publicly avow allegiance to the group's beliefs and values (an example being a study of recruitment and conversion to an eastern religious movement); the "ardent activist," who embraces behaviorally and verbally the group ideology, goals, and rhetoric (used to study the peace movement groups); and the "credentialed expert," which involves the use of professional credentials and an institutional base as the grounds for justifying and legitimizing research (e.g., for studying social service agencies

and for securing access to their clients records). These are only a few of the strategies used by field researchers to facilitate relational access and rapport, but they are sufficient to underscore both the importance and negotiated character of fieldwork relations and thus access and rapport. As well, they subtly suggest what Maurice Punch has called the “muddy” realities of creating trust with informants in the field. Indeed, creating socially intimate ties with informants along the lines just suggested often entails numerous moral dilemmas, including the ultimate aims and boundaries of relationships, the veracities of researcher identities, and even various forms of interactional deceit. Although it is beyond the purview of this essay to elaborate fully the implications of these dilemmas, suffice to say that ethnographers should be conscious of these issues in the everyday conduct of field relations. Formal regulatory approaches to these challenges may be inappropriate, given the unpredictability and negotiated nature of field research. Competent management of these dilemmas thus begins with what Punch called the researchers’ “individual responsibility and professional accountability,” but this must be attuned to the particular exigencies faced in the field.

Strategies to Control Relational Intimacy/Closeness

An ongoing challenge in field research is to secure and maintain a research role and its associated relationships that enables successful negotiation of the centrifugal forces that distance researchers from the events and information sources necessary for understanding the setting under study. An equally important challenge is to counter the centripetal tendencies that sometimes pull the researcher in too closely, clouding analytic capacities, draining emotions, and creating unnecessary ethical or political complications. In order to neutralize these centripetal tendencies and thereby successfully negotiate the occasional pull toward deeper involvement and even surrender, various strategies and tactics have been employed, sometimes with considerable foresight and sometimes on

the spot. Such countercentripetal strategies include “pre-empting” at the outset of a project, by articulating certain limitations and constraints on what will be done; “finessing” through the utterance of evasions and ambiguities in relation to member overtures and entreaties; “declining” directly and unambiguously member appeals; and “withdrawal” from activities. Such responses to centripetal overtures and appeals further underscore the negotiated character of the development and maintenance of viable fieldwork relationships and of the fieldwork process more generally.

Glossary

analytic induction Theory building in field studies through the collection of new cases that require the revision of extant theoretical understandings of the phenomenon.

emic The description and analysis of culturally significant categories of meaning used by the people in a social setting or culture under study.

etic The description of universal categories of human behavior for purposes of cross-cultural comparison irrespective of cultural significance.

grounded theory An inductive approach for generating and confirming theory that emerges from recursive field research.

informant The individual studied by field researchers.

member validation The sharing of research ideas and reports with informants in order to correct mistakes or to provide alternative interpretations of reported events.

purposeful sampling The selection of information-rich cases in order to deepen understanding of specific aspects of the topic of study.

triangulation The application of multiple research methods to provide complementary kinds of data in order to develop a multidimensional analysis.

Field study represents one of the earliest forms of social science research. The definitive characteristic of this type of research is that it includes *in situ* observation of naturally occurring social life. Field studies range from case studies of communities or social groups (e.g., classrooms) to comparative studies of generic social phenomena (e.g., crowd assembly and dispersal). Whatever the focus of investigation, all such research shares a commitment to

observation in close proximity to the social groups and phenomena under study. Unlike more narrowly circumscribed methods and techniques, field studies employ a wide range of information-gathering strategies and analytic approaches. Field researchers often triangulate with multiple methods (e.g., interviews, participant observation, unobtrusive measures) to provide various types of data and angles of vision from which to develop holistic analyses of their topics of investigation.

Historical Roots of Field Studies

Different research traditions and theoretical orientations tend to favor different methods. Interpretive traditions of social science inquiry emphasize cultural and contextual understanding of social action, and thus share more of an affinity with field research than is typically the case for more macrostructural and positivistic traditions of inquiry. Field studies facilitate rich understanding of social groups and settings, and are open to unexpected findings that redirect or modify analytic focus during the research process. Ethnography, a term often used synonymously with field study, entails not only an omnibus of data collection strategies, but also frequently includes reflexive self-observation in which the researcher's own experiences and relationships in the field are critical data for analysis. Though field studies can contribute to hypothetico-deductive research, they are particularly valuable when the research goal is to ascertain interpretive meanings and constructions of social action.

Modern field studies grow out of the two similar yet distinct social science disciplines of anthropology

and sociology. The roots of sociological field research can be traced to 19th-century proto-social scientists, such as British journalist Henry Mayhew, who conducted a massive observational study of poverty in mid-19th-century London. In the 1920s and 1930s, the University of Chicago's Department of Sociology developed a highly influential tradition of sociological field research under the guidance of Robert Park. Associated with the pragmatist philosophy of John Dewey and George Herbert Mead, and the closely aligned sociological perspective of "symbolic interactionism," "Chicago school" sociology produced major exemplars of field research, and largely defined this type of sociological inquiry in the United States. There were few explicit guidelines for sociological field research, however, until the 1960s, when sociologists began to focus attention on clarifying the skills and techniques most useful in this style of research.

Ethnographic field study has been the defining feature of sociocultural anthropology since the 1920s. Many people have contributed to this method, and to its centrality in anthropology, but the two people most responsible were Columbia University's Franz Boas, and Bronislaw Malinowski at the London School of Economics. Boas and Malinowski practiced and advocated for field observation by anthropologists, as opposed to the earlier practice of anthropologists' reliance on other observers, such as travelers, missionaries, and colonial officials. Boas and Malinowski independently developed similar programs that built on earlier methods. They instructed their students to take a census of the community under study and to map out the different social roles and groups and the relationships among them. Nevertheless, the approach they advocated, known today as participant observation, may be better understood as an antimethod. It was perhaps best characterized by Boas' student Ruth Benedict, as a form of "surrender," in which the researcher allows conditions of the field or interests of the informants to dictate foci and methods of investigation. These anthropologists, however, did not see the role of the anthropologist as a naive reporter of how other people live; they were struck by an often profound gap between what people do and how people account for what they do. They conceived of "culture" as some underlying or unconscious pattern, in the context of which beliefs and behaviors had sense and meaning that were often far from obvious. Above any particular method for discovering this "culture," they counseled time, patience, sympathy, and improvisation. Most of all, Boas and Malinowski established as the crucial elements of successful fieldwork two features that remain the *sine qua non* for ethnographic fieldwork: knowledge of the language and prolonged residence among the people. Consistent with sociological field researchers, Malinowski, Boas, and those who followed them argued that research questions and methods should emerge in the process of field research.

Anthropology has, of course, entertained theories that call for more specific and rigorous methods, but there have been relatively few field manuals written by or for anthropologists, and those that are in print are seldom cited in ethnographic monographs. Far more influential than discussions of specific field techniques have been individual accounts of particular fieldwork experiences. Any concrete advice these books offer—from wearing canvas sneakers and maintaining good health, to being patient, sympathetic, and good humored—would likely seem banal to anyone who has not actually done participant-observation fieldwork. But the main task of these books is to provide inspirational examples of how a researcher might innovate and improvise in the field, and cautionary tales of the psychological and emotional challenges of fieldwork. All of these works suggest that, in participant observation fieldwork, the ethnographer's own body and persona are the primary tools of research—that objective facts about a culture are learned only through the most subjective and personal relationships with other people.

Field studies have been a consistent feature of interpretive sociology and cultural anthropology. Though field research has long been used by some notable researchers in various fields (e.g., education, business, and medicine), this methodological approach exploded in popularity during the 1990s as researchers across a wide range of disciplines sought to achieve more contextualized understanding of social life. Today, ethnographic field studies are a common and accepted (if sometimes controversial) research strategy in the human sciences.

Field Study Design

Given the wide range of variation in field studies, it is not appropriate to define the method's techniques and strategies narrowly. It is fitting, however, to explore the basic generic tasks that are fundamental to most field research. Specifically, all field researchers face the tasks of accessing observational sites, collecting observations, and analyzing data. Important issues must be addressed in accomplishing these tasks.

Accessing Observational Sites

The accessing of observational sites by field researchers typically includes at least four basic tasks: locating appropriate research sites, establishing viable fieldwork roles, gaining Institutional Review Board approval of informed consent procedures, and getting informed consent. As with all aspects of field research, the accessing of observational sites is an emergent process of discovery and creativity. Researchers begin this process with varying degrees of focus on their topic of study, whether it is

a social group (e.g., a religious denomination) or a category of activity (e.g., social protest). The initial phase of field research involves exploring prospective sites and evaluating their potential for yielding data for analysis. At this stage, the researcher should cast a wide net and pay attention to the potential availability of various kinds of data—prominently including participation in and observation of ongoing social action, but also including opportunities for interviews, the availability of artifacts related to the topic of study, and unobtrusive forms of data (e.g., documents such as group newsletters). So, for instance, an educational field researcher interested in the classroom performance of elementary school students would want to explore (among other things) the opportunities for classroom observation, willingness and availability of key individuals (e.g., teachers and students) to be interviewed, and accessibility of pertinent documents (e.g., student projects and grade reports). In the course of early, exploratory research, some settings are likely to be found to be more easily accessible and to have richer potential for data collection and triangulation. These locations then are likely to become key initial sites for field observation, but it is important to maintain openness to new potential sites and valuable kinds of data.

Access to social settings and social actors requires gatekeeper approval and the creation or appropriation of fieldwork roles. Observational field research entails the researcher becoming the “research instrument”—that is, the medium through which data are collected via observation and are rendered into field notes. Social scientists have extensively debated the ethics of covert observation, in which the researchers’ goals are not revealed or disguised. The American Anthropological Association’s code of ethics expressly prohibits covert research, and Institutional Review Board procedures and the code of ethics of the American Sociological Association severely limit covert studies. Overt researchers (by far the majority of fieldworkers today) must create or assume fieldwork roles that maximize access to data. In some cases, a role will exist in the field that can be appropriated for this purpose—such as an educational researcher taking on the role of teacher’s aide. In other settings, roles need to be created or improvised, as in improvisation of the “buddy-researcher” role in fieldwork with the homeless. The main goal is to facilitate effective data collection, which may require different fieldwork roles in different settings. Team field research offers advantages in the range of fieldwork roles (including multiple roles within the same setting) and access to various kinds of data.

The ability to access research sites and “subjects” (typically referred to as “individuals,” “informants,” or “participants”) is also frequently conditional on gaining university-based Institutional Review Board approval for the research. Though Institutional Review Board (IRB)

procedures were originally developed to protect human participants in federally funded medical research, in recent years IRBs have taken an increasingly active role in evaluating and sanctioning research in the social sciences. The requirements for IRB approval vary dramatically across universities. At some universities, only funded research requires IRB approval, and at many universities, certain kinds of data, such as observation in public settings, are exempt from IRB approval requirements. Given that approval protocols and criteria of evaluation are somewhat institutionally idiosyncratic, researchers must become familiar with their specific university’s requirements.

Field studies pose several significant problems in relation to Institutional Review Board procedures. First, because the research design and foci of investigation in field studies tend to emerge during the research process rather than being tidily formulated prior to beginning data collection, field researchers’ proposals cannot be as neatly specified as, say, those of experimental researchers. Field researchers must be careful to provide sufficient detail in their IRB proposals to satisfy review board members, while maintaining flexibility in pursuing new research leads along the way. This may require, among other things, the submission of revisions to IRB proposals at later stages in the research. Second, informed consent requirements have been formulated primarily for medical research in the United States and are ill suited for many fieldwork situations. By “informed consent,” institutional review boards generally mean that the researcher must provide prospective informants with a clear account of the potential costs, or risks, and benefits of participation in the research. IRBs typically conceive of consent as an individual act. Notions of “risk,” “benefit,” and “consent,” however, are culture bound, and academic IRBs are largely unable to guide fieldworkers in the negotiation of consent across a cultural boundary. Fieldworkers, moreover, often work within communities that have collective representation and require collective consent. In addition, research in foreign countries usually requires the authorization of the local government. In many field sites, gender, class, and ethnic divisions may complicate the consent process, because individuals, community organizations, and governments may be in conflict. In such situations, conventional informed consent formulas may be inadequate, and true informed consent may require careful negotiation across several local group boundaries.

In actuality, as the foregoing comments suggest, field researchers have a long tradition of endeavoring to protect their research informants, often extending far beyond the protocols of Institutional Review Boards. However, fieldworkers face a significant problem in relation to the protection of human participants, because social science researchers do not have legal authority to protect those

whom they study. Unlike attorneys and medical professionals, social scientists may be subpoenaed to release their research data, if the data are believed to be relevant to the potential prosecution of their research participants. Researchers who study illegal behavior, or who may acquire knowledge of illegal behavior inadvertently as a result of their research, may thus be placed in a difficult position in which research ethics are in conflict with legal demands. There is no standard protocol for handling these conflicts. Lacking legal protection, several scholars in recent years have served jail time rather than turn over their research data to legal authorities. As long as field researchers feel a responsibility not to harm those whom they research, while having none of the legal authority accorded to medical and legal professionals, fieldworkers must be prepared to face legal challenges and ethical dilemmas in the protection of the foci of their research. Fortunately, the overwhelming majority of field studies do not generate such dilemmas.

Gathering Data

Field Notes

Field notes describing the researcher's experiences and observations in the field are the fundamental data of field research, representing the most crucial data log from which analysis is developed. The most widely recommended technique for writing field notes is for the researcher to make jotted notes inconspicuously in the field and to expand on them later. Conscientious—indeed compulsive—field note writing is critical to high-quality research and analysis, and it is important to write field notes promptly after observations in order to ensure maximum recall. Field notes should be concrete and richly descriptive accounts of events, people, things heard and overheard, conversations among people, and conversations with people. The purpose of field notes is to provide a fertile informational base from which to create rich, descriptive, and analytic accounts. Because fieldworkers often alternate between outsider's and insider's perspectives, they frequently distinguish between two different kinds of accounts. An etic account provides a description of observed actors, actions, and objects in a language that the fieldworker considers "objective" or "universal" (in other words, employing distinctions and categories that can apply to many different cultures; such a description would prove the basis of a "cross-cultural analysis"). An emic account provides a description of observed actors, actions, and objects in terms of distinctions meaningful (either consciously or unconsciously) for the informants (in other words, the description of actors, actions, and objects is a means to elicit a description of locally used categories).

In addition to descriptive accounts of field observations and experiences, field notes should also include

researchers' protoanalytic musings as they emerge during the course of research. Such musings are an essential part of the field research process. They can be highly useful in guiding the direction of emergent field research (e.g., sensitizing the researcher to the need to explore new settings) and in creating analytic foci for their studies. As mentioned earlier, field studies rely on a range of data beyond the researcher's field notes. Indeed, field research has two advantages over more predesigned research strategies. First, it is more open to the emergence of the research design through attention and surrender to the leads of accumulated data; second, researchers are situated in social settings where new kinds of data, from cultural artifacts to agency records, may be found. Researchers should be consistently alert to the possibilities of both revising their foci on the basis of emerging analyses, and of pursuing serendipitously emerging data.

Sampling

Though sampling issues are important in field studies, just as in other forms of social science research, sampling strategies in field studies vary according to the goals of the research and field practicalities. If the goal is to generalize individual characteristics or behaviors to a population, then random probability sampling is the most appropriate technique. However, most field researchers seek instead to develop holistic understandings of social groups, cultural settings, and/or generic social processes. In these cases, random sampling is less useful. Insofar as sampling strategies are consciously pursued in field studies (and this varies widely), assorted types of "purposeful" sampling tend to be invoked. In contrast to probability sampling, purposeful sampling is designed in the course of inquiry to pursue emergent analytic leads or to facilitate the development of analytic insights. A range of purposeful sampling techniques has been developed, including the relatively widespread techniques of maximum variation sampling and negative case sampling. Maximum variation sampling involves searching for the range of variation in a particular phenomenon (e.g., kinds of behavior exhibited in a specific social settings or situation). Utilizing this method involves observing and documenting unique cases until saturation is achieved. Negative case sampling—often used in conjunction with analytic induction (discussed later)—entails seeking out manifestations of the phenomenon of interest that do not fit existing theoretical understandings.

Whatever the sampling strategies pursued by field researchers, the cases sampled (whether they are individuals, groups, or social settings) must be informationally rich so as to provide ample contextual data for understanding and illustrative or anecdotal information for writing field reports. The point of sampling in field studies is to maximize richness of observations so as to enable

detailed holistic analysis and recursive development of theoretical formulations regarding the topic of study.

Relationality, Reflexivity, and Recursivity

All field research involves relationships with local people. These relationships may be more or less detached. More positivist studies rely on a high degree of detachment, in which the researcher is studying the people in question, and the people may be identified as “subjects” or “respondents.” Researchers working within such a paradigm may consider relationships with local people to be a means to the ends of research; in such cases, emotional, conceptual, economic and political differences between researchers and locals are obstacles that intrepid fieldworkers must overcome.

In more humanistic or interpretive paradigms, researchers conceive of field relationship as analytically significant in and of themselves, or as significant proxies for the political or economic relationship between the researcher’s society and the informants’ society. In these cases, emotional, conceptual, economic, and political differences between researchers and locals may be objects of study and sources of insight. Thus, humanistic or interpretive studies rely more on attachment, in which the researcher is learning about some aspect of the local people’s world or lives, and the people are identified as “informants” or “collaborators.”

The heart of the participant observation method of fieldwork is to rely on personal relationships as a way of learning about another culture. Indeed, newly arrived fieldworkers are commonly childlike in their naiveté, and rely on their hosts for all sorts of practical knowledge and assistance. The acceptance of dependency and of a “student” role in relation to field informants facilitates the fieldworkers’ rapport with those they study, acknowledges the informants’ status and power, and eases access to local meanings and practices that are the focus of ethnographic research. Thus, although a successful grant proposal suggests a certain mastery on the part of the researcher, fieldwork effects a massive reversal.

It is seldom possible to achieve a consistent or stable balance between attachment and detachment in relationships. Most fieldworkers alternate between one extreme and the other. Researchers often experience a tension between these two extremes (leading some to identify themselves oxymoronically as “stranger and friend” or “marginal native”). Nevertheless, the tension between these two extremes can be highly productive, yielding analytic insights through the processes of reflexivity and recursivity. Reflexivity involves a reversal in perspective in which the research becomes the object of study—to achieve what Paul Ricoeur called knowledge of one’s self by means of a detour through the other. Some degree of self-reflection is practically inevitable during fieldwork because informants often question and

comment on the researcher. Moreover, fieldwork typically reveals psychological and cultural biases on the part of the fieldworker. Those who pursue objective research are wise to attend to these revelations in any attempt to reduce observer bias. In addition to research-driven field notes, fieldworkers should therefore keep a diary or journal in which they record their own feelings and personal judgments. Such reflection is also important because it helps fieldworkers to monitor their own mental and physical health, which is essential because, in field research, the person is an instrument of research. In the 1950s and 1960s, some anthropologists published memoirs or autobiographical novels in which they reflected on these personal thoughts and feelings; such works were meant both to inspire and to caution future fieldworkers. In recent years, reflections on fieldwork have become more popular and influential, in part because they reveal not only personal biases on the part of fieldworkers, but shared biases that reveal fieldwork to be not so much a form of scientific study as a cross-cultural encounter. Consequently, fieldwork sometimes reveals as much about the culture of the researcher as it does about the culture being studied.

Recursivity refers to the effect that experiences in the field have on the direction of research. This process often occurs in the course of research in the field: regardless of the theoretical orientation of the researcher, or the questions or methods established before entering the field, field research inevitably reveals unanticipated phenomena and questions. Unexpected political, economic, or physical barriers to research, or the demands of local informants, may also lead to revision of the project. In some cases, the researcher must immediately revise his or her foci, questions, and methods. In other cases, it is precisely the successful conclusion of a well-planned research project that raises new questions. Recursivity may also occur in the course of writing after returning from the field. For many anthropologists, recursivity is made possible by the detachment that comes from distance in time, space, and mind (achieved through the process of academic writing). Thus, much recent ethnography is dedicated to discovering the questions raised by field research, in order to suggest new research.

Data Analysis

Field researchers utilize various data analysis strategies that range along a continuum of procedural rigor and explicit specification. More explicit and codified strategies, such as Anselm Strauss and Juliet Corbin’s version of grounded theory, James Spradley’s elaboration of Ward Goodenough’s componential analysis, and Christina Gladwin’s work, presented in her book *Ethnographic Decision Tree Modeling*, involve standardized techniques for manipulating data. Similarly, computer-assisted

qualitative data analysis software (CAQDAS) packages, such as ETHNOGRAPH and NVIVO, provide techniques and frameworks for logging and categorizing data in ways that facilitate specific kinds of analysis. However, many field researchers feel that standardized techniques and CAQDAS programs are overly mechanistic and that they insert their own logic into the research process, prematurely obstructing the emergence of analysis. Such divergences notwithstanding, most field researchers engage in some form of field note coding, sorting their data into different themes and issues. The initial coding of field notes should occur during the research process, as field notes are being written. Though researchers vary widely in their coding practices, the coding should enable easy access to materials relevant to a particular issue or theme, as well as access to all materials relevant to specific informants. Subsequent waves of data coding, or refinement of coding categories, may be useful as analysis proceeds.

Whatever the coded categories and analytic agenda, the hallmark of high-quality field research is the development of theoretically relevant and informed analysis that is based in detailed and nuanced “thick descriptions” of social phenomena. Therefore, field researchers must strive to ensure that their descriptions accurately represent the beliefs and experiences of their informants. Extended field observation enhances the likelihood of attaining deep familiarity with the social world under investigation, as does frequent checking of observations with informants while in the field. Further, field researchers often share their written reports with their informants—a process sometimes referred to as member validation—asking them for feedback, to correct mistakes or to provide alternative interpretations of reported events. Such feedback may be used to revise the analysis or, in some cases, may influence the researcher to reformulate the entire study, as in Mitchell Duneier’s research with Greenwich Village sidewalk magazine vendors in the 1990s.

Writing Field Study Reports

Field study reports (e.g., articles, books, and official reports) vary depending on the researchers’ goals, their audiences, and the social science traditions within which the studies are situated. Two important interrelated issues in this regard are idiographic versus nomothetic levels of analysis, and realist versus subjective or evocative narrative styles. The analytic agenda of field reports may range along a continuum from idiographic to nomothetic in focus. Idiographic reports focus solely on understanding individual cases in their full particularity, whereas nomothetic reports compare the individual case or cases studied with other cases and seek to establish

generalizable theoretical propositions. Both idiographic and nomothetic reports should include substantial descriptive material, such as field note and interview excerpts, but the heightened emphasis on generalization in nomothetic reports typically means that more of the text will be written at an abstract theoretical level than is the case for idiographic reports.

Similarly, narrative styles in field reports range along a continuum from realist “objective” accounts to subjective confessional accounts. The presentation of data and the acceptable evidentiary claims of these different narrative styles vary. Authors who provide realist objective accounts tend to utilize more standardized types of data collection analysis. These authors typically devote a section of their reports to explicit discussion traditional methodological issues such as sampling strategies and analytic protocols. Their reports focus primarily on others in the research settings, with relatively little of the analysis proceeding from self-reflexive observations on the part of the researcher. In contrast, in confessional or subjective field study reports, the researcher’s experiences and personal reflections assume a far more prominent role. Indeed, some confessional subjective accounts—often referred to as “evocative autoethnography”—tend to focus almost exclusively on the researcher’s personal experience. The goal of such confessional narratives is primarily to evoke in the reader an understanding of the researcher’s emotional experience.

Whatever the level of analysis and narrative style, field study reports are characterized by a faithful and richly descriptive rendering of situated action and cultural understandings in the setting or area of study. This is in keeping with the two fundamental criteria of field research: (1) *in situ* observation of naturally occurring social life and (2) an emergent research design that allows observations in the field to influence the direction and foci of analyses. These principles of field research, which served as guiding lights for the early sociological and anthropological researchers who developed them, remain the most important legacy of field study methods.

Fisher, Sir Ronald

Nancy S. Hall

*University of Delaware, Newark, Delaware, USA and
University of Maryland, College Park, Maryland, USA*

Glossary

eugenics The concept of improving a breed by the careful selection of parents, especially in regard to the human race.

Fundamental Theorem of Natural Selection The rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time.

genetics The science of heredity, concerning the similarities and differences that appear among related organisms.

natural selection Sometimes called “survival of the fittest”; Charles Darwin’s theory that those organisms that can best adapt to their environment are the most likely to survive.

statistics The science of the collection, analysis, and interpretation of numerical data.

Sir Ronald Fisher made major contributions in the fields of both statistics and genetics. He provided a rigorous theoretical foundation for modern statistics, revolutionized the methodology of experimentation on variable material, helped to reconcile the theories of Mendel and Darwin, suggested a numerical basis for natural selection, and made many discoveries about how the mechanisms of heredity actually operate.

Introduction

Sir Ronald Fisher (1890–1962) was one of the most prolific scientists of the 20th century. Statisticians consider him to be one of the founders of modern statistics, both for his contributions to theory and for his many developments of applied techniques. In population genetics, Ronald Fisher is one of the first names mentioned. Along with J. B. S. Haldane and Sewall Wright, Fisher contributed to the neo-Darwinian synthesis, the

integration of Darwin’s theory of natural selection with Mendel’s theory of heredity. Fisher was active in statistics and genetics for all of his professional life, doing his own research and publishing prodigiously.

Biography and Honors

Ronald Aylmer Fisher was born on February 17, 1890, in London, England. He was the youngest son of George and Katie Heath Fisher. Young Fisher was educated at Harrow School and then at Gonville and Caius College, Cambridge University, where he excelled at mathematics but maintained a strong interest in biology. After graduating in 1912, he spent an extra year at Cambridge, studying statistical mechanics under Sir James Jeans and the theory of errors under F. J. M. Stratton.

As a child he was precocious, but it was apparent that his vision was poor. He wore thick glasses all of his life. Because of his poor vision, Fisher was ineligible for military service during World War I and spent the war years as a teacher at several boys’ schools. In 1919, he accepted a 6 months’ position at Rothamsted Experimental Station at Harpenden, north of London; there nearly 80 years of agricultural research data had not been rigorously analyzed. Six months, however, became 14 years. In 1917, he married Ruth Eileen Guinness and began raising a family; eventually they had eight children.

At Rothamsted, between 1919 and 1933, Fisher published articles and books on statistics, genetics, and eugenics. He received his Sc.D. degree from Cambridge University, in 1926 and was elected a Fellow in the Royal Society in 1929. In 1933, he became Galton Professor of Eugenics at University College, London, and continued to publish prodigiously. In 1943, he accepted the post of Arthur Balfour Professor of Genetics at

Cambridge, where he stayed until his retirement in 1957. He was knighted in 1952, becoming Sir Ronald Fisher.

Fisher moved to Adelaide, Australia, in 1959 and died there in 1962, of complications following cancer surgery. During his lifetime, he published seven books, 594 articles, and several hundred book reviews. He was knighted, received nine honorary degrees, was awarded the Royal Society's Darwin and Copley Medals, received numerous other honors, and was elected to membership of five foreign academies of science.

Fisher as Statistician

Fisher is regarded by many as one of the founders of modern statistics. Any beginning student of statistics will find in his text a detailed description of the analysis of variance, without any mention that the technique was developed in the 1920s by Sir Ronald Fisher. Similarly, the student will learn to use the *F*-ratio without being informed that it is so named as a tribute to Fisher. But Fisher's importance in the field of statistics ranges far beyond elementary applications. Fisher's work in statistics can be largely grouped in three areas, all of equal prominence: the theoretical foundations of statistics, practical applications and methods, and experimental design.

In 1922, Fisher published "On the Mathematical Foundations of Theoretical Statistics." In earlier papers he had begun considering the accuracy of estimates based on samples drawn from large populations. The 1922 paper clarified the method of maximum likelihood, defined several terms important to the field, and made clear the necessity of considering the sample and the larger population separately. According to Fisher, the population has "parameters" that one does not know; from the sample one calculates one or more "statistics," such as the mean or the standard deviation, in order to estimate the unknown parameters. Ideally, a statistic should be "sufficient"; the statistic computed from the sample should contain all possible information about the unknown parameter. That is, for example, the sample standard deviation s should contain all of the information about the population standard deviation σ that can be obtained from the sample. Additionally, a statistic should be "efficient"; that is, information that the sample contains should not be lost in the process of computing the statistic from the data. Finally, a statistic should be always be "consistent"; the larger the sample size, the closer the statistic should come to the actual parameter.

The 1922 paper, published in the *Philosophical Transactions of the Royal Society*, was a landmark achievement. Fisher followed it with many other papers on statistical theory and applications. (Many of these, in complete text, are available on-line.) Fisher did not

always provide adequate mathematical proofs in his papers; there was considerable controversy over some of his statistical proposals. The method of maximum likelihood was later seen to have less generality than Fisher had hoped. However, he was both a visionary and a very competent mathematician. In one memorable paper, proving the general case of a specific theorem put forth by "Student" (William Sealy Gosset, 1876–1937), Fisher offered that something could be seen "instantly" if a geometrical view was considered; what followed were 2 pages of geometry and then 12 pages of calculus. Fisher himself pictured statistical theory in multidimensional spaces. He once suggested at the beginning of a paper that the 10 items of data should be considered as the 10 coordinates of a single point in Euclidean 10-space; needless to say, few people could comfortably follow his reasoning.

Fisher's quick mind and his lack of tolerance for any logical or scientific view with which he disagreed led to lively exchanges and sometimes to disagreements that lasted for years. He had an ongoing disagreement with Karl Pearson and later a similar one with Pearson's son Egon Pearson and with Jerzy Neyman. Their technical disagreements led to personal animosity.

The technique known as analysis of variance, which Fisher regarded as simply a way of arranging arithmetic, is a widely used method of determining whether there really is a mean difference between three or more groups. The statistician would say that there is a significant difference at the 0.05 level, meaning that the probability is less than 5% that the apparent differences happened by pure chance. Suppose that one has three groups of eight people each; each group has been on a different diet plan. One wants to find out which of the three diet plans results in the greatest weight loss—to determine whether one plan really is better than the others. The weight loss of each individual is recorded. The mean is the average of the weight loss within the group. The variance of each group (a term originated by Fisher; actually the square of the standard deviation) is the sum of the squared differences from the mean, divided by 1 less than the group size (here, divided by 7). Fisher's analysis of variance compares the group variances to the variance of the entire set of participants and then uses tables of probabilities to determine whether there is a significant difference between the diet plans.

Closely related to analysis of variance is the more complex analysis of covariance, also developed by Fisher, to remove the influence of an uncontrolled variable on other random variables and thus increase the precision of the experiment. Fisher provided the mathematical techniques to make feasible factorial experiments. For example, a crop can be fertilized with three kinds of fertilizer, singly and in combination, and the effect of each fertilizer as well as interactive effects can be studied.

The development of the analysis of variance reflected Fisher's continuing interests in statistics, genetics, and eugenics. Fisher used an early form of analysis of variance in his 1918 paper, "The Correlation between Relatives on the Supposition of Mendelian Inheritance," in which he demonstrated that the principles of Mendelian genetics could account for similarities and differences among relatives and that, in fact, these observed variations were just what should be expected. (Recall that until Mendel's principles became known, in the early 1900s, there was no understanding of why, for example, a young man might have the hair color of his mother's uncle rather than that of either of his parents, or of why two parents having brown eyes might have a child with blue eyes.)

Fisher then used versions of analysis of variance in his early papers discussing accumulated data at Rothamsted; the 67 years of data from the wheat grown continuously on the Broadbalk fields led to the first of a series of papers entitled "Studies in Crop Variation." That series also included reports of very recent agricultural research at Rothamsted; Fisher himself remarked that he began to develop analysis of variance in the 1918 paper and put it in final form in the second "Studies" paper in 1923, on the fertilizing of potatoes.

In 1925, Fisher's *Statistical Methods for Research Workers* was published and the transformation of research methods was under way. The book was poorly received by statisticians, with several neutral or unfavorable reviews, but was quickly adopted by researchers, first in agriculture, then in biology, then in psychology, and then, within 10 years, by almost everyone whose research involved variable material and relatively small group, or sample, sizes. Between 1925 and 1970, *Statistical Methods* went through 14 editions and was published in seven languages. Part of the statisticians' objection, and the researchers' relief, was that Fisher had deliberately omitted proofs. *Statistical Methods* was a handbook of directions on how to set up experiments and how to evaluate the resulting data. *Statistical Methods*, examined today, looks like any other basic statistics book, but it was the first of its kind.

In 1931, Fisher made the first of several lengthy visits to George Snedecor at Iowa State Agricultural College (now Iowa State University) at Ames, Iowa. At that time, Snedecor's group was virtually the only agricultural statistical research facility in the United States. Through Snedecor and his students, Fisher was influential in the establishment of several more centers combining agricultural research and statistical methods at a number of state universities.

One of Fisher's major innovations in statistics and in research methodology was the concept of randomization. Until the 1925 publication of *Statistical Methods for Research Workers* and Fisher's subsequent activities that promoted the use of randomization, it was customary for

the researcher to deliberately arrange the experimental plots, or subjects, and the experimental treatments as she chose, in an effort to eliminate variations extraneous to the experiment. Ideally, all of the subjects should be exactly alike, but this is usually impossible. Fisher was concerned about eliminating extraneous differences, but he was also concerned about the elimination of bias, some covert correlation among the experimental subjects that might influence the data being collected. This bias might be inherent in the experimental material, as, perhaps, a drainage flow from north to south across some of the field plots, or a bias introduced, perhaps accidentally, by the researcher in her groupings: perhaps the subjects in one group were predominantly tall or predominantly of Scottish descent.

Fisher's solution to the elimination of bias was randomization, in concert with ample replication. There should be as many subjects (or experimental plots) as possible and the assignment to treatment should be, not by the whim or plan of the researcher, but by some actual randomizing device, such as a deck of cards, dice, or a random-number table.

A second benefit of randomization, according to Fisher, was that randomization makes possible a valid test of significance—a measure of how dependable the conclusions drawn from the experiment are. Suppose an experiment is carried out, data are collected, and mathematical analysis of those data produces one or more statistics, descriptions of some property of the experimental population. The researcher needs to know whether the results were simply due to chance or whether the indicated differences really do exist. A test of significance is expressed as a probability. If an experimental difference is significant at the 0.05 level, mentioned previously, then there is only 1 chance in 20 that the perceived difference was due to chance. Fisher's concern was that if the experimental material and treatments were arranged systematically rather than through randomization, then more than one test of significance was possible and so none of these was dependable.

Another Fisherian innovation, one that permits very unlike subjects to be used in the same experiment, was an experimental design called randomized block. The essence of a randomized block design is that the material *within* the blocks should be as similar as possible. There can be wide differences, if need be, *between* the blocks. Observed variations within blocks can then be used to allow for the differences between the separate blocks, which may be under very different conditions. As an example, one can consider a case in which there are five types of fertilizer to be tested (on the same crop) with three fields available. However, one field is level and dry, one is on a hillside, and one is marshy. One way to do this is to lay out five plots in each of the three locales, or blocks. Thus, a block consists of five plots in a homogenous

locale. Within each block, the assignment of fertilizer types to plots should be made by some randomizing device (a deck of cards, for example, or a random number table). Later, after harvest and measure of the yields, the comparative performances of fertilizer A in the three blocks (and also that of fertilizers B, C, D, and E) could be used to eliminate the “block effects” from the calculations in comparing the five fertilizers.

The last nine pages of the 1925 *Statistical Methods for Research Workers* discussed experimental design. Those pages expanded into an entire book in 1935, *The Design of Experiments*, which went through eight editions and was eventually published in three other languages. In this book, both persuasive and educational about randomization, Fisher presented the classic randomization story: the lady tasting tea. The story was apparently based on an actual event at Rothamsted in the 1920s; at an afternoon tea, a woman declared that she could tell by taste whether the tea or the milk had been placed in the cup first. Fisher and the other men in the group did not believe it, and, partly for its entertainment value, Fisher set about to design an experiment. They assembled eight identical cups, put milk first in four and tea first in four, and presented all eight cups, properly randomized, to the woman for her inspection. Fisher used this tale to introduce the concept of randomization and went on to develop it in later chapters. (Legend has it that the woman got all eight cups right.)

Fisher sometimes used wit to drive home his point. Part of his perspective on experimental methodology was the now customary expectation that the statistical analysis of an experiment will be included in the planning of the research. In 1938 in a speech to the Indian Statistical Institute, he remarked that to call in the statistician after the completion of the experiment may be like calling in the mortician; he can perhaps say what the experiment died of. Fisher’s point, of course, was that a plan for analysis of the data is as important as the plan for collecting the data.

Fisher as Geneticist

Among Fisher’s major accomplishments in genetics were his genetic theory of natural selection, his work on dominance and the evolution of dominance, and his discovery of the genetic basis for the very complex Rhesus factor in human blood groups. Fisher had a lifelong interest in genetics and always had breeding experiments of some sort under way. Throughout his entire adult life, he kept a breeding population of mice or chickens or, for a time, snails, wherever he was living. In addition to his many papers on genetics, in 1949 Fisher published a book, *The Theory of Inbreeding*.

One problem in genetics early in the 20th century was that Mendel’s principles seemed to apply in many plants and animals, but that Mendelism was based on a concept of discrete factors. (Recall that Mendel’s experiments with peas involved smooth seed versus wrinkled seed, short plant versus tall plant, etc.) It was difficult to see how discrete factors could be responsible for the continuous variation that was obvious in human heredity. One argument was that human hereditary attributes were dependent not on a single factor, or single gene, but on the additive effects of several genes; that is, any particular human feature was influenced by many genes. Fisher’s 1918 paper, discussed above, “The Correlation between Relatives on the Supposition of Mendelian Inheritance,” showed mathematically that if one used the rules of Mendelism and a many-gene assumption, then the observed continuous variation was exactly what should be expected.

Fisher’s 1930 *Genetical Theory of Natural Selection* began not with his own theory but with a brief review of Darwin. Charles Darwin had introduced the theory of evolution by means of natural selection in his 1859 *On the Origin of Species*. Darwin had assumed that the usual mechanism of inheritance was blending. (There is no evidence that Darwin knew of Mendel’s work.) In blending inheritance, the theory was that mating a white flower and a red variant would produce a pink bloom. That pink then mated with a white would produce a lighter pink; within several generations the red variation would be “swamped” out of existence. Since under this theory so much variation disappeared in each generation, Darwin had to assume a very high rate of spontaneous variation in nature, in order to have sufficient variation for natural selection to proceed. In the first chapter of *Genetical Theory*, Fisher pointed out that Mendelism, in effect, solved Darwin’s problem, because in Mendelian inheritance variation was conserved, rather than being usually lost, and could reappear in later generations.

Fisher stated his Fundamental Theorem of Natural Selection as “The rate of increase in fitness of any organism at any time is equal to its genetic variance in fitness at that time.” One result of this is that large populations, likely to have more variance, are more likely to adapt to changing conditions and thus more plentiful species are more likely to survive than less numerous ones. Also, the larger populations have a greater opportunity for favorable variation to occur, because more variations will be present in the population. By treating Darwinian natural selection from a mathematical viewpoint, Fisher helped to develop the theoretical foundations of what came to be called the Neo-Darwinian Synthesis (of Mendelian genetics and Darwinian natural selection), as did J. B. S. Haldane and Sewall Wright. Fisher and Wright had an ongoing difference of opinion, sometimes referred to as the Fisher–Wright debate, about whether species change was more likely to happen within a large

population (Fisher) or within a small isolated population (Wright).

Fisher as Eugenicist

In the later chapters of *Genetical Theory of Natural Selection*, Fisher expressed his concerns for the future of human civilization. A staunch believer in eugenics, he believed that since the lower classes, whom he regarded as less fit, were reproducing at a faster rate than the upper classes, this was working to the detriment of society. As an undergraduate at Cambridge, Fisher was a founder and first president of the Cambridge University Eugenics Society. This brought him into contact with Major Leonard Darwin, a son of Charles Darwin and president of the Eugenics Education Society of London. Leonard Darwin became a close friend and advisor of Fisher's.

A survey of Fisher's publications will show that in addition to his many papers on statistics and genetics, interspersed are papers dealing solely with eugenics and the state of mankind. When Fisher became Galton Professor of Eugenics at University College London in 1933, along

with the position came the editorship of the *Annals of Eugenics*. Fisher edited the *Annals* for many years. In addition to his many papers on eugenics in a variety of journals, Fisher contributed several hundred book reviews to the *Eugenics Review*.

Glossary

analysis of variance Statistical methods for comparing means by dividing the overall variance into parts.

fixed-effects models Statistical methods for estimating causal effects, in which each individual serves as his or her own control.

panel data Information on each survey unit for multiple time points.

pooled time-series cross-section data A single data set formed from pooled panel data, containing information on multiple survey units for multiple time points.

random-effects models Statistical methods in which the data describe a hierarchy of different populations, with differences constrained by the hierarchy.

Fixed-effects models are a statistical technique (a form of regression analysis) for analyzing nonexperimental data. In the presence of unmeasured, unchanging variables that are correlated with the independent variable of interest and also exert their own effect on the dependent variable, fixed-effects models come closer than does ordinary regression analysis to achieving unbiased estimates of causal effect.

Introduction

Problems of Causal Inference with Nonexperimental Data

Random-assignment experiments provide the best means for testing causal effects. When trying to learn the effect of a treatment (for example, a medical treatment) on humans, there is no better evidence than the results of

a randomized experiment. In this situation, a target population is identified, a sample is drawn, and individuals are randomly assigned, some to receive the treatment, others not. After a period of time, outcomes for the two groups are compared. Because of randomization, in the average sample, the two groups will be identical prior to treatment (although there will be some deviations from sample to sample). This similarity between the groups prior to treatment extends to all possible characteristics, including those that may be difficult or impossible to measure. As a consequence, in the absence of other forces acting differentially on the two groups during and after the treatment period, any later (posttreatment) average differences between the two groups must be attributed to the effect of the treatment. No better evidence can be brought forward for the effect of one variable on another.

But experiments are difficult and costly to undertake. And resources aside, there are legal and moral restrictions to undertaking random assignment to “treatment” involving most variables that are the usual subjects of social scientific inquiry. Examples include parental and family characteristics, education, marriage, childbearing, employment, union membership, and so on. Thus, for most variables involving effects that social scientists would like to understand, no experimental random assignment to values of the variable ever has been, or likely ever will be, undertaken.

Without random assignment, individuals who score higher on a variable (for example, those who spend many years in a certain type of job) also differ systematically on other characteristics, compared to those who score lower on this variable. As a consequence, any differences in outcomes between the two groups (say, earnings during or postemployment) may be due not to the variable of interest (in this case, the particular job

type), but to some other variable with which it happens to correlate. This uncertainty as to whether differences in outcomes among individuals who differ on an independent variable of interest are really caused by this variable, or are merely caused by some other variable correlated with it, is the chief problem of causal inference with non-experimental data. The usual solution attempted for this problem is to estimate a multivariate statistical model, in which the independent variable of interest, and other variables correlated with it, act together to determine the outcome. Such models (usually regression analysis models) enable estimation of the effect of interest, “controlling for” other variables that may be correlated with it. That is, if Y is the outcome, X is the independent variable of interest, and Z_1, \dots, Z_k are the variables correlated with X , the effects of which it is desired to control, regression analysis allows adjusting Y for the effects of the Z values and estimating the “pure” or “net” effect of X on Y , thus controlling for the effects of the Z values on Y .

Because of the importance of this issue, some version of this regression approach has for some time been the most common data analysis technique in social scientific research. However, it has a flaw. It can only control (adjust for) Z variables for which there are measures available on the data. And investigators have come to realize that many potentially important Z variables may not be measured on commonly available data sets. For example, individuals who attain more years of schooling (X) may also be more intelligent or ambitious (unmeasured Z). Or, workers employed in typically “female” jobs (X) may be less motivated by money and more motivated to help people (unmeasured Z). Thus, even after a standard regression analysis, the danger still exists that unmeasured Z variables, correlated with X , and exerting their own effect on Y , may cause incorrect (biased) judgments of the effect of X on Y . This is the problem for which the method of fixed effects is a partial solution.

Fixed-Effects Models as a Partial Solution

How, in the absence of randomization, is it possible to control (adjust for) correlated variables that are not even measured on a data set? The answer is to utilize, for each variable and unit of analysis under study, multiple measures of the variable. Suppose, for example, that it is desired to estimate the effect on an individual’s earnings of being employed in job that is predominantly performed by female workers. And suppose that there are work histories for a sample of workers, and that these histories include information on the percentage of females employed in each of the different jobs a worker has held over her or his lifetime. Then, for each of the multiple measures of the variables to be included in the analysis,

subtract the average score (across the multiple measures) for the unit of analysis. (For example, take each of the percent female scores for every job an individual has held, and subtract the individual’s average of these from each score. Also take the amount of money the worker earned in each of these jobs, and subtract the worker’s average of these from each score. Do the same for all variables that are under study and change across jobs (for example, the years of work experience the worker had at the time she or he took each job).) Then pool the multiple observations for each individual (in this case, each job held by each individual) into one data set. Finally, regress the dependent variable, with its within-person mean subtracted (in this case, the worker’s earnings in each job minus the average of the worker’s earnings across all jobs) against the set of independent variables, also with their within-person mean subtracted. (Thus, the set of independent variables includes the percentage of females in each job held by each individual minus the within-person mean of these across jobs, the work experience of each individual at the time they took each job minus the within-person mean of these across jobs, and so on.) The resulting coefficient for the effect of the percentage of females on earnings is called the fixed-effects estimator.

How does this estimator control for unmeasured Z variables, such as the ambition to earn a lot of money? It is likely that workers scoring high on this ambition remain this way throughout their careers. A high level of ambition may have helped them to earn more, compared to many otherwise identical workers, and may have caused them to seek employment in jobs with a lower percentage of females, compared to many otherwise identical workers. In this case, the fixed-effects estimator uses the individual as “his or her own control,” and, as a consequence, the effect of the ambition Z variable has been differenced away.

In an ordinary regression analysis, the result of failing to control this variable would be a biased coefficient for the effect of the percentage of females. But with the fixed-effects estimator, these effects of ambition have been removed from the analysis by the differencing procedure. This is because, for each job the individual held, their earnings were computed as a difference from their average earnings, and their “percent female” factor was computed as a difference from their average “percent female.” Thus, whatever the effects of the person’s monetary ambitions on each of these variables, it is captured in the person’s average for the dependent and independent variables, and subtracted from these variables. As a result, the fixed-effects regression coefficient measures the extent to which, for this individual, the jobs they held that were above their own average “percent female” produced earnings above their own average earnings. That is, by centering the observed variables on the person’s average over time, what is being measured is the extent to which,

when this person holds a job that is, say, 1% more “female” than is usual for them, their earnings fall below the level that is usual for them. The effects of the unmeasured Z variables are not permitted to bias the calculation because they determine the person’s average, and these effects have been eliminated by the construction of variables that are differences around this average.

Two caveats are in order. First, to succeed in removing the effects of variables such as Z in the preceding example, the variables should be unchanging across the multiple observations for each individual. Thus, the method works best for variables Z that can be assumed to be unchanging, or at most, are very slowly changing, across the multiple observations for each individual. Second, the method requires multiple observations for each individual, and that X , the independent variable of interest, vary across these observations. (Thus, for example, this method cannot be used to measure the effects of X variables such as race or gender, which do not change as an individual ages.) When these conditions are met, the fixed-effects method can be quite flexible and powerful. It applies when the same individual or other unit of observation (for example, a state or nation) is observed over time. It also applies to situations in which, for example, multiple siblings from the same family are observed, and the aim is to estimate the effect of family size (number of siblings) on outcomes for each sibling, and to do so while avoiding bias from the effects of unmeasured, unchanging family characteristics (such as genetic endowments and child-raising procedures).

Formal Aspects of the Models

Pooled Time-Series Cross-Section Data

The earliest and still most common use of fixed-effects models is to analyze pooled time-series cross-section data. These are data collected for a sample of cross-sectional units (for example, people, businesses, or nations) so that, for each unit, observations are made on the same variables at different points in time. (That is, a time series of observations is obtained for each cross-sectional unit.) These are then pooled together to make a data set that, for each variable, consists of multiple over-time observations for each cross-sectional unit.

If Y_{it} is the dependent variable for individual i at time t , and X_{1it}, \dots, X_{kit} are the independent variables X_1, \dots, X_k for individual i at time t , then the fixed-effects model for pooled time-series cross-section data can be written as follows:

$$Y_{it} = b_1X_{1it} + \dots + b_kX_{kit} + D_1 + \dots + D_n + e_{it}, \quad (1)$$

where D_1, \dots, D_n are dummy variables, each of which is coded 1 for all observations on one of the n

cross-sectional units and 0 for observations on all other units, and e_{it} is an error term possessing the usual properties for error terms in ordinary least-squares regression analysis. Thus, a fixed-effects model for pooled time-series cross-section data has essentially the same form as an “ordinary” regression analysis, but (1) with multiple observations over time for each unit of analysis (for example, persons) pooled into one data set and (2) with dummy variables for each of these units of analysis included among the independent variables. This implements the description of deviating each variable from its group mean, because the dummy control variables estimate the group means and net them out from the calculation. The dummy variables, D_1, \dots, D_n , measure the effects of individual otherwise unmeasured variables (such as ambition or ability) that are assumed to be relatively unchanging over time.

Families and Other Groupings

The fixed-effects method has another important social science application. This is when the multiple observations to be pooled for each unit, rather than occurring over time, occur for different members of a group. In research applications, this has most often been a group of siblings. In this case, Eq. (1) once again applies, whereby i indexes particular families, t indexes a particular brother or sister within each family, and the D_1, \dots, D_n estimate family averages for the outcome variable. As before, these dummy variable fixed-effects estimate and remove the effects of unchanging, unmeasured variables that may be correlated with the X variable of interest. For example, suppose that Y is child cognitive outcomes, X is family size, and there is an unmeasured, unchanging parental variable, “family intellectual climate,” which is negatively correlated with family size. In this case, the failure to measure and control family intellectual climate may lead to a biased estimate of the effect of family size on child cognitive outcomes. However, the fixed-effect estimate would be relatively free of such bias.

This example can be extended to other situations in which the data consist of multiple individual units of observation that are sorted into groups, whereby the individual units within each group may be subject to a causal force that is group specific and unmeasured. Examples include students in classrooms, workers in workplaces, patients in hospitals, cities within states or countries, work units within firms, and so on.

Dichotomous and Categorical Outcomes

In general, the preceding models are designed for, and have been most widely applied to, the prediction of dependent variables that are measured on a continuous scale. However, techniques do exist, and are beginning

to be more widely used, for extending these methods to the analysis of dichotomous and categorical variables.

Competing Models

A large literature exists for estimating models similar to those in Eq. (1), but instead of using dummy variables and “fixed effects,” these models assume “random effects.” That is, rather than assuming that these effects are fixed constants present in a particular observed sample, this method assumes that they are random variables from a distribution of values. (This “fixed” rather than “random” distinction is the source of the name, “fixed effects.”) The result is a more parsimonious specification, but one that, for estimation, must assume that the random effects are uncorrelated with the X variables in the model. This is a disadvantage, because it makes it impossible to net out correlated unmeasured variables that are the chief source of bias in nonexperimental studies.

Data Demands

Multiple Observations per Unit

As already noted, the fixed-effects methodology requires multiple observations per unit, with the dependent variable measured in the same metric at each time point. For pooled time-series cross-section, this means having over-time data for each unit. When individuals are involved, this is usually referred to as panel (compared to cross-sectional) data. Any individual who has data only for a single time point must be dropped from the analysis. Similarly, for families and other groupings, there must be multiple observations for each family or group members. Thus, any family or group having only one sibling (member) in the data must also be dropped from the analysis. When families are involved, this could lead to the non-random loss of a large percentage of cases from the analysis, and could potentially be a significant cause of bias in the study.

Other Issues

The fixed-effects methodology makes additional demands on the data to be analyzed. Perhaps most significantly, it removes only the effects of unchanging unmeasured variables. Also, it estimates effects only for those X variables that change their values at least somewhat across the multiple observations for each unit. For example, if individuals are being observed over time, it is possible to estimate effects only for those variables that show change over time. Examples include age, work experience, job characteristics (to the extent that at least some workers do change their jobs over the period covered by our data), family characteristics such as married or not, and number

of children (if these change for at least some individuals over time), and so on. Variables that do not change (gender, race/ethnicity, year of birth, innate personal characteristics) cannot have their effects estimated [although these effects are removed from the analysis by the dummy variable (fixed-effect) coefficients]. Variables that change only a little bit, and only for a relatively small percentage of individuals (for example, years of schooling completed, when observed for adults who are in the middle of their employment careers), can have their effects estimated, but these estimates will be based only on those individuals whose variables do change, and only on those years during which they are observed. Thus, if fixed-effects estimation is thought of as taking the place of an actual experiment, then, in this case, the experiment involves increasing the schooling of some workers who have begun their employment career, rather than of younger students who have been continuously in school. Similarly, in the case of families and other groupings, families with only one sibling must be dropped from the analysis, and effects are estimated only for those variables that vary across siblings.

Incidentally, the time-series cross-section model has another strength. In addition to dummy variables (fixed effects) for individual units of observation, dummy variables can be included for each of the years the data are observed. This controls the effects of year-specific variables that might otherwise go unmeasured, and thus not accounted for in the analysis.

Estimation and Testing

The Dummy Variable and Difference Estimators

Equation (1) can be estimated using ordinary least-squares (OLS) regression, by simply using one dummy variable for each of the underlying units of observation (for example, each person, for which data for multiple observations per person have been pooled, or each family, for which data for multiple siblings per family have been pooled). As usual, when dummy variables represent a set of categories, if a constant term is included in the regression, one dummy variable must be omitted to avoid perfect multicollinearity. However, it is often quite cumbersome to code a dummy variable for each individual unit of analysis. Indeed, many panel data sets have thousands of individuals in the study, each of which is observed for as many as 10 or more time periods. Utilizing many thousands of dummy variables may go beyond what is possible with some statistical software, as well as leading to computational difficulties.

The solution is to construct each variable as a deviation (difference) from the group mean, and to perform a regression calculation with these deviated variables.

To understand how this works, consider the simple case of Eq. (1), in which there are only two time points, $t = 1$ or 2 . Write this equation for each of these time points:

$$Y_{i2} = b_1X_{1i2} + \cdots + b_kX_{ki2} + D_1 + \cdots + D_n + e_{i2}, \quad (2)$$

$$Y_{i1} = b_1X_{1i1} + \cdots + b_kX_{ki1} + D_1 + \cdots + D_n + e_{i1}. \quad (3)$$

Now, subtract Eq. (3) from Eq. (2). The result is

$$(Y_{i2} - Y_{i1}) = b_1(X_{1i2} - X_{1i1}) + \cdots + b_k(X_{ki2} - X_{ki1}) + (e_{i2} - e_{i1}). \quad (4)$$

As a result of subtraction, the individual-specific dummy variables have disappeared from the equation, leaving an ordinary regression of the change in Y on the change in X variables. This “first difference” model is the simplest form of fixed effects. When there are more than two time points, this differencing method can be extended by calculating the over-time average score of Y and the X variables for each individual, and subtracting this average from each time-specific score for the individual. Once again, the dummy variable (individual) fixed effects are differenced away, leaving each person/time-specific Y score minus the mean of these for the person regressed against similarly computed X variables. In this case, the OLS regression will give unbiased estimates, but the standard errors will have to be corrected. An identical development occurs when multiple siblings are grouped according to families. In this case, each variable for each sibling is deviated from the family mean, and the computation proceeds as described.

The fixed-effects estimator can also be understood as a “within-group estimator.” In an analysis-of-variance framework, there is also a “between-group estimator” that uses only the group-specific means. It can be shown that the ordinary least-squares estimator without fixed effects is actually a weighted average of the within- and between-group estimators.

Data Layout and Computation

In fixed-effects estimation, it is useful to sort the data so that the multiple observations for each unit of analysis (a person over time or siblings from the same family) are next to one another on the data. Typically, there is a variable, the values of which are the same for each of the multiple observations that are to be grouped together. Suppose this variable is called *ID*. Using the application SAS, a statistical analysis computer program created by the SAS Institute, the fixed-effects estimates are obtained using the PROC GLM procedure. This has a command called ABSORB, which will use the *ID* variable to group the data, create the deviations from group means, and perform the statistical analysis required. This also gives the correct standard errors for the effect estimates. Other

computer programs provide even more elaborate procedures for conducting these calculations. Particularly noteworthy is STATA, created by StataCorp, which has subprograms for cross-section time-series data that begin with “xt.”

Testing Goodness of Fit

As previously noted, the model usually competing with fixed effects is the random-effects model. This has the disadvantage that it assumes that the individual random effects are uncorrelated with the regressors X . It is just the possibility of such correlation that requires use of the fixed-effects model. The issue then becomes, is it possible to test the goodness of fit to the data of the fixed- versus random-effects model? The answer is yes. The Hausman test can reveal whether the fixed- or random-effects model fits the data better, and thus which one to use.

Substantive Uses of the Models

Effects of Occupations, Unions, and Other Memberships

One principal use of fixed-effects models has been to estimate the effects of membership in work-related organizations (occupations, unions, and so on) on earnings, net of variables that may be correlated with such membership, including unchanging variables (such as skill, energy, or motivation) that may be unmeasured. This technique has been used to demonstrate that employment in a highly female-worker-dominated occupation lowers wages, net of other characteristics, for both women and men. Labor economists have used the model to show that union membership raises earnings, with worker characteristics constant. Similar analyses of pooled time-series cross-section data are increasingly being used to measure the effects of marriage, childbearing, and divorce on outcomes such as mental health and earnings, controlling for unmeasured, unchanging characteristics of the individuals concerned.

Effects of Families and Other Groupings

A second use of these techniques has been to estimate the effects of changing group membership variables on child outcomes, net of unchanging, unmeasured group membership variables. In one study, twins were used to control for genetic factors when measuring the effect of schooling on earnings. Families with multiple siblings were used in another study to test the effect of the number of children in the household on the intellectual attainment of these children, net of unmeasured, unchanging characteristics, such as family intellectual climate. In contrast to prior

studies that did not use fixed effects, the latter study found that the number of siblings has no causal effect on children's intellectual attainment, once unmeasured, unchanging family variables are controlled via fixed-effects estimation.

Program Evaluation

A particularly attractive use of fixed effects occurs for evaluating social programs and interventions using quasi-experimental data collected over time. For example, suppose U.S. states are observed over a time period in which some program or policy (for example, welfare eligibility regulations, or capital punishment as a deterrent to homicide) is "turned on and off" by legislation. The data can then be pooled for each state over time, allowing estimation of a fixed-effects model with dummy variables for states, in which the key independent variable indicates, for each state in each time period, whether the policy is on or off. Here the state dummy variables control a host of state-specific factors, such as local culture, institutions, and social structure, that might otherwise bias the estimate of program effects. Fixed effects have also been used in program evaluations based on individual-level data and labor markets.

Other Areas

Increasingly, social scientists are coming to realize that fixed-effects estimation is potentially useful across a very broad range of circumstances in which pooled cross-section time-series or otherwise grouped data are analyzed, including economic and political science scenarios.

Strengths and Limitations

Strengths of the Model

As previously noted, the great strength of fixed-effects estimation is that it controls for the effects of correlated unmeasured, unchanging variables that may otherwise bias estimates of causal effect.

Limitations of the Model

Fixed-effects estimation uses only data on individuals having multiple observations, and estimates effects only for those variables that change across these observations. It assumes that the effects of unchanging unmeasured variables can be captured by time-invariant individual-specific dummy variables. Bias from measurement error is usually increased in fixed-effects estimators, which may be why fixed-effects estimates are usually smaller than those from cross-sectional data. Also,

problems can arise when fixed-effects estimation is used with models containing a lagged dependent variable, although methods exist to deal with these problems.

The Decision to Use Fixed Effects

In assessing panel or other grouped data, fixed-effects regression models are an attractive option to reduce possible bias due to unmeasured, unchanging variables that may be correlated with the variable of interest. The competing model is random effects, but this requires the assumption that the individual-level effects are uncorrelated with the regressors. Best practice is to test for this, using the test developed by Hausman.

Focus Groups

David L. Morgan

Portland State University, Portland, Oregon, USA

Glossary

degree of structure The extent to which the focus group interview is either directed by the research team (“more structured”) or left in the hands of the group participants (“less structured”).

funnel approach An interviewing technique that begins with broad, open questions in a less structured format, and then proceeds to more narrowly defined questions in a more structured format.

homogeneity The extent to which all of the participants in the focus group share a similar orientation to, or perspective on, the discussion topic.

question wording The actual content of the items in survey questionnaires and related measurement instruments.

saturation In qualitative research, the extent to which there is less new information in each additional round of data collection.

segmentation A strategy for creating homogeneous subsets of focus groups within a larger project, by assigning participants to groups according to prespecified characteristics, e.g., gender or previous experiences.

The use of focus groups is a technique for collecting qualitative data. Focus groups typically bring together six to eight participants who engage in an open-ended discussion about topics that are supplied by the researchers. Focus groups are thus a form of interviewing whereby the researcher provides the focus, which the group uses as the basis for their discussion. For measurement purposes, focus groups are most often used as a preliminary method that provides input to the development of survey instruments, questionnaires, and other measurement instruments in the social sciences. With that emphasis in mind, the first portion of this article describes the advantages of using focus groups as a preliminary step in

creating questionnaires; this is followed by a summary of the most important concerns in designing and using focus groups.

Introduction

Focus groups serve a general-purpose method for collecting data, and as such, they can serve a wide range of purposes. In particular, qualitative researchers frequently use focus groups in a self-contained fashion, in that the groups are the sole source of data for a study. From a measurement perspective, however, focus groups are most frequently used as a preliminary method that generates insights into what should be measured and how those measures should be constructed.

Various forms of group interviewing have played a role in the development of social science measures from very early in the 20th century. The basic format for what are now known as focus groups arose subsequently, in the 1990s, from the work of Paul Lazarsfeld and Robert Merton, although their approach applied to both individual and group interviews. From the 1950s through the 1970s, focus groups were far more common in marketing research than in the social sciences. This changed as group interviewing began to play a more prominent role in creating survey instruments, from the 1980s onward. This strategy relies on a sequential approach that begins by using focus groups as an input to the creation of quantitative research instruments. This amounts to collecting focus group data to enhance the effectiveness of measures that will be used in survey or experimental research, especially in areas in which researchers want to take a fresh approach to well-studied topics and for new topics for which researchers lack basic information. As the following discussions show, however, the knowledge

gained through such preliminary focus groups can also serve a variety of other related purposes.

Advantages of Focus Groups in Creating Measures

It might initially seem more logical to use individual rather than group interviews in the development of questionnaire items, because it is almost always individuals who respond to these instruments. In reality, however, the choice of a preliminary method needs to be driven by developmental work. Focus groups have a distinct advantage for this task, because they can reveal a wide range of responses to topic in question. This is notably useful in designing measurement items that apply equally well to the full range of people who will respond to a questionnaire.

Researchers have offered three specific justifications for using focus groups (and other qualitative methods) as inputs to the development of quantitative measures. In discovery-oriented uses, the focus groups are largely exploratory, and the goal is to uncover topics that should be measured. In development-oriented uses, the focus groups examine a prespecified set of issues, and the goal is to locate ways to measure these substantive topics. Finally, in definition-oriented uses, the focus groups supply detailed information, in order to specify the final question wording for specific research topics. This distinction between discovery, development, and definition as three different uses for preliminary focus groups is most useful for heuristic purposes. Actual research projects often include more than one of these purposes. Even so, distinguishing among these three uses has important implications for how the focus groups are conducted. In particular, the research designs that are most effective for discovering new ideas are likely to be quite different from the designs that are best for defining well-developed concepts.

The use of focus groups as inputs to measurement goals that emphasize either discovery, development, or definition is examined in the next three sections. The emphasis is on applications in the area of survey research, along with a brief, concluding discussion on related uses for focus groups in the development of experiments and interventions.

Discovery-Oriented Uses of Focus Groups

The primary reason for beginning a survey project with discovery-oriented focus groups is to gather basic information about a poorly understood topic or population of respondents. This approach emphasizes the strengths that qualitative methods offer in exploratory research. Too

often, preliminary focus groups in survey research are stereotyped as dealing solely with issues of question wording, but in an explicitly exploratory study, the essential goal is to learn what should be asked, prior to worrying about how to phrase the actual questions. Early social science research on autoimmune disease syndrome/human immunodeficiency virus (AIDS/HIV) is a classic example of using preliminary focus groups when entering a new field of study. Although the need for epidemiological data led these projects to rely on large-scale surveys, the researchers recognized that they knew very little about the lives of the people who were at highest risk. Hence several of these projects began with focus groups and other open-ended interviewing techniques as a way to learn more about the range of issues that the survey should cover.

One of the key advantages of discovery-oriented designs is to improve the specification of the models that the quantitative research will test. When relatively little is known about either the topic being studied or the people being surveyed, there is a serious danger that a crucial topic will get omitted. This failure to include important variables is not just a matter of missed opportunities, it is actually a source of potentially serious statistical bias in the form of "specification error." For example, leaving an important variable out of a multiple regression will affect the values of all of the coefficients that are estimated. There is no statistical solution for specification error, so, if there are doubts about whether a survey includes a wide enough range of relevant variables, then a set of preliminary, discovery-oriented, focus groups studies can help clarify the factors that matter to the respondents. In general, discovery-oriented focus groups are most useful when a researcher is uncertain about what to measure with regard to a topic or population of interest.

Development-Oriented Uses of Focus Groups

In projects that rely on preliminary focus groups for development, the goal is to learn how a set of key issues operates in the lives of the people being studied. Often this amounts to locating questions that will operationalize a theoretical concept. This approach emphasizes the strengths of qualitative methods for learning about others' perspectives on the things that interest the researcher.

Development-oriented versions of focus groups typically search for a set of questions that can adequately cover a predetermined topic. The discussions in focus groups let researchers hear the respondents' perspectives on that topic. Using preliminary focus groups to develop operationalizations for the key concepts in a survey reveals the behaviors and opinions that the respondents associate with the research topics. This can be especially helpful when creating sets of questions that apply equally well to several categories of respondents, such as men and

women, different ethnic groups or age groups, and so on. For this purpose, comparing focus groups from each of the major categories of respondents can increase the likelihood of developing questions that are equally meaningful to all the respondents. In general, development-oriented groups are most useful when a researcher has clear ideas about the topics to measure, but is uncertain about the proper items to capture these domains.

Definition-Oriented Uses of Focus Groups

When definition is the purpose that drives the use of preliminary focus groups in a project, the goal is to determine the final content of the survey instrument. This approach emphasizes the strengths of qualitative methods for studying social life both in detail and in context. The primary reason for beginning a survey research project with a definition-oriented qualitative study is to assist in creating the actual item wording for the questionnaire. Because the quality of the data in a survey depends directly on the questions that are asked, it is not enough just to ask about the right topics (discovery), or to locate question topics that cover the researchers' interests (development); beyond those essential goals, it is also necessary to write the questions in language that the respondents cannot only understand easily, but in language that also means essentially the same thing to both the respondents and the researchers (definition).

Regardless of the theoretical or practical concerns that motivate an interest in a particular research topic, asking effective survey questions requires an understanding of how the survey respondents talk about these topics. Put simply, researchers cannot create meaningful questions unless they understand the language that the respondents use. Once again, a useful example comes from research on AIDS with gay and bisexual men; focus groups helped researchers to locate appropriate wordings for asking about a range of sexual behaviors. In general, definition-oriented groups are most useful when a researcher knows the content areas for the measurement instrument, but is uncertain about the best ways to state the final wording.

Preliminary Focus Groups in Experimental Interventions

One obvious parallel between survey research and experimental interventions is that both methods frequently rely on similar kinds of measurement instruments, such as self-completed questionnaires or in-person surveys. The measurement instruments in experimental interventions can thus benefit from preliminary focus groups in the same ways that survey research can.

A different purpose for preliminary focus groups in intervention studies is to create and deliver programs that are well suited to the people who will participate in them. The same set of three basic advantages also applies to these practical purposes, because it is useful to (1) discover the program participants' needs and constraints, (2) develop programs that will effectively meet these needs, and (3) define program procedures that will work in practice and not just in theory. This similarity follows directly from the shared goal of generating preliminary input, in order to develop materials that will match the thoughts, feelings, and experiences of those who will participate in the subsequent portion of the project.

Additional Advantages of Preliminary Focus Groups

Two different sets of advantages can arise from using preliminary focus groups to develop measures. The first set involves the classic criteria of reliability and validity. The second set is less directly related to the properties of the measures, but may be just as important for the overall success of the research project.

Increased validity is the most obvious attraction of locating questions that are meaningful to the people who will respond to measurement instruments, including the essential goal of ensuring that the questions mean the same thing to both the researchers and the respondents. In the extreme case, preliminary focus groups may show that a set of theoretically generated constructs of interest to the researchers actually has very little relevance to the respondents. For example, research group was asked to use focus groups in developing survey questions that would operationalize a particular theory of how couples handled household finances; instead, the researchers found that almost no one described their lives in terms that fit the prespecified theoretical categories. Without this qualitative research, it still would have been possible to write questions that captured this particular theory, even though those items might not measure anything that was meaningful to the respondents.

The reliability of the survey instrument can also benefit from preliminary focus groups. This is especially true for checklists and attitude scales, which require parallel measures, i.e., multiple items, each targeting the same underlying phenomenon in a similar way. Thus, preliminary focus groups can improve both the reliability and validity of survey measures by generating a sufficient number of survey items that effectively capture what a topic means to the survey respondents.

The uses for preliminary focus groups can also go beyond improvements to reliability and validity. Often, quantitative researchers start with relatively limited

purposes for focus groups, such as defining the wording for survey questions or program materials, but come away from this preliminary qualitative work with a whole new set of ideas. In particular, preliminary focus groups can also contribute to surveys and experiments by generating hypotheses and by building relationships between the research team and the research participants.

Quantitative researchers seldom undertake focus groups solely for the purpose of generating hypotheses, because they almost always have a set of research questions already in place. This does not, however, preclude the possibility of pursuing additional hypotheses. Further, there is no requirement that hypotheses must be deduced strictly from theory. In many situations, it makes just as much sense to generate hypotheses inductively through qualitative research, which provides direct contact with the people whose behavior the researchers are trying to understand.

Another common benefit in preliminary focus groups comes from building relationships with the people who will actually be participating in the research project. The value of these relationships is particularly obvious in projects that work with a specific community or target population. In those cases, access to the people who provide the data may require both an understanding of and a connection to the local community. Even with random sampling, this kind of prior contact can provide practical insights that increase the efficiency and effectiveness of the actual fieldwork.

Generating hypotheses and building relationships are further demonstrations of the benefits that can result from using focus groups to create careful connections between those who design research projects and those who participate in them. In each case, the advantages of this approach arise from learning more about the research participants' perspectives and understanding more about the context in which the larger research project will operate.

Designing Focus Groups for Measurement Purposes

Given that focus groups can be used in a number of different ways for a number of different purposes, what are the essential considerations in designing preliminary focus groups as an input to creating measures?

Group Composition

Focus groups work best when the participants are as interested in the topic as the researchers are. Because the conversation among the participants produces the data in focus groups, it is important to bring together a set of

people who can easily talk to each other about the topic of interest. The selection of participants for a focus group must thus consider not only the information that individuals have to share with the researchers, but also the ability of the participants to carry on a comfortable group discussion.

The classic approach to facilitating comfortable group discussions is to emphasize homogeneity in the composition of focus groups by bringing together people who share a similar perspective on the topic in question. One obvious advantage of this similarity is the tendency to minimize conflict. In addition, an initial degree of homogeneity can be used to stimulate a process of "sharing and comparing," whereby the participants explore the ways that they are both similar and different with regard to the topic. Conversations that contain such comparisons can be especially useful for developing measures, because they provide insight into the range of issues that need to be considered in constructing measures.

The idea of segmentation is an important extension of relying on homogeneity in the composition of focus groups. With this approach, the total set of participants is divided into a set of homogeneous segments, and different focus groups are conducted with the members of each segment. For example, if a series of questions need to be equally effective in measuring the responses of Americans of European and African descent, then the focus groups would be segmented into separate groups by race. Dividing a set of focus groups into separate, homogeneous segments has two basic advantages. In addition to using the similarity within each group to facilitate conversations among the participants, concentrating the differences between groups also simplifies analytic comparisons across the segments. This approach is well suited to creating measures for use in diverse populations because it allows the researcher to compare the sets of separate groups to determine the ways that the various segments are either similar or different.

Another aspect of group composition that needs to be considered is the number of people in each group, and this also depends on how the participants relate to the topic. If the topic is important to the participants, then each of them will have a fair amount to say, and a smaller group will allow everyone an opportunity to be heard. When the participants are less involved with the topic, however, a larger group is more likely to produce enough ideas to generate a discussion through the participants' reactions to those ideas.

Interview Structure

In addition to planning who will participate in the groups, it is also important to decide how the group discussions will be conducted. This aspect of focus groups is usually summarized in terms of interview structure, with some

research projects using a more structured approach than others.

Interview structure consists of two interrelated aspects of focus groups: the interview questions and the moderating strategy. These two elements are connected because an interview that contains a relatively small number of broad questions requires a different moderator style than does an interview that asks about a larger number of more specific topics. Thus, a less structured interview will usually combine a smaller number of very open-ended questions with a moderating style that emphasizes hearing from the participants. In contrast, a more structured interview will combine a larger number of more specific questions with a moderating style that emphasizes the needs and interests of the research team.

For measurement purposes, less structured focus groups are typically associated with discovery-oriented purposes, whereas more structured approaches are well matched to definition-oriented purposes. When the research goals emphasize discovery, the researchers are trying to learn the participants' perspectives on the topic, so a less structured discussion gives the participants the opportunity to pursue a broad set of topics in whatever ways they see fit. Alternatively, when the research goals emphasize definition, the researchers already have a well-specified agenda, so a more structured approach ensures that participants concentrate on the predefined needs of the research team.

In the intermediate case of development-oriented research, a "funnel approach" is frequently useful because it combines elements of both more and less structured interviews. A funnel approach begins the interview with one or two broad, open questions, which lead into a series of more specific questions. The interview thus starts with a less structured approach that emphasizes the participants' point of view, and proceeds to a more structured approach that concentrates on the researchers' agenda. This funnel approach is also useful in projects that combine a range of goals in terms of discovery, development, and definition.

Number of Groups

There are no hard and fast rules that determine the number of focus groups to conduct. Ultimately, the number of groups depends on the familiar constraint imposed by the underlying variability of the population. When there is relatively little variability in the population, then the researcher will begin to hear the same things during the second or third group. This sense that additional data gathering is not producing new information is known as saturation in qualitative research. If, however, there is a wide range of opinions or experiences in the larger population, then it will take a larger number of focus groups before nothing new is being said in each additional group.

Because the level of variability in the population is difficult to specify when working with new topics or new categories of participants, it is especially dangerous to limit preliminary research to only one focus group. Conducting only one group does not provide any information about the variability of the population, so it is impossible to know whether a second group would be nearly identical or completely different. In projects that use multiple segments, the same concern applies to running only one group per segment. It is thus advisable to conduct a minimum of at least two groups per segment.

Analysis Procedures

The analysis strategy for these focus groups should be determined by the larger goal of generating inputs for measurement construction. Because this goal is simpler than the interpretive work that accompanies many full-scale qualitative studies, the analysis procedures can also be simpler. In particular, it would seldom be necessary to use either qualitative analysis software or a detailed coding system to analyze data that serve primarily as an input to creating questionnaires.

The standard procedure for capturing data in focus groups is to audiotape the discussions. Transcribing these tapes can be a time-consuming and difficult task, which is most useful either when there are a great many tapes to be compared or when the content of each discussion needs to be examined in careful detail. One common alternative to transcribing is to have more than one member of the research team present during the group discussion, so they can meet and debrief after the discussion. This approach is most effective when the observers have a prior protocol that directs their attention to the aspects of the discussion that are most likely to be useful for the purpose at hand.

Practical Concerns in Using Preliminary Focus Groups

The most serious limitation in the use of focus groups arises from the fact that they almost always rely on small nonrandom samples. Hence, the data that they produce must be used with caution, even when the goal is simply to provide preliminary inputs. In particular, both the nonrandom samples and the subjective group discussions undermine the value of producing numerical data as part of the focus group process. There may, however, be other purposes for quantitative techniques within a research project that uses focus groups. For example, a brief preliminary questionnaire can provide useful background data about the participants. In addition, interview questions that use a show of hands or other forms

of counting can help stimulate the group discussion. The danger arises from going beyond such simple, descriptive purposes to a more dubious attempt to drawing meaningful, numerical conclusions from such data.

A different limitation arises from the fact that focus groups only produce verbal statements about attitudes and preferences, which may not translate into actual behaviors. This potential gap between attitudes and behaviors is a problem in all forms of self-reported data. Still, there is a vividness to hearing people state and defend their beliefs in focus groups, and this can mislead researchers into placing an unjustifiable amount of faith in these attitudes.

Donald Dillman provides a useful counterexample from a project that he and his co-workers conducted at the U.S. census, when their extensive experience with a topic led them to question what they heard in focus groups. In that case, the participants examined a number of different envelopes that could be used to mail census materials, and reported a strong negative response to an official-looking format. Because of their past success with official-looking envelopes, these researchers did a test and found that such a mailing actually produced a significantly higher response rate, compared to the format that the focus group participants preferred. The moral of this story is that focus groups are more useful for learning about experiences, feelings, and opinions, rather than for predicting behavior.

This tendency to rely too heavily on the data from focus groups is also present in the mistaken assumption that preliminary qualitative research reduces the need for thorough pretesting. It is thus essential to remember that preliminary focus groups provide only inputs to the development of measures; they do not provide any guarantee that those measures will perform as desired. As always, the only way to determine the actual effectiveness of a measure is to test it.

Future Directions

The relationship between focus groups and pretesting, as just discussed, is part of a broader series of issues involving different techniques for improving the quality of questionnaire measurements. In particular, even though focus groups are frequently grouped together with cognitive interviewing as “developmental tools” in survey research, these methods typically serve distinct purposes. Currently, very little is known about optimum strategies for combining focus groups with cognitive interviewing and other developmental strategies.

One simple hypothesis is that items and instruments developed via focus groups would need less refinement through cognitive interviewing, based on the assumption that such items were already “closer” to the respondents’

perspective. This is, however, an empirical question. What is needed is research that investigates the potential overlap in the preliminary contributions of focus groups, cognitive interviewing, and other developmental strategies. An increase in our understanding of what each of these techniques can contribute would not only increase efficiency but would also allow researchers with limited resources to select the tools that were most likely to address their particular problems.

This lack of data about the relationships between various developmental tools is, however, only one part of a larger gap in knowledge about the value of focus groups as a preliminary input to measurement construction. In fact, there is no clear-cut evidence that preliminary focus groups actually improve the quality of measurement instruments in the social sciences. Instead, it simply seems to be an article of faith that researchers who listen to their future respondents will produce instruments that are superior to what they would have written in the absence of this additional input. This oversight is especially surprising in light of the considerable research literature that investigates the effectiveness of a wide range of practices in survey research.

Questioning the extent to which focus groups truly do contribute to measurement points to a paradoxical situation. On the one hand, the past two decades have produced a tremendous increase in the use of focus groups as a preliminary tool in the development of surveys and questionnaires. On the other hand, there is little systematic evidence that addresses the value of these procedures. At this point, it is necessary to produce clear demonstrations of the increased quality in measures that is due to focus groups—and making use of that evidence will provide the best way to improve future uses of focus groups for this purpose.

The widespread use of focus groups in the development of measures supports the value of hearing from research participants prior to presenting them with questionnaires. Despite the lack of research on how developmental focus groups affect the quality of measures, there is little doubt about the value of improving our understanding of the people who will provide the data. This is where focus groups make the biggest difference, by helping us do the best possible job of asking people meaningful questions about the things that matter most to them.

Frameworks of Probabilistic Models for Unfolding Responses

Guanzhong Luo

*Murdoch University, Perth, Western Australia and South China
Normal University, Guangzhou, China*

Glossary

cumulative response process A response process in which the ideal direction principle applies.

ideal direction principle The probability that a person gives a positive response to an item depends on the difference between the locations of the person and the item. This person–item difference may be positive or negative. The probability is 1 when the person–item difference is positive infinity.

ideal point principle The probability that a person gives a positive response to an item depends on the distance (absolute value of the difference) between the locations of the person and the item. This person–item distance is always non-negative. The probability is maximized when the person–item distance is 0.

unfolding process A response process in which the ideal point principle applies.

This article provides a summary of the frameworks of models for unfolding responses. The origin of the term “unfolding” is first explained in the context of constructing a deterministic unfolding model, which is a prototype of modern probabilistic unfolding models. Among the three different response formats for the unfolding process, the single-stimulus format is fundamental. Second, a general form of probabilistic unfolding models for dichotomous responses in the single-stimulus format is described, with the focus on the significance of the item unit parameter for the structure of the model. This general form highlights the role of a single peaked function in the unfolding process. Then a general form of probabilistic unfolding models for responses in pairwise format is derived. Consequently, a general form of probabilistic

unfolding models for polytomous responses is then established using the rating formulation approach. As direct results of the frameworks of unfolding models, some basic techniques of confirming the desirable response process are presented.

Structure of the Unfolding Response Process

Psychological measurement in social sciences, which concerns the attitudes, beliefs, preferences, or other constructs (topics) of individuals, is often carried out by means of questionnaires. A questionnaire consists of statements (items) expressing certain affective evaluation of the construct concerned. A primary task of the measurement is to locate respondents and statements on an affective continuum (unidimensional) or space (multidimensional) according to the responses given by the respondents. Responses can be invoked in various formats, including single-stimulus (direct-response), pairwise-preference, and ranking formats. A questionnaire in a single-stimulus format asks respondents to give each of the statements in the questionnaire a direct preference level. This preference level may range from highly negative to highly positive (e.g., from “strongly disagree” to “strongly agree”) or may be expressed as a frequency scale (e.g., from “never” to “always”). A questionnaire in a pairwise-preference format gives a pair of items at a time and asks respondents to choose the more preferable one against the other. A questionnaire in a ranking format asks respondents to rank the items according to their preference, from the most preferable to the least preferable. Among these three response formats, the single-stimulus format, also

known as the direct-response format, is fundamental, because a response within this format is governed directly by a single person–item distance. A response with pairwise-preference and ranking formats is governed by the comparison of the distances between the person and the items involved. The focus of this article is on a framework of probabilistic models for responses with a single-stimulus format, though a framework for the pairwise-preference format will also be derived from the framework for the single-stimulus format. The rest of this article is restricted on unidimensional situations.

Louis Thurstone pioneered studies on attitude measurement in the 1920s, using both the ideal direction and the ideal point principle. Clyde H. Coombs, a student of Thurstone's, carried on the research within the ideal point framework with a more systematic approach. Coombs introduced the term “unfolding” when he analyzed ranking data (collected with a questionnaire in ranking format) in the early 1950s. Based on this concept, he established his unfolding theory, which covered various types of data in different response formats. In particular, his milestone work in dealing with single-stimulus data (collected with a questionnaire in single-stimulus format) provided a prototype of the modern probabilistic unfolding models. In the unidimensional case, the affective continuum on which the person and the item are located is termed the “latent trait” continuum. In single-stimulus data, the manifest response that a person n gives to item i is denoted as x_{ni} , which can be dichotomous or polytomous. In the case of dichotomous responses, a legitimate response is either “agree/yes” (positive, $x_{ni} = 1$) or “disagree/no” (negative, $x_{ni} = 0$). The principle for the unfolding process is that the response x_{ni} is determined by the person–item distance $|\beta_n - \delta_i|$, where β_n is the location of person n and δ_i is the location of item i . Coombs explicitly defined x_{ni} as a step function of the person–item distance:

$$x_{ni} = \begin{cases} 1, & \text{when } |\beta_n - \delta_i| \leq \rho, \\ 0, & \text{when } |\beta_n - \delta_i| > \rho. \end{cases} \quad (1)$$

Here, β_n is also known as the ideal point for the person. The value of ρ in Eq. (1) determines the two thresholds between the response interval for a positive response “yes” ($x_{ni} = 1$) and two disjoint segments for a negative response “no” ($x_{ni} = 0$), as shown in Fig. 1.

Although two very different segments on the latent trait give rise to a negative response, according to Coombs, a negative manifest response is certain if the absolute value of the person–item difference is greater than the given value of ρ , regardless of in which segment the person is located. In this sense, the responses are folded, as shown by the heavy line in Fig. 1. The task of the data analysis is to unfold these responses to recover the underlying latent trait continuum with the locations of the persons and items involved. In addition, the value of ρ is to be recovered or estimated. The distance

Figure 1 Coombs' deterministic unfolding model, showing the “yes” interval (Y) and “no” segments (N).

between the two thresholds (2ρ) is termed the “latitude of acceptance,” an important concept in attitude theory. Originally, ρ was defined as a person parameter. In the frameworks described later in this article, however, ρ is considered as an item parameter in order to avoid the problem of overparameterization.

It can be seen that Coombs' original unfolding model for direct responses in Fig. 1 is deterministic in the sense that the probability for a positive response, $\Pr\{x_{ni} = 1\}$, is 1 when the absolute value of the person–item distance is less than ρ , and 0 otherwise. The concept of probabilistic unfolding models naturally arises when a single peaked function is used in the place of the rectangle function. Figure 2 shows that Coombs' deterministic unfolding model for direct responses defines $\{x_{ni} = 1\}$ as a certain outcome in the interval $[\delta_i - \rho, \delta_i + \rho]$, whereas a probabilistic unfolding model allows the probability $\Pr\{x_{ni} = 1\}$ to be any number between 0 and 1.

Using the concept of probabilistic unfolding models for single-stimulus format, it is straightforward to obtain the probabilities for responses with a pairwise-preference format. For an item pair (i, j) , the pairwise responses are coded as $x_{nij} = 1$ when person n chooses item i against item j . A pairwise-preference format requires respondents to choose the one that is comparatively more preferable of the pair. It implies that the underlying responses with a single-stimulus format on these two items are either (0, 1) or (1, 0), that is, one and only one item in this pair must be given a positive response. Then the probability that item i is chosen against item j can be expressed in terms of the probability for a positive response on item i and the probability for a negative response on item j , given the condition that only one item in this pair is given a positive response:

$$\begin{aligned} \Pr\{x_{nij} = 1\} &= \frac{\Pr\{x_{ni} = 1\} \Pr\{x_{nj} = 0\}}{\Pr\{x_{ni} = 1\} \Pr\{x_{nj} = 0\} + \Pr\{x_{ni} = 0\} \Pr\{x_{nj} = 1\}}. \end{aligned} \quad (2)$$

Figure 2 Probabilities of unfolding models: deterministic vs. probabilistic.

From Eq. (2), the probability of any item rank can also be expressed in terms of the probabilities for all item pairs. Therefore, it is widely accepted in the literature that the family of unfolding models includes all the models for all three response formats mentioned earlier, the underlying response function of which is single peaked. Consequently, the response process governed by these models is generally termed the “unfolding” process. Because of the shape of the response functions in Fig. 2, they are also known as single-peaked response processes.

A Framework of Dichotomous Probabilistic Models for the Unfolding Response

During the 30 years since Coombs developed his unfolding theory, particularly in the late 1980s and 1990s, various other specific probabilistic unfolding models for dichotomous responses have been proposed. Suppose that N persons give responses to a questionnaire consisting of I items. For any person n with location β_n and any item i with location δ_i , the response variable is denoted as $X_{ni}: x_{ni} \in \{0, 1\}$. By specifying different probabilistic functions that conform to the unfolding principle, various probabilistic unfolding models have been proposed. In particular, the followings models are frequently referenced in the literature and are used in real applications.

1. The simple square logistic model (SSLM):

$$\Pr\{X_{ni} = 1 \mid \beta_n, \delta_i\} = \frac{1}{1 + \exp[(\beta_n - \delta_i)^2]}. \quad (3)$$

2. The PARELLA (parallelogram analysis) model:

$$\Pr\{X_{ni} = 1 \mid \beta_n, \delta_i, \gamma\} = \frac{1}{1 + [(\beta_n - \delta_i)^2]^\gamma}, \quad (4)$$

where $\gamma (> 0)$ is a structural parameter of the model.

Figure 3 Construction of the hyperbolic cosine model from the Rasch model for polytomous responses.

3. The hyperbolic cosine model (HCM):

$$\Pr\{X_{ni} = 1 \mid \beta_n, \delta_i, \theta_i\} = \frac{\exp(\theta_i)}{\exp(\theta_i) + 2 \cosh(\beta_n - \delta_i)}. \quad (5)$$

The probability for a negative response $\Pr\{X_{ni} = 0\}$ for the individual models is implied as $\Pr\{X_{ni} = 0\} + \Pr\{X_{ni} = 1\} = 1$. Among these models, the HCM is distinguished in that it is derived from the Rasch model rather than being specified descriptively. This in fact reveals the relationship between the cumulative process and the unfolding process. In constructing the HCM, the “disagree” response is resolved into two latent components, “disagree below,” which reflects that the person may be located below the statement, and “disagree above,” which reflects that the person may be located above the statement. Then the Rasch model for three ordered response categories was applied to these two components of the “disagree” response together with the single “agree” response. The final form of the HCM was obtained by summing the probabilities of the two latent components of the “disagree” response to reflect the single manifest “disagree” response. After summing up the probabilities of the two latent components of the “disagree” response, the HCM gives the probabilities for both positive and negative responses as in Eq. (5). Figure 3 shows the probabilistic functions of the HCM (solid lines) and the corresponding Rasch model for three categories (dashed lines).

Another significance of the HCM of Eq. (5) is in involving a second item parameter, θ_i , in addition to the item location, δ_i . However, an obvious limitation of Eq. (5) is that it involves two types of functions. The statistical meaning of θ_i in this form is also unclear because $\delta_i \pm \theta_i$ are not exactly the crossing points of the probabilistic curves for positive and negative responses of the HCM. Let

$$e^{\theta_i} = 2 \cosh(\rho_i), \quad (6)$$

then Eq. (5) can be re-expressed into the following form, which involves only the hyperbolic cosine function:

$$\begin{aligned}\Pr\{X_{ni} = 1 | \beta_n, \delta_i, \rho_i\} &= \frac{\cosh(\rho_i)}{\cosh(\rho_i) + \cosh(\beta_n - \delta_i)}, \\ \Pr\{X_{ni} = 0 | \beta_n, \delta_i, \rho_i\} &= \frac{\cosh(\beta_n - \delta_i)}{\cosh(\rho_i) + \cosh(\beta_n - \delta_i)}.\end{aligned}\quad (7)$$

The parameter $\rho_i (\geq 0)$ in Eq. (7) defines the two thresholds $\delta_i \pm \rho_i$ in the following sense. When $|\beta_n - \delta_i| < \rho_i$, a positive response ($X_{ni} = 1$) is more likely: $\Pr\{X_{ni} = 1\} > \Pr\{X_{ni} = 0\}$. When $|\beta_n - \delta_i| > \rho_i$, a negative response ($X_{ni} = 0$) is more likely: $\Pr\{X_{ni} = 0\} > \Pr\{X_{ni} = 1\}$. When $|\beta_n - \delta_i| = \rho_i$, $\Pr\{X_{ni} = 0\} = \Pr\{X_{ni} = 1\} = 0.5$. As shown in Fig. 3, $(\delta_i \pm \rho_i)$ are the two points of intersection of the positive and negative response curves. That is, when $|\beta_n - \delta_i| = \rho_i$, $\Pr\{X_{ni} = 0\} = \Pr\{X_{ni} = 1\} = 0.5$. Based on this fact, ρ_i is termed the unit parameter of item i . It is noted that when $\theta_i < \ln 2$, Eq. (6) cannot be solved. Therefore, Eq. (6) is valid only when $\theta_i > \ln 2$. In fact, when $\theta_i > \ln 2$, the probability for a positive response in Eq. (5) is always less than that for a negative response, regardless of the locations of the person and the item.

As shown in the preceding discussion, the hyperbolic cosine function and the item unit parameter ρ_i in Eq. (6) are structural rather than *ad hoc*. It is noted that the hyperbolic cosine is a non-negative monotonic and even function. These properties are considered essential for the HCM. By replacing the hyperbolic cosine function in the equation while retaining its essential properties, a general form of the probabilistic unfolding models for dichotomous responses can be proposed as follows:

$$\begin{aligned}\Pr\{X_{ni} = 1 | \beta_n, \delta_i, \rho_i\} &= \frac{\Psi(\rho_i)}{\Psi(\rho_i) + \Psi(\beta_n - \delta_i)}, \\ \Pr\{X_{ni} = 0 | \beta_n, \delta_i, \rho_i\} &= \frac{\Psi(\beta_n - \delta_i)}{\Psi(\rho_i) + \Psi(\beta_n - \delta_i)},\end{aligned}\quad (8)$$

where β_n , δ_i , and ρ_i are as defined earlier, and the function Ψ (the operational function) has the following properties:

- (P1) Non-negative: $\Psi(t) \geq 0$ for any real t .
- (P2) Monotonic in the positive domain: $\Psi(t_1) > \Psi(t_2)$ for any $t_1 > t_2 > 0$.
- (P3) Ψ is an even function (symmetric about the origin): $\Psi(t) = \Psi(-t)$ for any real t .

As mentioned before, the hyperbolic cosine function holds these properties. In general, the property P1 ensures that the probability of Eq. (8) is non-negative. Properties P2 and P3 ensure that for any item location δ_i and unit ρ_i , the probability is a single peaked function of person location parameter β_n . Figure 4 shows the

Figure 4 Probabilistic curves of the general unfolding model for dichotomous responses, with different values of the item unit.

probabilistic curves for a positive response when the values of item unit increase. It is observed that for β_n , δ_i fixed at any value, $\Pr\{X_{ni} = 1\}$ is a monotonic function of ρ_i .

It is trivial to confirm that after some simple re-expression, the models in Eqs. (3) and (4) are special cases of Eq. (7). In particular, the implied value for the item unit parameter in the SSLM of Eq. (3) and the PARELLA of Eq. (4) are 0 and 1, respectively. These two models can be extended by allowing a variable item unit. Furthermore, some more new models can also be specified with various operational functions that hold the properties P1–P3. In this sense, Eq. (8) provides a framework of probabilistic unfolding models for dichotomous responses. With this framework, the general properties of probabilistic dichotomous unfolding models are more transparent. For example, it is proved that the item unit ρ_i is not a scale parameter except in the case of the PARELLA model, with which the operational function is specified as $\Psi(t) = [t^2]^\gamma$. In this special situation,

$$\frac{[\rho^2]^\gamma}{[\rho^2]^\gamma + [(\beta_n - \delta_i)^2]^\gamma} = \frac{1}{1 + [((\beta_n - \delta_i)/\rho)^2]^\gamma}. \quad (9)$$

Using Eq. (8) with Eq. (2), a general form for pairwise-preference responses can be obtained as

$$\Pr\{X_{nij} = 1\} = \frac{\Psi(\rho_i)\Psi(\beta_n - \delta_j)}{\Psi(\rho_i)\Psi(\beta_n - \delta_j) + \Psi(\rho_j)\Psi(\beta_n - \delta_i)}. \quad (10)$$

When $\rho_i = \rho_j$, the general form of Eq. (10) can be further simplified:

$$\Pr\{X_{nij} = 1\} = \frac{\Psi(\beta_n - \delta_j)}{\Psi(\beta_n - \delta_j) + \Psi(\beta_n - \delta_i)}. \quad (11)$$

Figure 5 Probabilistic curves of unfolding models with pairwise-preference formats ($\delta_i = -1$, $\delta_j = 1$). HCM, Hyperbolic cosine model; SSLM, simple square logistic model.

Figure 5 shows the probabilities function in Eq. (11) when the underlying models are the HCM, SSLM, and PARELLA, respectively. It is noted that the asymptotic probabilities are different for different underlying models. For example, when $\delta_i < \delta_j$,

$$\lim_{\beta_n \rightarrow -\infty} \Pr\{X_{nij} = 1\} = \begin{cases} 1, & \text{with the SSLM;} \\ \frac{\exp(\delta_j - \delta_i)}{1 + \exp(\delta_j - \delta_i)}, & \text{with the HCM;} \\ 0.5, & \text{with PARELLA;} \end{cases}$$

$$\lim_{\beta_n \rightarrow +\infty} \Pr\{X_{nij} = 1\} = \begin{cases} 0, & \text{with the SSLM;} \\ \frac{1}{1 + \exp(\delta_j - \delta_i)}, & \text{with the HCM;} \\ 0.5, & \text{with PARELLA.} \end{cases} \quad (12)$$

When $\delta_i > \delta_j$, a similar result [exchange $+\infty$ with $-\infty$ in Eq. (12)] can also be observed. These asymptotic probabilities reveal the difference of the three specific models. Asymptotically, with the SSLM, the preference on item i against item j becomes certain, regardless of the locations of the items involved. With the PARELLA, however, the preference on item i against item j becomes totally random, though also regardless of the locations of the items involved. With the HCM, the asymptotic probability is a logistic function of the location difference of the items, which is the Rasch-type probability for pair comparison. This fact again points to the relationship between the HCM and the Rasch model. In summary, the difference in the asymptotic probabilities reflects the difference in the assumptions on the measurements to be carried out, and it provides a guideline in selecting the right model, i.e., one that conforms to the requirement of a particular measurement task within the unfolding framework.

A Framework of Polytomous Probabilistic Models for Unfolding Responses

It is generally suggested that polytomous responses provide more information, compared to dichotomous responses, when the same set of statements is used. The Likert scale is a pervasive example of using polytomous response. However, the development of probabilistic unfolding models for polytomous responses lagged behind the demand that arises from real applications. In past few years, some probabilistic unfolding models for polytomous responses have been individually developed, either as the extension of the HCM or using the rationale similar to what was used in developing the HCM. The general form of polytomous unfolding models described in this section helps to understand the fundamental structure and properties of the unfolding process in the polytomous response format. The general form is constructed by means of the rating formulation with which the threshold form of the Rasch model for polytomous responses is constructed. The rating formulation for general cumulative and single-peaked processes is summarized in the following discussion, but readers may skip it and jump to the paragraph after Eq. (18).

Rating Formulation

In a general context, a polytomous response variable X with possible value $\{0, 1, \dots, m\}$ can be mapped into an observation of a random dichotomous vector $Z = (Z_1, Z_2, \dots, Z_m)$ as

$$(Z = (\underbrace{1, 1, \dots, 1}_k, \underbrace{0, 0, \dots, 0}_{m-k})) \iff (X = k),$$

$$k = 0, 1, \dots, m. \quad (13)$$

The collection of possible mapping observations of X to Z is

$$\Omega' = \{(\underbrace{1, 1, \dots, 1}_k, \underbrace{0, 0, \dots, 0}_{m-k}), \quad k = 0, \dots, m\}. \quad (14)$$

Let $\Delta = \{0, 1\}$; all the possible outcomes of $Z = (Z_1, Z_2, \dots, Z_m)$ are

$$\Omega = \underbrace{\Delta \times \Delta \times \dots \times \Delta}_m.$$

It is evident that $\Omega' \subset \Omega$. Let the marginal probabilities of Z_k on Ω be

$$p_k \equiv \Pr\{Z_k = 1\},$$

$$q_k \equiv 1 - p_k = \Pr\{Z_k = 0\}, \quad k = 1, \dots, m. \quad (15)$$

Then according to Eq. (13) and the definition of the conditional probability on $\Omega' \subset \Omega$,

$$\begin{aligned} \Pr\{X = k\} &= \Pr\{Z = (\underbrace{1, 1, \dots, 1}_k, \underbrace{0, 0, \dots, 0}_{m-k}) \mid \Omega'\} \\ &= \frac{\Pr\{Z = (\underbrace{1, 1, \dots, 1}_k, \underbrace{0, 0, \dots, 0}_{m-k}) \mid \Omega\}}{\Pr\{\Omega' \mid \Omega\}} \\ &= \frac{(\prod_{l=1}^k p_l)(\prod_{l=k+1}^m q_l)}{\gamma}, \quad k = 0, \dots, m; \end{aligned} \quad (16)$$

where

$$\gamma = \sum_{j=0}^m \left(\prod_{l=1}^j p_l \right) \left(\prod_{l=j+1}^m q_l \right) \quad (17)$$

(when $j=0$, $\prod_{l=1}^j p_l$ is defined as 1; when $j=m$, $\prod_{l=j+1}^m q_l$ is also defined as 1). Conversely, $\{p_k, k=1, \dots, m\}$ can be expressed in terms of $\{\Pr\{X=k\}, k=0, 1, \dots, m\}$. That is, an equivalent expression of Eq. (16) is

$$\begin{aligned} p_k &= \frac{\Pr\{X = k\}}{\Pr\{X = k-1\} + \Pr\{X = k\}}, \quad k = 1, \dots, m; \\ \sum_{k=0}^m \Pr\{X = k\} &= 1. \end{aligned} \quad (18)$$

In the context of the cumulative process, the rating formulation was first introduced to construct a class of Rasch models for polytomous responses in terms of a set of latent dichotomous Rasch variables. In the context of unfolding modeling, it was applied to construct the general form of probabilistic unfolding model for polytomous responses. If a set of latent dichotomous unfolding variables have the probabilistic functions as specified in the general form for dichotomous unfolding models,

$$\begin{aligned} p_k &= \frac{\Psi(\rho_{ik})}{\Psi(\rho_{ik}) + \Psi(\beta_n - \delta_i)}, \\ q_k &= 1 - p_k = \frac{\Psi(\beta_n - \delta_i)}{\Psi(\rho_{ik}) + \Psi(\beta_n - \delta_i)}. \end{aligned} \quad (19)$$

Then according to Eq. (16), a general form for polytomous unfolding responses is expressed as

$$\begin{aligned} \Pr\{X_{ni} = k \mid \beta_n, \delta_i, (\rho_{il})\} \\ = \frac{(\prod_{l=1}^k \Psi_l(\rho_{il}))(\prod_{l=k+1}^m \Psi_l(\beta_n - \delta_i))}{\lambda_{ni}}, \quad k = 0, \dots, m; \end{aligned} \quad (20)$$

where δ_i and β_n are the location parameters for item i and person n , respectively; $\{\rho_{ik}\}$ are the thresholds for item i ; and

$$\begin{aligned} \lambda_{ni} &\equiv \gamma_{ni} \prod_{l=1}^m [\Psi_l(\rho_{il}) + \Psi_l(\beta_n - \delta_i)] \\ &= \sum_{k=0}^m \left(\prod_{l=1}^k \Psi_l(\rho_{il}) \right) \left(\prod_{l=k+1}^m \Psi_l(\beta_n - \delta_i) \right). \end{aligned} \quad (21)$$

The essential properties of the general form of probabilistic unfolding models for polytomous responses include that (1) its expectation is a single peaked function of the person location parameter and (2) for each latent dichotomous variable Z_k , if and only if $|\beta_n - \delta_i| = \rho_k$,

$$p_{nik} = \Pr\{Z_k = 1\} = \Pr\{Z_k = 0\} = q_{nik} = 1/2. \quad (22)$$

These two properties confirm that Eq. (20) follows the unfolding process. In particular, when the thresholds are properly ordered,

$$\rho_{i1} > \rho_{i2} > \dots > \rho_{ik} > \dots > \rho_{im}, \quad (23)$$

then within each interval formed by adjacent thresholds, the corresponding category has the greatest probability. Figure 6 shows the probabilistic curves for Eq. (20) (in solid lines), together with the curves for the latent dichotomous variables (in dashed lines) (the operational function is the hyperbolic cosine function).

Specified Probabilistic Models for Unfolding Responses

The Simple Square Logistic Model for Polytomous Responses

Let

$$\Psi(t) = \exp(t^2). \quad (24)$$

Then according to Eq. (20),

$$\begin{aligned} \Pr\{X_{ni} = k\} &= \frac{\exp\{\sum_{l=1}^k \rho_{il}^2\} \exp\{(m-k)(\beta_n - \delta_i)^2\}}{\lambda_{ni}}, \\ k &= 0, 1, \dots, m-1; \end{aligned} \quad (25)$$

where

$$\lambda_{ni} = \sum_{k=0}^m \exp\left\{\sum_{l=1}^k \rho_{il}^2\right\} \exp\{(m-k)(\beta_n - \delta_i)^2\}. \quad (26)$$

The PARELLA Model for Polytomous Responses

Let

$$\Psi(t) = t^2. \quad (27)$$

Figure 6 Probabilistic curves of the general unfolding model for polytomous responses.

Then according to Eq. (20),

$$\Pr\{X_{ni} = k\} = (\beta_n - \delta)^{2(m-k)} \prod_{l=1}^k \rho_{ik}^2 / \lambda_{ni},$$

$$k = 0, 1, \dots, m-1; \quad (28)$$

where

$$\lambda_{ni} = \sum_{k=0}^m (\beta_n - \delta)^{2(m-k)} \prod_{l=1}^k \rho_{ik}^2. \quad (29)$$

[For notational convenience, $\beta_n - \delta^{2(m-k)} = 1$ when $k = m$, regardless of the value of $(\beta_n - \delta)$.]

The Hyperbolic Cosine Model for Polytomous Responses

Let

$$\Psi(t) = \cosh(t). \quad (30)$$

Then according to Eq. (20),

$$\Pr\{X_{ni} = k\} = [\cosh(\beta_n - \delta)]^{m-k} \prod_{l=1}^k \cosh(\rho_{il}) / \lambda_{ni},$$

$$k = 0, 1, \dots, m-1; \quad (31)$$

where

$$\lambda_{ni} = \sum_{k=0}^m [\cosh(\beta_n - \delta)]^{m-k} \prod_{l=1}^k \cosh(\rho_{il}). \quad (32)$$

In addition, it is also known that the general hyperbolic cosine model (GHCM) for polytomous unfolding response and graded unfolding model (GUM), both

derived from the Rasch model for polytomous responses, are special cases of Eq. (20). Therefore, all properties held by Eq. (20) apply to these models.

When an Unfolding Model Should Be Used

Compared to the Likert scale, which is still popular in the field of attitude measurement due to its simplicity, the probabilistic models for unfolding responses have advantages: (1) attitudes are identified with latent trait instead of manifest scores, (2) statements and persons are located simultaneously on the attitude continuum, (3) use is made of the development of advanced probability and statistics, in particular as related to parameter estimation and test of fit, and (4) they are operational with modern computing technologies. In attitude measurement or other measures that concern affective perceptions, because the single-peaked or unfolding process is generally implied, use of an unfolding model should be first considered.

However, the cumulative process is also relevant in situations in which the attitudes to be measured indicate degrees of positive affect. For example, it is known in advance that almost all teachers and students in a school think that information technology (IT) is somehow useful. If the purpose is to investigate to what extent teachers and students are positive toward IT use in the school, the use of the cumulative model is appropriate. Items such as "Computers are necessary in the library," "Computers are necessary in each classroom," and "Each student in the class should be equipped with a computer"

Table I Comparison of Response Patterns for Cumulative and Unfolding Processes

Person	Scalogram item						Parallelogram item					
	1	2	3	4	5	6	1	2	3	4	5	6
1	0	0	0	0	0	0	1	1	0	0	0	0
2	1	0	0	0	0	0	1	1	1	0	0	0
3	1	1	0	0	0	0	0	1	1	1	0	0
4	1	1	1	0	0	0	0	1	1	1	1	0
5	1	1	1	1	0	0	0	0	0	1	1	1
6	1	1	1	1	1	0	0	0	0	0	1	1
7	1	1	1	1	1	1	0	0	0	0	0	1

are all positive toward the use of IT, but clearly to different degrees. If the cumulative process is applied, the ideal deterministic structure will have a typical pattern, as shown in the first scalogram block in Table I. That is, all items present positive attitudes toward the topic, but to different degrees. A person agrees only to statements with locations lower than that of the person. However, where the attitudes are expected to range from highly negative, through neutral, to highly positive affect, the use of the unfolding process is justified. For example, the use of capital punishment creates a big debate among the general population. Statements reflecting a positive attitude (e.g., “Capital punishment gives the criminal what he deserves”) as well as those presenting negative attitude (“Capital punishment is one of the most hideous practices of our time”) are needed to cover the whole range of attitude intensity toward capital punishment. If the unfolding process is applied, the ideal deterministic structure will have the typical parallelogram pattern shown in Table I. That is, different items provoke different attitudes (from extremely negative to extremely positive). A person agrees only to statements with locations close to that of the person. Table I shows both patterns when the responses are dichotomous (0 = disagree, 1 = agree) with persons and items are sorted according to their locations (from lowest to highest).

It can be demonstrated that if a general framework of unfolding models [Eq. (8) for dichotomous responses or Eq. (20) for polytomous responses] is applied, the data collected should be essentially in the structure of parallelogram with random variations. This fact can be used after data collection to check if the unfolding process is actually in place. However, it involves ordering items and persons by their locations, which is hardly feasible before the analysis of the data. Nevertheless, the correlation coefficients between the responses on pairs of statements can be used to examine whether the selected process is operating. If the cumulative process is applied, the correlation coefficients should all be positive. If the structure of the data follows the frameworks of unfolding models

described in this article, the structure of the correlation coefficient matrix should be as in Table II. The construction of Table II only involves ordering of items by their locations. It is often possible to roughly map out the relative locations of the statements involved according to the conceptual understanding of the statements. Therefore, looking into the correlation coefficient matrix is often used for the purpose of confirming the response process.

It is stressed here that the difference in the structures of the correlation coefficient matrices for the two different response processes is meaningful only in situations when the latent trait continuum involved is unidimensional—that is, the location of an item or a person is described by a real number. In these unidimensional situations, the factor analysis or principal component analysis on these two types of correlation coefficient matrices will produce different results. When the cumulative process is applied, because the correlation coefficients between pairs of items are positive, only one major principal component (factor) will be found and the loadings of all items to this component are positive. When the structure of the data follows an unfolding process, however, two major factors will be found, with the first factor pointing to the items’ directions (positive or negative) and the second pointing to the degrees to which the item location is close to the origin (neutral point of the continuum). Therefore, factor analysis could be used for the purpose of detecting the violation of the desirable response process.

Galton, Sir Francis

Nicholas W. Gillham

Duke University, Durham, North Carolina, USA

Glossary

correlation The statistical technique that measures and describes the relationship between two variables. The method was invented by Francis Galton, who stated that correlation “was a very wide subject indeed. It exists wherever the variations of two objects are in part due to common causes.”

eugenics Defined by Francis Galton as dealing with “questions bearing on what is termed in Greek, *eugenes*, namely, good in stock, hereditarily endowed with noble qualities.”

ogive Used by Galton in 1875 to describe the shape of the curve obtained when graphing the inverse normal cumulative distribution function, which has a sinuous shape similar to that of an ogee molding.

regression Used to characterize the manner in which one set of variables (for example, on the *Y* axis of a graph) changes as the other set of variables (for example, on the *X* axis of that graph) changes. For Francis Galton, who invented regression analysis, regression was more a biological problem than a statistical one. Regression to the mean, which he observed in sweet peas and in anthropometric measurements, meant that the underlying hereditary processes were always driving metric characters such as height or weight back toward the mean and would effectively counterbalance natural selection.

Sir Francis Galton (1822–1911) is undoubtedly best remembered as the father and chief cheerleader of the eugenics movement. Because of the great breadth of his interests, Galton has sometimes been called a dilettante. However, his research and published work actually are grouped around two central themes. During the first part of his career, Galton focused on African exploration, geography, and travel writing. He also became interested in meteorology, a natural extension of his interests in exploration and geography, and he

constructed retrospective weather maps that led to his discovery of the anticyclone. The second part of Galton’s career opened when he read *On the Origin of Species* by his cousin Charles Darwin. He concluded that it might be possible to improve the quality of the human race by selective breeding. He recognized that if what he called “talent and character” were heritable, this should be apparent from pedigree analysis. Hence, he attempted to assess the inheritance of these qualities in the pedigrees of famous men and by comparing qualitative similarities and differences between identical and nonidentical twins. He also made composite photographs of men with similar occupations, whether in crime or in military service, to see whether they shared common facial characteristics. Anyone interested in fingerprinting will soon come across Galton’s name, for he was responsible for establishing proper criteria for their identification and also for making a famous calculation suggesting that the probability that two fingerprints from different individuals will match is very low. He also collected great quantities of anthropometric data, probably hoping that this information might relate to “talent and character.” Last, he is remembered in psychology for his pioneering studies of mental imagery.

Counting and Measuring

A defining characteristic of all of the work of Sir Francis Galton (1822–1911) was his use of quantitative methods, whether they related to planning for the correct amounts of supplies for his African expedition, the number of fidgets members of an audience made during a scientific presentation, or anthropometry. To analyze these data, Galton made use of existing statistical tools, rudimentary at best, and developed important new ones such as regression and correlation analysis. Galton was passionate about quantitative data and development of new

statistical methods for data analysis; he played a central role in founding of the field of biometry.

Establishing the exact point at which Francis Galton became interested in quantitative methods is not possible, but his enthusiasm for mathematics clearly blossomed in 1840 while he was a medical student at King's College in London. His cousin, Charles Darwin, was living nearby. Darwin had also begun his career as a medical student, but at Edinburgh rather than King's College. Darwin hated medicine and eventually wound up at Cambridge. There he was befriended by John Stevens Henslow, a professor of botany, and the *Beagle* voyage followed. Darwin, 13 years older than Galton, newly married, and a recently elected Fellow of the Royal Society, had recently published his *Beagle Journal*. He appears to have been instrumental in stimulating Galton to transfer to Cambridge. Darwin also helped Galton to argue successfully with his father in favor of this move. At Trinity College, Cambridge, Galton's plan was to study for honors in mathematics. In order to improve his chances of succeeding in the mathematics Tripos, Galton took advantage of private tutors or coaches. These were often exceptionally gifted men who did not wish to lead the monastic (and celibate) life of a don. One such coach was William Hopkins, the greatest of the early Victorian mathematics tutors. However, Galton suffered something akin to a nervous breakdown. It also became clear to Hopkins that Galton did not have sufficient talent to succeed as an honors graduate in mathematics, so Galton took an ordinary degree from Cambridge. Nevertheless, for the rest of his life, he was in awe of talented mathematicians and of Cambridge.

After Cambridge, Galton planned to return to his medical studies at King's College, but his father died and Galton, lacking a compass to direct him, spent the next few years in travel and sport. Little is known about this period of Galton's life, with the exception of his journey up the Nile with friends, which was followed by an excursion to the Middle East. Suddenly, in 1849, Galton decided to mount an expedition in South Africa to Lake Ngami, recently discovered by David Livingstone. This expedition did not reach Lake Ngami, but represented the first European exploration of northern Namibia; the details are of concern here primarily as they relate to Galton's passion for quantification. This was evident in the exceptionally careful way in which Galton determined the quantities of supplies that he needed to take with him and in the careful measurements he made of latitudes, longitudes, and temperatures. The leadership of the Royal Geographical Society, which had sponsored Galton's expedition, was so impressed that it awarded him one of the two gold medals the organization presented annually; a year before David Livingstone was so honored. The reason was that Galton, unlike Livingstone, had provided quantitative data to accompany the report of his expedition.

Galton next wrote articles and two books on travel. One of these, a classic called *Art of Travel*, reprinted as recently as 2001, is filled with practical tips for surviving in the bush. In the book, Galton's penchant for numbers also bubbles up time and again. For instance, he discusses the loads different pack animals should be able to carry over long distances, how the outstretched hand and arm can be used as a substitute for a sextant, and the calculations that should be made on becoming "lost." Subsequently, Galton served for many years on the Council of the Royal Geographical Society, where he consistently badgered different explorers for quantitative data. Livingstone got so mad at one point that he complained to Roderick Murchison, the society president, "Put Arrowsmith [the cartographer, John Arrowsmith] and Galton in a hogshead and ask them to take bearings out of the bunghole. I came for discovery and not for survey and if I don't give a clear account of the countries traversed, I shall return the money." Galton's passion for analyzing quantitative data made him instantly receptive to the possibilities provided by the normal distribution and led to his discovery of the important statistical concepts of regression and correlation.

The Normal Distribution

At the time Galton was introduced to the normal distribution by his old friend William Spottiswoode: the distribution, which came from astronomy, was known as the error curve, and was referred to as such during Galton's lifetime. Spottiswoode combined an interest in geography and mathematics with the business of running an important family printing firm. In 1861, Spottiswoode published a paper in which he attempted to fit the normal curve to the distribution of direction of orientation of 11 mountain ranges, to see if they possessed a common pattern. Although the fit was somewhat questionable, Spottiswoode was enthusiastic about the results. Galton must have been familiar with the paper and, when Spottiswoode reviewed the properties of the normal distribution with his friend, Galton was delighted by "the far-reaching applications of that extraordinarily beautiful law which I fully apprehended." Galton was by then interested in human heredity and had written a two-part article entitled "Hereditary Talent and Character," which he published in *Macmillan's Magazine* in 1865. The publication of *On the Origin of Species* by Darwin in 1859 had sparked his interest in this subject and he soon became convinced that human ability was probably a hereditary attribute. But how was he to show this? His starting point was to examine the male relatives of famous men using a kind of partial pedigree analysis. He predicted that if "talent and character" were heritable, the closest male relatives (i.e., fathers and sons) were more likely to be

talented than were more distant relatives. He recognized that environment might play a role too, but argued that environmental contributions were negligible in contrast to the role heredity played.

Soon after Galton and Spottiswoode had discussed the properties of the normal distribution, Galton began to study the work of the Belgian astronomer, Adolph Quetelet, who was also an able statistician and population biologist. Quetelet's first attempt in this regard was to compare the actual and theoretical distributions of chest measurements for 5738 Scottish soldiers. The agreement was good and Galton was impressed. The papers published in *Macmillan's* served as precursors for Galton's 1869 book *Hereditary Genius: An Inquiry into Its Laws and Consequences*, in which he presented much more extensive pedigree analysis for large groups of men having different talents (e.g., judges, statesmen, and soldiers). It is reasonable to ask why women were excluded from Galton's pedigrees of the famous: in fact, he does list some notable women in the tables he used to summarize pedigrees of the prominent. However, the nature of Victorian society was such that most occupations and professions were closed to women, so Galton had no way of assessing their abilities in a systematic fashion.

In *Hereditary Genius*, Galton also made use of the normal distribution for the first time. As he did not actually have quantitative data for height, he constructed

a theoretical normal distribution for this parameter, which he showed in the book. He cited Quetelet's data on the chest measurements of Scottish soldiers and the heights of French conscripts as evidence that observation fit expectation. But how was Galton to measure mental ability? He decided to see whether examination marks for admission to the Royal Military College at Sandhurst fit a normal distribution. He used only the statistics for 1868, and the data revealed a clear normal distribution at the upper tail and the center, but there were no low scores to fill out the distribution, because the numbers had either been eliminated or those likely to have low scores had eschewed competition. In *Hereditary Genius*, Galton also published a table (Fig. 1) in which he attempted assess the distribution of "ability" in the British male population, which he estimated to be 15 million. He then employed a numerical value he had earlier obtained for men of reputation (~ 1 in 4000) to establish his highest and lowest (idiots and imbeciles) grades of natural ability; Galton used a Gaussian distribution to calculate the expected number of individuals in each of 12 classes intermediate between the high and low ends.

Galton later invented a new statistical tool. He wished to design a metric that would permit him to arrange any set of measurements on a single statistical scale. He found that if he graphed his data in a series of ranks according to the exponential function that describes the normal

Figure 1 The table published in 1869, in Galton's *Hereditary Genius: An Inquiry into Its Laws and Consequences*, showing Galton's attempt to assess the distribution of "ability" in the British male population. Below the table in the original publication, it was explained that "the proportions of men living at different ages are calculated from the proportions that are true for England and Wales." The data were credited to the 1861 census. Redrawn from Galton (1869).

Figure 2 Redrawings of two of Galton's original renditions of the ogive. (A) The earlier drawing, from 1875, shows the median and the quartiles. (B) The later drawing, from 1883, shows spikes with heights representing 21 equally spaced ideal data values. Redrawn from Stigler (1986).

distribution, he obtained a graceful, sinuous curve that was convex at the top and concave at the bottom (Fig. 2). He christened this curve the “ogive,” appropriating an architectural term with several meanings, one of which is a molding (an ogee) with the same shape of his curve. The distribution could be divided into quartiles; the middlemost would have a value of 0 (representing the average) whereas an individual in the upper quartile would have a value of 1 (representing one probable error above the mean), etc. Galton's ogive, now known as the inverse normal cumulative distribution function, is one of the most used and abused methods of scaling psychological tests. The terms “quartile” and “median” are also Galton's.

Regression

Not only was Galton interested in applying the normal distribution to continuously varying traits such as height, but he also wanted to study the heritability of such traits. Although he was particularly interested in examining anthropometric data, initially he lacked appropriate data, so, on the advice of Darwin and the botanist Joseph Hooker, Galton turned to a model system, sweet peas. He cited three reasons. Sweet peas had little tendency to cross-fertilize, they were hardy and prolific, and seed weight

was not affected by humidity. Galton planted his first experimental crop at Kew in 1874, but the crop failed. In order to avoid this outcome the following year, he dispensed seed packets widely to friends throughout Great Britain. The packets were labeled K, L, M, N, O, P, and Q, with K containing the heaviest seeds, L, the next heaviest, and so forth down to packet Q. Galton obtained fairly complete results from the progeny of 490 carefully weighed seeds. His discovery was that “the processes concerned in simple descent are those of Family Variability and Reversion.” By simple descent, Galton meant self-fertilization. Family variability referred to the degree of variation around the mean observed among progeny seeds irrespective of whether they were large, small, or average in size. Although the means of the distributions shifted to some extent between different sets of progeny, the degree of variation around the mean was similar for all. By reversion Galton meant “the tendency of that ideal mean type to depart from the parental type, ‘reverting’ towards” the mean of the parental population from which the parental seeds were selected. He then drew a diagram that plotted the seed diameter of progeny seeds on the y axis and parental seeds on the x axis, thereby constructing the first regression line (Fig. 3).

At first, Galton referred to the slope of the line as the coefficient of reversion, but then changed this to regression. Later, with aid of partial pedigree data he obtained from his anthropometric laboratory, established in connection with the International Health Exhibition held in London in 1884, Galton was able to show that regression to the mean applied to human stature as well (Table 1). This was to have a profound effect on Galton's view of the evolutionary process because Galton believed that regression to the mean would thwart the action of natural selection and that this would create a major problem for Darwin's theory of the origin of species. Hence, Galton supposed that evolution must proceed in discontinuous steps that could not be reversed by regression to the mean. The utility of regression analysis and the regression coefficient as statistical techniques was later recognized by Galton and others, but initially this was of strictly secondary importance to Galton, for whom the evolutionary and, hence, hereditary implications of regression to the mean were of primary significance.

Correlation

There are two accounts of how Galton came upon the idea of correlation. Sadly, the more romantic of these, which envisions Galton as having the notion while seeking refuge from a shower in a reddish recess in a rock near the side of a pathway on the grounds of Naworth Castle, is probably wrong. The plausible, and more believable, account is that Galton was working one day, using his anthropometric

Figure 3 A redrawing of the first regression line for inheritance of size in sweet pea seeds that was presented by Francis Galton at a Royal Institution lecture in 1877. From Pearson (1930).

Table I Number of Adult Children of Various Statures Born of 205 Mid-parents of Various Statures^a

^a All female heights have been multiplied by 1.08. In calculating the medians, the entries have been taken as referring to the middle of the squares in which they stand. The reason why the headings run 62.2, 63.2, etc., instead of 62.5, 63.5 etc., is that the observations are unequally distributed between 62 and 63, 63 and 64, etc., there being a strong bias in favor of integral inches. This inequality was not apparent in the case of the mid-parents. From Galton (1886).

data to plot forearm length against height, when he noticed that the problem was essentially the same as that of kinship. He summarized these data in 1888 in a table in one of his most important papers “Co-relations and Their Measurements, Chiefly from Anthropometric Data.” Galton extended his correlation data to head breadth versus head length, head breadth versus head height, etc. He also calculated the first set of correlation coefficients, using the familiar symbol r . Most of his values for r were quite high, between 0.7 and 0.9.

Natural Inheritance and the Birth of Biometrics

Galton's paper on correlation, coupled with what is probably his most important book, *Natural Inheritance*, published in 1889, led to the foundation of the field of biometrics. *Natural Inheritance* synthesized much of the work that Galton had done on heredity, anthropometrics, and statistics. From the viewpoint of this article,

its chapters on statistics and their application are of most importance. Galton showed his readers how to apply statistical tools to their data by using illustrations from the anthropometric data he had collected. Regression was also discussed, but not correlation; Galton seems to have discovered this statistic after *Natural Inheritance* went to press. He then applied his statistical techniques to human traits such as stature and eye color, and, more fancifully, to artistic ability and disease.

During his long career, Galton had not attracted disciples, but his paper on correlation and *Natural Inheritance* changed that. It is true that prior to the publication of these works, one important British statistician, Francis Ysidro Edgeworth, had been influenced by Galton, but Galton's most important disciples, at least from the viewpoint of statistics and quantitative analysis of biometrical data, were Raphael Weldon, a zoologist, and Karl Pearson, who was able to add to statistical analysis a mathematical rigor that was beyond Galton's reach. Pearson, a mathematics graduate of King's College, Cambridge, had been appointed the Goldsmid Professor of Applied Mathematics and Mechanics at University College, London in 1884. Weldon, originally trained in zoology and morphology at St. John's College, Cambridge, was appointed university lecturer in morphology at St. John's in 1884. Weldon's interest in invertebrate morphology rapidly diminished in favor of quantitative analyses of parameters such as carapace length in samples of the common shrimp, *Crangon vulgaris*. He was quick to recognize the significance of the statistical treatments laid out in *Natural Inheritance* and Galton's correlation paper, and was soon in touch with Galton, who helped him with the statistical analysis of his data, especially as it applied to calculating correlation coefficients. Before long, Weldon and Pearson got to know each other and became fast friends. In 1891, Weldon was appointed a professor at University College, London, where he collaborated with Pearson not only on biometric research, but also on matters relating to university politics. In 1901, largely in a reaction against the nonquantitative geneticist, William Bateson, whom Pearson felt had prevented publication of an important paper submitted to the Royal Society, Pearson and Weldon founded the journal *Biometrika*, with Galton as an advisor. Thus, the science of biometrics was born. Toward the end of his life, Galton endowed a professorship in eugenics at University College. In 1911, the year of Galton's death, Pearson was appointed the first Galton Professor of Eugenics, a position he would hold until 1933, when he was replaced by another great biometrician, R. A. Fisher. The Galton professorship and its predecessor, the Galton Laboratory for the Study of National Eugenics, have long since shed their association with eugenics, and instead have built a reputation for distinction in human genetics.

Glossary

chasing An attempt to recoup gambling losses by playing longer, playing more frequently, and/or increasing bet size.

continuous gambling format Any wagering event for which there is a short time interval between placing the bet, playing the game, and learning the outcome.

gambling The act of risking money, property, or something of value on an event for which the outcome is uncertain.

pathological gambling A mental disorder that includes the following essential features: (1) a continuous or periodic loss of control over gambling, (2) a progression in gambling frequency and in the amounts wagered, in the preoccupation with gambling, and in the acquisition of monies with which to gamble, and (3) a continuation of gambling involvement despite adverse consequences.

problem gambling Behavior related to gambling that creates negative consequences for the gambler, for others in his/her social network, or for the community.

A number of prominent social science methodologies are used in the field of gambling studies. Among researchers and scholars, there are debates over the proper terminology to describe problem gambling and over the best practices for determining accurate problem-gambling prevalence rates in general population surveys. Approaches to social measurement of gambling behavior include qualitative, longitudinal, public policy, and sociohistorical analyses.

Introduction

What Are Gambling Studies?

Gambling is a basic human activity dating back to ancient times and found in nearly all cultures through the ages.

Although the gambling urge is nearly universal, the public mind-set toward gambling varies considerably among societies, and changes over time within societies. Human-kind's experience with gambling shows that the activity has been variously regarded as a sin, a vice, an unfortunate but tolerable weakness of human nature, an evolutionarily appropriate behavior, an adult form of play, a buffer to existential anxieties caused by chance events, and a teacher and mirror of cultural values. Congruent with the global proliferation of legalized gambling over the past few decades, gambling studies have emerged as a multidisciplinary research thrust, focusing on enhancing our understanding of the role that gambling plays in society. Gambling studies encompass diverse academic disciplines such as medicine, psychology, economics, law, business, political science, mathematics, sociology, history, and the humanities, and are fundamentally concerned with explaining the ubiquity and persistence of gambling activity, the behavior patterns of gambling participants, and the personal, social, economic, and cultural consequences of widespread gambling.

Gambling studies research is published in mainstream academic journals; however, the preponderance of academic literature in this field is found in specialized journals, including *International Gambling Studies*, *Journal of Gambling Studies*, *Gaming Law Review*, and *Electronic Journal of Gambling Issues*, and in published conference proceedings and government and research institute reports.

Overview

Gambling-related social science has concentrated more on perceived deviant aspects of the activity than on its normative dimensions and has featured methodologies that include survey, sociohistorical, ethnographic, public policy analysis, and longitudinal perspectives. This article

highlights the prominent measures and methods used by social scientists to study the phenomenon of gambling. Included in the analysis are rationales for and descriptions and limitations of the representative methods and measures used.

Problem-Gambling Prevalence Research

Rationale for Gambling Studies

Legislative blessing for gambling is based on the premise that the social good of the activity outweighs any negative outcomes. A problem with this presumption is that most of the benefits of gambling are tangible and easily quantifiable in economic terms, whereas the costs to society are often hidden, indirect, not immediately noticeable, and are impossible to measure precisely. The costs alluded to are burdens that problem gamblers impose on other citizens who gamble responsibly or who do not partake in gambling at all. In order to justify offering legal gambling, governments must allay citizens' concerns that the social costs of the activity are not overly onerous. One way this is done is through problem-gambling prevalence surveys. Such surveys have been completed in nearly one-half of the American states, in 9 of the 10 Canadian provinces, and in several overseas jurisdictions. The object of problem-gambling prevalence surveys is to identify accurately the percentages of individuals in a population with and without the disorder. Generally, the higher the percentage of problem and at-risk gamblers in a population, the higher the social costs of gambling and the greater the need for public policy to ameliorate the situation. For example, in making decisions about funding prevention and treatment services for problem gamblers, legislators need sound estimates of the numbers in the general population who require help for their out-of-control gambling, their demographic profiles, and the likelihood that they will use these services if they are made available.

Semantic Differences

A variety of terms have been applied to individuals whose out-of-control gambling has an adverse effect on their lives and creates harms for those around them (e.g., family, friends, and co-workers) and for society in general. The term often employed by lay audiences and Gamblers Anonymous (GA) members is "compulsive"; however, researchers and problem-gambling treatment specialists avoid this term on the grounds that the label implies that the individual is participating in an unenjoyable activity. Because gambling can be a pleasing activity, even for those who later develop problems, terminology inferring compulsiveness is considered a misnomer.

"Problem gambling" is used by both lay and professional audiences to specify all of the patterns of gambling behavior that compromise, disrupt, or damage personal, family, or vocational pursuits, and covers a continuum from moderate-risk to seriously out-of-control gamblers. Psychiatrists and mental health therapists prefer the term "pathological," which incorporates several assumptions basic to the medical perspective of aberrant gambling, including the notion that pathological gambling is a chronic and progressive disorder and a conviction that there is a clear distinction between a pathological and a social gambler.

Based on the imprecise terminology used to describe out-of-control gambling and the methodological chaos this creates, use of the label "disordered gambling" has been recommended for the following reasons: (1) disordered gambling embraces all of the previously used terms, and (2) a disorder suggests a wide range of gradually shifting behavior. Semantic differences pertaining to uncontrolled gambling continue to confound gambling studies scholars, because no clear-cut choice has emerged; however, "problem gambling" and "disordered gambling" are the terms with the most academic currency at the moment.

Measuring Problem Gambling

The Diagnostic and Statistical Manual of Mental Disorders

After several years of advocacy by problem-gambling treatment specialist Dr. Robert Custer, the 1980 (third) edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) provided the first official diagnostic criteria for pathological gambling. Classified as an "impulse control disorder," the inclusion of pathological gambling in the American Psychiatric Association publication dramatically altered social attitudes toward out-of-control gambling. Although not officially considered an addiction, pathological gambling was often treated as such by researchers and therapists. With two exceptions ("chasing" and "bailout"), the DSM-III pathological gambling criteria were similar to those used for diagnosing substance and drug dependence. The association between pathological gambling and addiction was further highlighted when "tolerance" and "withdrawal" were included as pathological gambling criteria in the 1994 revised DSM-IV. The fact that pathological gambling was considered a disease or a medical condition challenged the prevailing legal perception of pathological gambling as a vice, and has impacted the justice system in terms of proving culpability, assigning responsibility, and determining type and length of sentencing, when problem gambling is used as a mitigating factor to explain criminal behavior.

The South Oaks Gambling Screen

Several years after publication of the DSM-III pathological gambling criteria, an instrument based on these diagnostic criteria, the South Oaks Gambling Screen (SOGS), quickly became the lead assessment tool for diagnosing and identifying out-of-control gamblers. Although designed and tested for clinical use, the SOGS also became the instrument of choice for estimating problem-gambling prevalence rates in the general population. The SOGS is a 20-item, dichotomous (yes/no) response scale that asks respondents about gambling patterns, behaviors, and impacts that gambling has on their lives. A SOGS score can range from 0 to 20, and cutoff points are used to distinguish between three gambler subtypes: nonproblem (SOGS score of 0, 1, or 2), problem (SOGS score of 3 or 4), and probable pathological (SOGS score of 5 or higher). One advantage of the SOGS is its comparability both across and within jurisdictions; however, challenges have been made regarding its efficacy in nonclinical settings, including the charges that (1) SOGS is an accurate measure in a clinical situation, where the prevalence of the disorder is high, but is less sensitive in population studies, where base rates of problem gambling are much lower; (2) the imprecision of SOGS in population studies leads to classification errors (either false positives or false negatives) that compromise the validity of the scale; (3) SOGS has not been validated for use with special populations (e.g., adolescents and various ethnic groupings); and (4) because of the wider dispersion of legal gambling, prevalence surveys in the early 1990s showed the demographic profile of problem gamblers was changing to include more females and middle income individuals. Consequently, some SOGS items

have been considered less than appropriate. For example, SOGS items relating to borrowing from loan sharks or liquidating stocks or securities might pertain to middle-aged, middle-income males, but less so to young males and middle-aged females experiencing problems in controlling their gambling behavior.

The 1994 DSM-IV Problem-Gambling Criteria

As a result of empirical research findings and rigorous statistical testing, new pathological gambling criteria were adopted for the 1994 DSM-IV (Table I). Pathological gambling was then considered to be persistent and recurrent maladaptive gambling behavior as indicated by a positive response to ≥ 5 of the 10 criteria shown in Table I.

The DSM-IV criteria were readily accepted by researchers and treatment specialists as the standard for diagnosing pathological gambling; however, the criteria had not been adapted for population research. As part of the American National Gambling Impact Study Commission in 1998, a new instrument [the National Opinion Research Center DMS Screen (NODS)] was devised to assess the prevalence of problem and pathological gambling in the general population. The NODS uses the 10 DSM-IV pathological gambling criteria, but in some instances asks more than one question per category. The end product is a 17-item scale requiring “yes” or “no” answers from the perspective of two time frames—lifetime and current (within the past year). A maximum NODS score is 10 (even though respondents can answer affirmatively to all 17 questions, only one positive response per category is counted) and the scores are

Table I DSM-IV Criteria for Pathological Gambling

<i>Criterion</i>	<i>Definition</i>
Preoccupation	Is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)
Tolerance	Needs to gamble with increasing amounts of money in order to achieve the desired excitement
Withdrawal	Is restless or irritable when attempting to cut down or stop gambling
Escape	Gambles as a way of escaping from problems or relieving dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, or depression)
Chasing	After losing money gambling, often returns another day in order to get even (“chasing” one’s losses)
Lying	Lies to family members, therapists, or others to conceal the extent of involvement with gambling
Loss of control	Has made repeated unsuccessful efforts to control, cut back, or stop gambling
Illegal acts	Has committed illegal acts (e.g., forgery, fraud, theft, or embezzlement) in order to finance gambling
Risked significant relationship	Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
Bailout	Has relied on others to provide money to relieve a desperate financial situation caused by gambling

used to distinguish four gambler subtypes: (1) low risk—one or no reported DSM-IV criteria, (2) at risk—one or two DSM-IV criteria, (3) problem gambler—three or four DSM-IV criteria, and (4) pathological gambler—five or more DSM-IV criteria. A unique feature of the NODS is the use of filter questions to determine respondent eligibility for continuing the interview. One filter question asks whether the person had ever lost \$100 or more in a single day of gambling; if they had not, respondents are then asked if they had ever lost \$100 or more over an entire year of gambling. A yes answer to either question continues the interview. The rationale for the filter questions is based on research showing a strong correlation between problem-gambling behavior and having experienced significant monetary losses. The NODS was tested for validity and reliability with clinical and general populations as well as gambling venue patron samples. NODS was found to have strong internal consistency and retest reliability and to be a superior instrument for estimating problem-gambling prevalence rates and for investigating correlates.

The Canadian Problem Gambling Index

As noted earlier, growing concern with the SOGS prompted Canadian researchers to develop improved ways of measuring problem-gambling prevalence in general population surveys. One of these new instruments, the Canadian Problem Gambling Index (CPGI), has gained currency in Canada, Australia, and New Zealand. The CPGI grew out of an interest in addressing problem gambling from a community public health perspective, as opposed to viewing problem gambling as a disease requiring health care intervention. A three-person team designed the instrument after reviewing the problem-gambling literature, investigating theories and models purporting to explain problem gambling and analyzing various measures (including the SOGS) used to distinguish problem from nonproblem gamblers. Preliminary testing of the CPGI included an evaluation by an international panel of gambling research experts, pilot studies with three groups (i.e., a general population random sample, regular gamblers who responded to newspaper ads, and problem gamblers in treatment), and a national randomly sampled survey of 3120 adult Canadians. CPGI reliability was evaluated by readministering the instrument to a subsample of 417 respondents from the initial national survey and was validated through clinical interviews conducted by problem-gambling treatment specialists with 143 national survey respondents. As a result of this preparation, the CPGI was the first problem-gambling behavior measurement tool to have been rigorously tested prior to its use in general population surveys. Furthermore, it was the first problem-gambling measure to have established and published psychometric properties before its use in problem-gambling prevalence surveys.

Emerging from this process, the CPGI is a 31-item instrument containing an embedded 9-item scale labeled the Problem Gambling Severity Index (PGSI); the PGSI is the measure used to separate respondents into one of four gambler categories (nonproblem, low risk, moderate risk, and problem). As opposed to the SOGS and NODS yes/no response categories, the four possible answers to the PGSI questions include “never,” “sometimes,” “most of the time,” and “almost always.” A score of 1 is given for a response of “sometimes”; 2, for “most of the time”; and 3, for “almost always”; thus, there is a range of possible scores from 0 to 27. PGSI cutoff points used to discriminate the four gambler subtypes are nonproblem (PGSI score = 0), low risk (PGSI score = 1 or 2), moderate risk (PGSI score = 3–7), and problem gambler (PGSI score = 8 or more). The CPGI does not use the term “pathological” to categorize a gambler subtype, because in the developers’ view, the term is too closely associated with addiction and a medicalized view of gambling disorders, in contrast to the public health orientation of the CPGI.

Comparison of the NODS and CPGI

As a result of updated DSM-IV problem-gambling criteria and an intensification of empirical research, significant progress has been made in developing and refining instruments to measure problem gambling among the general population. The result is fewer misclassifications and increased confidence in problem-gambling prevalence estimates. Still unresolved are questions concerning the cutoff points used to differentiate gambler subtypes, which tend to be arbitrary, and the fact that scale items are not weighted to distinguish between severe and less severe problem-gambling indicators; for example, feeling guilty about gambling behavior, facing criticism of gambling behavior, and lying about gambling activity are scored the same as committing illegal acts to support a gambling habit or family breakups caused by excessive gambling. Moreover, neither of these instruments has been validated for use in adolescent populations.

The NODS is based directly on the DSM-IV pathological gambling criteria, whereas the PGSI (the CPGI subscale used to differentiate gambler subtypes) makes selective use of DSM-IV criteria (e.g., it uses tolerance, chasing, and bailout but omits criteria such as preoccupation, withdrawal, and illegal acts). The NODS items are more amenable to empirical measurement in that questions are asked about specific behaviors (have the respondents ever engaged in them, and if so, how often), whereas the PGSI is concerned more with respondents’ perceptions about how gambling impacts their lives. Both measures separate respondents into four gambling subtypes based on problem-gambling severity; the NODS provides both lifetime and current problem-gambling prevalence rates, versus the PGSI, which refers only to

the previous 12 months; however, the PGSI offers four response choices versus just two for the NODS, which allows for finer distinctions in assessing gambling behaviors.

Methodological Issues

The academic debate over the best way to measure problem gambling continues. The lack of consensus on methodological issues has practical implications for gambling regulators and treatment specialists who are calling for pertinent, evidence-based data revealing how serious and widespread problem gambling is in their jurisdiction and what they should do about it. Partly because of these snags in problem-gambling measurement, changing the research focus from prevalence to incidence studies has been recommended. In general terms, jurisdictional problem-gambling prevalence rates vary according to the menu of gambling formats offered, the prize structure of the games, and the length of time the games have been operating. In other words, the more legal gambling formats available (especially continuous formats such as electronic gambling machines and casino games) and the longer these formats have been offered, the higher the problem-gambling prevalence rate. Gambling formats differ in terms of their impacts on a citizenry. For example, lotteries and raffle play are relatively benign compared with continuous games such as video lottery terminals (VLTs) and slot machines, which have a more pronounced addictive potency.

Other Problem-Gambling Prevalence Survey Measurement Issues

In addition to scholarly disputes over the most appropriate tool for measuring problem gambling in a population, differences of opinion exist about the value of telephone surveys and the validity of certain survey questionnaire items. Most problem-gambling prevalence studies have been telephone surveys, which have the primary advantage of capacity to reach large numbers of respondents in a short period of time, and in a cost-effective manner. Despite their popularity, telephone surveys generally, and problem-gambling prevalence surveys particularly, contain flaws that can skew response rates (generally in the direction of underestimating the problem):

- Response rates have declined in the past decade partly because of telephone survey and telephone solicitation fatigue; a response rate of 60% is now considered “good.”
- Households in upper and lower income categories and in which English is not the primary language spoken tend to be underrepresented.
- Most telephone surveys exclude institutions such as college or university residences, penal institutions, and

mental health facilities. Gambling problems have been found at higher rates in all of these populations.

- Respondents being interviewed in the presence of other family members may modify their answers.
- Respondents with a severe gambling problem may refuse to participate in a telephone survey investigating their gambling behavior or, if they do participate, may be reluctant to divulge the truth to a stranger on the telephone. Also, problem gamblers are often not home because they are out gambling, or if at home, do not answer the phone for fear it is a bill collector or loan shark.

To some extent these problems can be reduced by using weighting to adjust sampling imbalances after the data collection is completed, using more complete sampling frames and improving response rates by having more callbacks and better trained interviewers; however, these improvements invariably add time and cost to a project.

The validity of some problem-gambling prevalence survey data has been challenged because of questionnaire item ambiguities; a case in point being questions pertaining to gambling expenditures. Respondents are asked “How much do you spend on gambling?” The reference point is a particular time frame (e.g., a typical session, per week or per month) or a specific gambling format over a specific time period (e.g., horse racing, lotteries, casinos). Gambling expenditure data have been criticized on the grounds that the questioners make no attempt to confirm the uniformity of responses by clarifying how respondents derive their answers. Confusion about gambling expenditures stems from respondents’ differing interpretations of how to calculate losses (to wit: is it the net amount lost, the total amount initially staked, or the total amount wagered in a session?). Each can be a reasonable way of interpreting the question; however, accepting responses at face value and averaging those to arrive at community or subsample gambling expenditure rates can lead to data distortion. It is suggested that net expenditure is the most relevant measure because this represents the actual amount lost and is the true cost to the gambler. Consequently, it is recommended that future studies provide clear instructions on how to calculate net gambling expenditures and point out that wins reinvested during a session are not part of the calculation.

Meta-analysis

Meta-analytic research has been conducted on 120 problem-gambling prevalence studies that had taken place in North America over the previous decade. The studies reviewed represent both adults and adolescents in the general population, university students, adults and youth in clinical and prison populations, and a variety of “special” populations, including women, specific ethnic groups, and gambling industry employees. The meta-analysis empirically integrated the findings from these

diverse studies for the purpose of establishing more accurate estimations of problem-gambling prevalence rates and identifying factors that affect these rates.

The main findings of the meta-analysis included the following measurement and methodology factors:

- Disordered gambling is a robust phenomenon that research can identify reliably across a wide range of investigative procedures that vary in quality of method.
- Disordered-gambling prevalence rates were assessed by 25 different instruments; the SOGS or a SOGS derivative was used in more than half the studies.
- A substantial degree of collinearity among the studies made it difficult to interpret the meaningfulness and significance of the various prevalence estimates.
- The validity of all the prevalence studies reviewed was questionable to the extent that none of the studies was evaluated by an independent means of assessment (for example, having a sampling of survey respondents undergo a diagnostic interview with a gambling treatment specialist to determine whether they had been properly categorized).
- The meta-analysis also recommended that confidence intervals be routinely reported and that specific problem-gambling prevalence rates be listed (e.g., male rates versus female rates) instead of aggregate rates for an entire population.

Longitudinal Research in Gambling Studies

Prominent gambling studies researchers have stressed the need for longitudinal designs to determine the natural history of both disordered and responsible gambling. As gambling studies research evolves, it is evident that certain questions about gambling and problem gambling cannot be answered definitively by one-time surveys or clinical research. Longitudinal research (or cohort research, as it is sometimes referred to) is required to measure changes in gambling behavior over time, to correlate gambling patterns and behaviors with the availability of various legalized gambling formats, and to determine the social and economic impacts of gambling and problem gambling on communities and society at large. Although in its infancy in gambling studies, longitudinal research is becoming an increasingly popular study design because of its presumed superiority over "snapshot" or "cross-sectional" studies. Longitudinal research includes the following advantages:

- Following a group of respondents over time allows researchers to better understand the onset, development, and maintenance of both normative and problem gambling behavior.

- Longitudinal data allow respondents to be compared with themselves at different times as well as to other respondents in the same cohort.

- Because of the time dimension, longitudinal data help identify factors that moderate and exacerbate an individual's gambling participation and thus allow the researcher to infer causality.

- Sorely needed research on the social and economic impacts of legalized gambling on individuals, families, and communities can be done most precisely and expeditiously using a longitudinal design.

- Longitudinal studies produce broad and deep databases that can be used by researchers across many academic disciplines; they may prove more cost-efficient in the long run, as compared to creating many smaller data pools with each new project.

Despite the obvious benefits of longitudinal studies, practical and logistical barriers make them difficult to mount; for example, there is the massive funding required for a multiyear commitment; there are problems with maintaining research team continuity over a lengthy time period and with sample attrition; there is the danger that repeated testing of individuals may influence gambling behavior and/or behavioral reports; and there is the knowledge that longitudinal data confound aging and period effects (e.g., is a person's sudden gambling interest due to being 18 and at the age of majority, or because a casino opened in the area?). Although not yet abundant, longitudinal research in gambling studies is becoming more commonplace, sophisticated, and theory based.

Qualitative Research Methodology in Gambling Studies

The focus of qualitative research in gambling studies has been on particular gambling settings, whereby researchers use firsthand observations to describe ongoing gambling scenes; identify social roles, rewards, and what constitutes deviant behavior; and illustrate how gambling participation is integrated into players' lifestyles. Examples of gambling scenes investigated in this manner include poker clubs, horse race betting (both on and off track), bridge, pool, and golf. Studies of this nature have also investigated the processes and impacts of gambling addiction; for example, in one study working with Gamblers Anonymous members, the research identified the phenomenon of "chasing" after lost money in an attempt to remain in action. In another study, addicted female electronic gambling-machine players were observed and interviewed, with the aim of explaining gender differences in gambling behavior.

Classic studies in this genre have used a form of participant observation known as autoethnography, which

is a cultural study conducted among one's own people. Autoethnographers share the perspective of a participant and present the view of an insider; the advantages of this approach include ease of entrée into the gambling scene, familiarity with the gambling scene, knowledge of the jargon, and a longitudinal outlook (because of a lengthy immersion in the scene). The primary drawbacks of this method are potential researcher bias and loss of objectivity (insiders may take basic assumptions for granted and may be incapable of viewing the scene impartially). To overcome this inclination, the researcher must constantly analyze his/her motivation and deal with the question of bias straightforwardly via a transparent disclosure of the data-gathering methods used.

Typically, these studies are classified as "exploratory" or "preliminary," because they are not always guided by a preconceived model; indeed, they are often informed by the grounded theory perspective. This approach features interdependence and reflexivity in the collection, coding, and analysis of data; this should cause data to blend and merge throughout the investigation. Data gathering often includes "purposive sampling," which is the practice of identifying and interviewing respondents known to be familiar with the subject in question. The "snowball" method is frequently used in combination with purposive sampling to expand the base of potential key informants; this technique allows identified authorities on the topic to recommend others whom they know to be conversant with the gambling scene. The researcher typically proceeds from raw data (observations and interviews), to classification (which involves the "constant comparative" method to ensure that conceptual categories accurately represent reality), to hypothesis generation, and, ultimately, to formal theory.

The grounded theory approach is used to develop substantive and formal theory through a process whereby the researcher continually redesigns and integrates theoretical concepts as new material is received. The researcher may not know in advance where the data will lead and the resultant hypotheses are always subject to revision. In other words, the emerging theory directs the efforts of future research. Using this approach to study the Nevada race book scene in the 1980s, John Rosecrance began by identifying participant demographic characteristics, attributes, social groupings, and degree of integration into society at large. Next, Rosecrance depicted the social world of the race book by describing the routine activities of the participants (e.g., horse selection, betting behavior, rationalizing race results) and outlining the roles, norms, sanctions, and social hierarchy that regulate group behavior. From this general milieu perspective, Rosecrance moved to an analysis of individual gambling careers, describing how an interest in race horse betting started and evolved, the coping mechanisms used to stay in the activity, and how respondents rationalized their

involvement in this social world. Finally, Rosecrance used his empirical data to generate substantive hypotheses relating to the costs and rewards of participation in the gambling scene, thus explaining how individuals were able to sustain their involvement. These hypotheses were then integrated into a theory that depicted participant behavior in the race book social world and produced insights that could be extrapolated into similar social worlds.

Another approach to gambling-related ethnographic research is the work of Natasha Dow Schull on the links between gender, the lived experience of addiction, and the increasingly technological circumstances of life in modern society. Focusing on self-declared, video poker-addicted Las Vegas mothers, Dow Schull conducted fieldwork at casinos, supermarkets, gaming industry trade shows, and technology laboratories; she also attended Gamblers Anonymous meetings and group therapy sessions for problem gamblers and interned at a hospital where a pharmaceutical drug trial for video poker addicts was based. Besides observing in these settings, Dow Schull interviewed medical doctors, problem-gambling counselors, gaming engineers, and casino managers, as well as the mothers hooked on video poker. Using this eclectic data-gathering approach, Dow Schull presented findings that challenge gender stereotypes of female video poker players. On the one hand, Dow Schull's study concurred with previous research showing that escape from daily routines is the main motivation for addicted female video poker players; however, Dow Schull claimed that this desire to escape is triggered by the stress experienced in meeting the demands and responsibilities in performing the societal role of "good mother." Paradoxically, by escaping into machine gambling play, these women become "antimothers"—uncaring, unemotional, self-absorbed individuals whose behavior jeopardizes their children's welfare. Complicit in fostering this role transformation, according to Dow Schull, is the gaming industry, which develops technologies that capitalize on some women's propensity to seek an altered state of reality.

Cultural Studies

Several noteworthy gambling-related works have emerged from the "cultural studies" tradition, which is a blend of social history and sociology. The premise of this approach is that past events cannot be understood without reference to prevailing social structures, and that universal categories such as class, race, and gender must be applied to the analysis. Central to the cultural studies schema is the concept of hegemony or social control—the process whereby dominant ideas, ideologies, meanings, and values are transmitted through various cultural practices so as to maintain patterns of power and privilege in society. Ostensibly, the moral and philosophical legitimacy of this

elite worldview is tacitly accepted and taken for granted by the general populace, with the effect being that alternative structures and meanings are downplayed or ignored.

Gambling studies within the cultural studies framework typically track community sentiments, competing discourses, strategic partnerships, and legislative activity to show how gambling laws and public policies have been shaped and framed. Temporally, these studies cover eras in which gambling went through stages of being considered a sin, a vice, and ultimately, a harmless amusement. For example, there have been cultural studies of Canada's gambling landscape from 1919 to 1969, of lower class gambling practices in England from 1845 to 1960, and of Western culture gambling practices from the earliest time to the present. These studies rely on archival data from diverse sources, including government, police, newspaper, church, and reformist group records; social and legal histories; and, depending on the time period under review, interviews with key informants. Pitfalls are encountered in reconstructing history from these sources: urban, upper class, and male voices tend to dominate over rural, lower class, and female voices, and more historical data are available from groups opposed to gambling than from adherents of the activity. In addition, there is always the possibility that researchers' opinions, prejudices, and other biases may affect data processing and interpretation.

The analytical hook used by researcher Suzanne Morton in studying Canadian gambling is the social values pertaining to gambling—in particular, their derivation, negotiation, and maintenance. Morton found that (1) antigambling views had been softened by the general secularization of a pluralistic society as reflected in more permissive attitudes toward activities such as marijuana use, extramarital sex, and Sunday observance; (2) vested interest groups, hoping to benefit from looser gambling laws, have euphemized the vocabulary of gambling by using “gaming” and “gaming revenue” as opposed to “gambling” and “gambling losses” to subtly change public discourse on the activity; and (3) by tying gambling-generated funds to charitable causes and keeping taxes down, governments effectively neutered morality arguments and helped launch gambling as a powerful social, economic, and political force in Western society.

Public Policy Analyses

Policy analysis, as defined by Leslie Pal, is “the disciplined application of intellect to public problems.” Discipline implies that the analysis is systematic, rational, and empirical—more than perfunctory musings. As a recognized academic subdiscipline, public policy analysis explores public policies, the elements that comprise them, the processes that produce them, and the impacts they have on society. For the majority of participants, gambling

may be the harmless amusement it was intended to be; however, because of the potential for cheating, exploitation, and overindulgence, the law has historically taken an iron-fisted approach toward gambling. At the same time, history has shown that the activity cannot be completely suppressed and that there is no good reason to outlaw all forms of gambling because it is a long-standing, naturally occurring, mainstream, cultural practice. Given this reality, policymakers strive to create a balance between regulation and outright prohibition by enacting legislation that stipulates where, when, in what form, and under what conditions gambling is permissible. Because of the state and provincial autonomy that exists throughout North America, the gambling terrain is characterized by a patchwork of conflicting jurisdictional policies. Indeed, Dr. Margaret Beare argues that the expansion of legal gambling formats in North America has created a sense of ambiguity that has “resulted in inconsistent policy, limited research and evaluation, inadequate funding for gaming regulation and enforcement, and little concern for the potential social consequences of gambling.”

Academic analyses and critiques of gambling policy have highlighted inadequate gambling policies and the adverse impacts they create, with an outlook toward fostering sound gambling policy and responsible gambling industry practices. Examples of works in this genre include Clotfelter and Cook's *Selling Hope: State Lotteries in America* and Goodman's *The Luck Business*. These studies use interview data from industry leaders, government officials, and academic experts and publicly available information such as gambling revenues, unemployment rates, crime data, advertising expenses, economic impacts, and so forth to ascertain the efficacy of government gambling policies. Clotfelter and Cook showed that American state lotteries function as a significant source of state revenue; they are an attraction for individuals from low-income, low-education and minority backgrounds and are deceptively marketed to attract new players. To remedy this situation, the Clotfelter and Cook recommend a new lottery model that is consumer oriented rather than profit driven. This would mean greater transparency in advertising sales pitches, informing consumers about the odds of winning, higher payouts for winners, and more innovative product lines.

In *The Luck Business*, Goodman questioned the economic justifications used by policymakers to expand legal gambling offerings in the 1980s and 1990s—in particular, the promise of an economic renaissance. In Goodman's view, pre-expansion economic impact studies were distorted because many of these reports were commissioned by casino companies and governments failed to recognize the degree to which expanded gambling formats would cannibalize existing businesses. Governmental underestimation of the financial and social burdens created by

addicted gamblers may end up outweighing any societal benefits accrued from the activity. To redress the economic imbalance of existing gambling policies, Goodman made the following recommendations:

1. Rethinking the ways that state and local governments use gambling as a public policy tool and greater involvement in the process by federal governments.
2. Limiting the ways that states and private industry can advertise and encourage gambling.
3. A national moratorium on gambling expansion until the social and economic impacts of widespread legal gambling have been assessed.
4. Based on the preceding assessment, deciding a new which gambling formats should be allowed, how much gambling is appropriate in a jurisdiction, where gambling outlets should be located, and how gambling revenues should be dispersed.

Final Thoughts

Until 20 years ago, gambling in North America was a low-profile public issue in terms of its variety and availability; immoderate gambling was rarely framed as being problematic, governmental concern about gambling was minimal, and scholars were indifferent to the activity. However, social science research has significantly broadened and deepened our understanding of gambling to the point where there is general concurrence on the following points:

- Gambling is a mainstream cultural activity that is practiced in a socially responsible manner by the majority of those who partake in the activity.
- There is such a phenomenon as problem gambling and it is exacerbated by intermittent reinforcement schedules and fast-paced gambling formats.
- Elevated problem-gambling prevalence rates and higher per capita annual wagering rates in a jurisdiction are associated with the widespread availability of gambling outlets, particularly electronic gambling devices.
- Pressure to expand gambling comes not from the public, but from vested interest groups (e.g., governments, the gambling industry, aboriginal groups, and charities) that stand to benefit from the expansion; as a consequence, commercial considerations generally take priority over social ones.
- Governments that sanction gambling are faced with the conundrum of maintaining gambling revenues, while at the same time suppressing its harmful impacts. Costly treatment programs for problem gambling are seen to be less effective than is public policy that emphasizes preventative measures that immunize those susceptible to gambling addiction, or at least

minimize the trauma for those who already have a gambling problem.

As legalized gambling offerings proliferate, social science research will continue being a critical means of assessing the societal impacts of this expansion and, it is hoped, will provide the basis for enlightened public policy in this domain.

Game Theory, Overview

Ram C. Rao

University of Texas, Dallas, Richardson, Texas, USA

Glossary

asymmetric information The type of data acquired when a move by Nature occurs before any player acts, and some, but not all, players are ignorant of what Nature chose.

best response A player's optimal choice of action in response to a particular choice of others.

common knowledge Something that all players know, with the shared understanding among all players that they all know the same thing.

contractible Some element that can be written into a contract so that the disposition of the contract is based on the exact outcome of the element, and a third party, other than the players, can help in verifying the outcome.

cooperative game An activity in which players can make binding agreements as to their actions.

equilibrium and Nash equilibrium A set of actions chosen by all players such that, given the choices of others, no player wants to change his choice unilaterally.

folk theorem A result, especially in repeated games, that many hold to be true, but which is proved formally much later.

incomplete information The type of data acquired when a move by Nature occurs before any player acts, and some players do not know what Nature chose.

informed player A game participant who has observed Nature's move in a game of asymmetric information.

mixed strategy A player's choice of action that attaches a probability to more than one available action.

Nature An entity that makes a probabilistic move with respect to one of the elements of the game.

noncooperative game A type of game in which players cannot make binding agreements as to their actions.

payoff Profits or utility to players after all players have chosen their action.

perfect information The type of data acquired when players know all that has occurred before their move.

players Participants in a game.

pure strategy A player's choice of a single action with probability 1, from among all available actions.

strategy Specifies action for a player at each information set in which he must move.

subgame perfect Nash equilibrium A Nash equilibrium to a game that is also a Nash equilibrium in every subgame.

Game theory may be used as a modeling device. The rudiments of noncooperative game theory include analyses of games of incomplete information, emphasizing the concepts of Nash equilibrium, subgame perfection, and perfect Bayesian equilibrium. Both illustrative examples and applications in economics and management are used here to provide the reader with a grasp of the scope and usefulness of the game theoretic model. Also presented are the challenges facing modelers who want to use game theory, and how some of those are being met by continuing research.

Game Theory as a Model

Why Game Theory?

Game theory can be viewed in terms of its mathematics or as a tool to model the interaction between decision makers. The word "game" is an apt one to describe this because, just as in common parlor games such as Chess or Hex, much of game theory is concerned with how individual entities (persons, or organizations) choose actions, taking into account how other participants do the same. These entities are called players, even though the decisions that they make are in the context of situations with real-world consequences, quite different from the entertainment that parlor games yield. Players are assumed to choose actions to maximize their expected utility, following the accepted model of single-person decision making. In this sense, game theory may be viewed as

a generalization of single-person decision theory to multiperson decision making. But there are many differences between the two. The utility resulting from a player's action cannot be determined without also taking into account the actions chosen by other players. Thus, game theory cannot prescribe an optimal action for an individual player without also offering a way for each player to anticipate what other players would choose. In other words, game theory is concerned with specifying actions for all players, ensuring that for each player, his/her chosen actions are optimal, given the actions of other players, implying that optimality is relative. As a result, it is generally difficult to define the best outcome from the view of all players. The value of game theory, then, lies in its ability to model the interaction between players. Such a model can help to explain observations involving multiperson decision-making situations, and can also rule out certain outcomes that might not otherwise be contemplated. There is another potential use of game theory. If one of the players can "go" (act) first and choose an action that he can commit to, then it is possible to come up with choices that will ensure outcomes favorable to the first player. For example, the tax code can be viewed as a choice of lawmakers. Based on that, citizens and corporations choose actions, given the tax code. Thus, the lawmakers and citizens can be viewed as playing a game. An analysis of such a game can help determine the best code from the lawmakers' viewpoint. And, what is more important, it would help to disabuse wishful lawmakers of predictions of outcomes that are deemed unreasonable in light of the analysis.

Questions

What should a person know about game theory to be able to apply it to problems in social science? This question can be answered using applications and illustrative examples, mainly in economics and management, that do not require advanced training. The deeper problems in economics and management that game theory has been used to analyze can be accessed in a large body of literature. The hard problems in game theory are not discussed here, yet the reader can get a feel for how the game theoretic model has been successfully used based on minimal domain knowledge beyond everyday experience. Issues that some would regard as drawbacks in using game theory are presented here, although others, including the author, view them as challenges.

Definitions

A game, denoted by G , can be defined as consisting of three elements: players, indexed by i ($i = 1, 2, \dots, N$); an action or strategy a_i , possibly a vector, chosen by player i , from a set $A_i = \{a_i\}$; and a payoff to player i , $\pi_i(a_i, a_{-i})$,

where a_{-i} denotes the actions of all players other than i . The payoff π_i is to be thought of as the utility to player i when he chooses a_i and the other players choose a_{-i} . A game defined in this way is represented in strategic form. An alternative representation of a game, called extensive form, is illustrated by considering a game such as chess. In chess, each player has a turn to make a move by choosing an action a_i , followed by other players, each in turn. The sequence of decisions forms a decision tree, or more correctly a game tree. Each turn to move by any player can be thought of as a stage in a multistage game. A multistage game is to game theory what dynamic programming is to single-person decision theory. In a multistage game, when it is a player's turn to move, he/she may or may not know what some or all of others' choices are. Depending on what the player knows, he/she is at a particular information set at each turn to move. Viewed this way, player i 's strategy, s_i , is defined as a specification of an action, a_i , at each information set, satisfying $s_i \in S_i$. Payoffs can be denoted in this case by $\pi_i(s_i, s_{-i})$, $s_i \in S_i$. In chess and other games, there could be a chance element, similar to the toss of a coin, that determines who moves first. Any such chance event is ascribed to what is denoted "Nature." Finally, assume that each player knows the payoffs and the structure of the game, and further that each player knows that the other players know the same information, and also knows that other players know that the other players know, and so on, *ad infinitum*. This type of knowledge of the game by all of the players is known as common knowledge.

Classification of Games

There are many ways to classify games. First, a game can be a cooperative or noncooperative game. In a cooperative game, the players can make binding commitments with respect to their strategies. Thus, members of the Organization of Petroleum Exporting Countries (OPEC), for example, play a cooperative game when they agree to what level of oil production each is to maintain. In contrast, supermarkets, say, choose pricing strategies noncooperatively. Here the concern is only with noncooperative games.

A very important basis for classifying games is the information that players have at the time of making a move. A game is said to be one of perfect information if, at his/her turn to move, each player knows all that has occurred up to that point in the game. Chess is an example of this type of game. In contrast, consider two firms submitting sealed bids on a contract. This can be conceptualized as similar to a game of chess, with one firm moving first and submitting a bid, followed by the other. Naturally, the first player does not know what the other will do. But what is more important is that the second player does not know what the first bid is.

The second player's information set consists of all possible bids that the first player could have made. Stated differently, the second player's information set contains many elements, each element corresponding to a possible bid by the first player. A game is said to be one of perfect information if, at each player's turn to move, his/her information set is a singleton. With this definition, it is easy to see that bidding for the contract is not a game of perfect information. When players move simultaneously, as in this case, the game is always one of imperfect information. An even more important distinction arises if Nature moves first, and the move is not revealed to at least one player. For example, suppose a human plays chess against a computer but does not know whether the computer is playing at the beginner or advanced level. When the human sees a particular move by the computer, he/she must recognize that the move could have resulted from either the beginner or the advanced level of playing. The player's information set is therefore not a singleton, even though he/she observed the move. In fact, it can be said that the human does not know which game he/she is playing; chess against beginner level or chess against advanced level. This is called a game of incomplete information. More generally, in games of incomplete information, one or more players do not know the game structure. Naturally, all games of incomplete information are also games of imperfect information. A special case of a game of incomplete information is one of asymmetric information. In a game of asymmetric information, the move by Nature is observed by some players but not by others. Consider the interaction between a car salesperson and a potential buyer. The buyer knows his/her budget but the salesperson does not. Thus, in the game of haggling, the salesperson's information is different from that of the buyer, and so there is a game of asymmetric information. As far as the salesperson is concerned, the buyer is a random draw, attributable to a move by Nature. And so, it is a game of incomplete information.

Equilibrium

Nash Equilibrium

In single-person decision theory, the main task is to characterize the optimal solution. In game theory, the task is to characterize the equilibrium. The equilibrium is understandable if the concept of best response is first understood. Consider player i 's choice in response to actions by the other players. Denote $b_i(s_{-i})$ to be i 's best response to s_{-i} . It is then defined as

$$b_i(s_{-i}) = \arg \max_{a_i \in A_i} \pi_i(s_i, s_{-i}). \quad (1)$$

An equilibrium s^* to a game is defined as the strategies of all players such that its components (s_i^*, s_{-i}^*) satisfy the following relationship:

$$s_i^* = b_i(s_{-i}^*) \quad \forall i \quad (2)$$

In other words, at equilibrium, each player's choice is a best response to the choices of the remaining players. In this sense, each player's choice is the solution to an appropriately defined optimization problem. Because each player is at his best response, each player is content with his/her choice. For this reason, this is called an equilibrium. Another equivalent way to define the equilibrium choices s^* is to impose the following inequalities at the equilibrium:

$$\pi_i(s_i^*, s_{-i}^*) \geq \pi_i(s_i, s_{-i}^*) \quad s_i \in S_i \quad \forall i \quad (3)$$

An equilibrium s^* is usually called a Nash equilibrium, named after John Nash. The essential property of Nash equilibrium is that once players arrive at such an equilibrium, no player can profit by deviating unilaterally from it.

Pure and Mixed Strategies

Thus far, strategies have been viewed as actions, or rules for action, at each information set of a player. The definition of strategies can be broadened by specifying a strategy as a probability function over the actions $a_i \in A_i$ corresponding to each information set of the player. A nondegenerate probability distribution would imply that the player's strategy tells him/her to mix among his/her actions, rather than have a unique action for a choice. For this reason, strategies defined in this way are called mixed strategies. A simple example will help illustrate the idea of mixed strategies. Consider a baseball pitcher pitching to a new batter. Suppose the pitcher is restricted to pitch a strike (meaning that the ball goes over the plate at the right height for the batter to be in a position to hit) or a ball (meaning that the ball goes far away from the batter, making it difficult to hit). So the pitcher has two possible actions from which to choose. Now, suppose the batter also has two options: to take a swing or to "see" the ball, meaning not to take a swing. If the batter swings at a strike or sees a ball, the batter wins, whereas the pitcher wins if he/she throws a strike and the batter sees, or he/she throws a ball at which the batter swings. If the pitcher decides to throw a strike for certain, the batter would swing and win. Likewise, if the pitcher decides to throw a ball for certain, the batter would see and win. The pitcher may then consider mixing pitches so that there is uncertainty as to whether he/she throws a strike or a ball. In other words, the pitcher may choose to employ a mixed strategy. In contrast, if the pitcher chooses to assign a probability of 1 to either of his/her actions, he/she would be employing a pure strategy. Thus,

a pure strategy is a special case of mixed strategies in which all actions but one have a zero probability of being chosen.

One advantage with broadening the definition of strategies in this way is that it assures us of the existence of a Nash equilibrium, possibly in mixed strategies, for any game G with a finite number of players, each of whose action sets contain a finite number of elements. John Nash first established this existence result in 1950.

Equilibrium in Pure and Mixed Strategies

Examination of a few game structures will help illustrate Nash equilibrium in pure and mixed strategies. Three of these structures are celebrated, both for their ability to illuminate key concepts and because they represent generic models of competition. All three games have two players, and each player has two possible courses of action.

Product Introduction (Prisoners' Dilemma)

This game contemplates two firms who may each introduce (I) or shelve (S) a new product (P). Table I shows the payoffs to each firm under the four possible combinations of actions. In the table, the rows represent the possible actions of firm 1, and the columns represent the possible actions of firm 2. The entries in each cell are the payoffs to the two firms. Thus, if both choose S , both are at status quo with a utility of 0; if both choose I , they incur costs, but no gains, with utility of -2 . Consider first the best responses of firm 1. It is obvious that $b_1(S) = I$ and $b_1(I) = I$. In other words, regardless of what firm 2 chooses, the best response of firm 1 is to choose I . For firm 1, the strategy S is strictly dominated because it is inferior in both scenarios (with firm 2 choosing S or I). The dominated strategy S for firm 1 can therefore be eliminated or deleted. By symmetry, S for firm 2 can also be deleted. This leaves a unique outcome arising from the dominant strategy of I for each firm. The Nash equilibrium for this game then is (I, I) , as indicated by $(-2, -2)$ in Table I. It can be seen that the Nash equilibrium is in pure strategies. Note also that the Nash equilibrium is unique. Finally, it yields lower utility to both firms than what they could achieve by cooperating and choosing S . Of course, then they

would not be at a best response. Though the best response ensures optimality in an appropriately defined maximization problem, the maximization problem may be undesirable if it is compared to what is possible under cooperative behavior, a feature that is a property of many noncooperative games. This game is often referred to as the prisoners' dilemma, replacing firms by prisoners, actions S and I by "deny" and "confess" (to a crime), and leaving the ordering of the utilities the same. In that game, "confess" is a dominant strategy for both, but if they could cooperate to choose "deny," they would be better off. This will be discussed further later.

Battle of the Sexes

The next illustrative game is called the battle of the sexes. In this game, the two players are a man and a woman. Each can choose to go to the ballet or to the baseball game. The payoffs to the two players are shown in Table II. In the table, when both the man and the woman choose baseball, the man gets a utility of 2 and the woman gets a utility of 1, and so on. It is easy to see that the man's best responses are given by $b_M(\text{baseball}) = \text{baseball}$ and $b_M(\text{ballet}) = \text{ballet}$. Likewise, the woman's best responses are $b_W(\text{baseball}) = \text{baseball}$ and $b_W(\text{ballet}) = \text{ballet}$. Thus, there are two Nash equilibria in pure strategies in this case. The first one has both players choosing baseball, and the second one has both choosing ballet. An important point to note here is that the Nash equilibrium is not necessarily unique. Moreover, whereas the man would prefer the first equilibrium—he obtains a utility of 2 as opposed to 1 in the second—the woman would prefer the second equilibrium. Thus, it is not possible, in general, to rank order Nash equilibria in terms of desirability. Finally, it is not clear how the two players can agree on one of the two equilibria if they cannot communicate in some way. Perhaps even talk that is nonbinding can help the two to get to one of the pure strategy Nash equilibria. Such talk that is nonbinding is termed "cheap talk."

Monitoring a Franchisee (Inspection Problem)

The final example will help illustrate the Nash equilibrium in mixed strategies. In this example, a franchisor may choose to monitor the performance of a franchisee or may choose "don't monitor." The franchisee can choose shirk or "don't shirk." The payoffs are shown in Table III.

Table I Product Introduction^a

Firm 1 (P1)	Firm 2 (P2)	
	S	I
S	(0, -0)	(-5, 10)
I	(10, -5)	(-2, -2)

^a Product P is either introduced (I) or shelved (S).

Table II Battle of the Sexes

Man	Woman	
	Baseball	Ballet
Baseball	2, 1	0, 0
Ballet	0, 0	1, 2

Table III Monitoring a Franchisee

Franchisor \ Franchisee	Franchisee	
	Shirk	Don't Shirk
Monitor	-1, -1	-3, 0
Don't monitor	-4, 1	0, 0

This game is also referred to as the “inspection problem,” for obvious reasons. Once again, the best responses of the franchisor can be seen to be $b_{FR}(\text{shirk}) = \text{monitor}$ and $b_{FR}(\text{don't shirk}) = \text{don't monitor}$. And the best responses of the franchisee are $b_{FE}(\text{monitor}) = \text{don't shirk}$ and $b_{FE}(\text{don't monitor}) = \text{shirk}$. It is obvious that there is no pure strategy Nash equilibrium by an examination of the best responses. For example, taking the outcome (monitor, shirk), though the franchisor is at a best response, the franchisee is not. Similarly, all four possible outcomes can be ruled out. Although there is no Nash equilibrium in pure strategies in this case, there exists a Nash equilibrium in mixed strategies. Let p denote the probability that the franchisor chooses monitor and let q denote the probability that the franchisee chooses shirk. Suppose $q = 0.5$. Then, the franchisor's expected profits are $0.5 \times (-1) + 0.5 \times (-3) = -2$, if he/she chooses monitor, and $0.5 \times (-4) + 0.5 \times (0) = -2$, if he/she chooses don't monitor. In other words, the franchisor is indifferent between his/her two actions if the franchisee follows the mixed strategy of $q = 0.5$. Because the franchisor is indifferent between the two actions, he/she can randomize across them. Suppose the franchisor chooses the mixed strategy $p = 0.5$. Then, it can be verified that the franchisee is indifferent between his/her two actions. The franchisee could, therefore, choose to randomize across his/her actions, and indeed choose $q = 0.5$. Thus, it is obvious that the pair $(p = 0.5, q = 0.5)$ is a best

response for each player and so constitutes a Nash equilibrium in mixed strategies. The key point to note here is that in mixed-strategy equilibrium, a player is indifferent across actions chosen with nonzero probability. Indeed, each of these actions is a best response to the other players' equilibrium mixed strategy. Moreover, if an action is not a best response at equilibrium, it is chosen with zero probability. Finally, the mixing probabilities of the other players make each player indifferent across actions chosen with nonzero probability. In fact, the battle-of-the-sexes game also a mixed-strategy equilibrium in addition to the two pure-strategy equilibria.

Informational Issues

Perfect Equilibrium

One of the central ideas in dynamic programming is Bellman's principle of optimality. This has force in multistage games in the following sense: a player's strategy should be such that it is a best response at each information set. To see how this might affect Nash equilibrium, consider the following variation of the battle of the sexes.

Subgame Perfection

Suppose in the game of battle of the sexes, the man moves first in stage 1 and makes a choice, followed by the woman, in stage 2, and the man gets to have the final say in stage 3. This multistage game can be represented in extensive form by the game tree in Fig. 1, similar to a decision tree in single-person decision situations. At the end of each terminal branch in the game tree are the payoffs to both of the players. Read Fig. 1 as follows: If in stage 1, at node 1, the man chooses baseball (BS), this leads to node 2 in stage 2 of the tree. If, on the other

Figure 1 A three-stage battle-of-the-sexes game in extensive form. BS, baseball; BL, ballet.

hand, the man chooses ballet (BL), this leads to node 3 in stage 2. At node 2, if the woman chooses ballet, this leads to node 5 in stage 3, and the man would choose again. At node 5, the best that the man could do is to choose ballet and get a payoff of 1, as opposed to a payoff of 0 by choosing baseball. Note that node 5 would give a payoff of 2 to the woman, and, using the same logic, node 4 would give her 1. Knowing this, at node 2, she would choose ballet. And similarly, at node 3, she would choose ballet. Given this, at node 1, the man could choose either ballet or baseball. The Nash equilibrium outcome to the three-stage battle of the sexes is unique: both the man and the woman go to the ballet. The equilibrium is specified as follows:

Man: Stage 1—at node 1, choose either ballet or baseball; stage 3—at nodes 4 and 6, choose baseball and at nodes 5 and 7 choose ballet.

Woman: Stage 2—at nodes 2 and 3, choose ballet.

One of the interesting things about specifying the equilibrium in this way is that even though, in equilibrium, nodes 4 and 6 would never be reached, what the man should do if the game ever got there is specified; i.e., the man's strategies are specified on off-equilibrium paths. Also, note that in solving for the equilibrium to the game starting at node 1, the games are first solved for starting at nodes 4–7 in stage 3, then these strategies are used from stage 3 to solve for games starting from nodes 2 and 3 in stage 2, resorting to backward induction to solve for the game. In doing so, the equilibrium is solved for all subgames, starting from every node. Thus, the equilibrium specified is a Nash equilibrium, not only to the game starting from node 1, but to every subgame. For this reason, the equilibrium is known as a subgame perfect Nash equilibrium. It is important to note that if sub-game perfection was not required, other Nash equilibria would

be admitted, including, for example, the man choosing baseball at nodes 1 and 4–7, and the woman choosing baseball at nodes 2 and 3. Finally, note that if the three-stage game had only two stages, containing nodes 1–3, with the man choosing in stage 1, at node 1, and the woman choosing in stage 2, at nodes 2 and 3, the subgame perfect equilibrium would be for both to choose baseball. In this way, it is seen that the concept of subgame perfect equilibrium has real force. It has been used to study many problems in economics, especially related to entry of firms, including sequential and preemptive entry. Essentially, the idea is that once a firm has entered, an incumbent would take that as given, and the subsequent behavior would be an equilibrium to the new subgame postentry, and it is this that must govern a firm's entry decision.

Incomplete and Asymmetric Information

Recall that if there is a move by Nature—a chance move—at the beginning of a multistage game, then the game is one of incomplete information. Consider the following example. A seller of an appliance, say, a refrigerator, knows that there is a probability p that the refrigerator has a defect that cannot be observed. Suppose the buyer also knows this. In other words, the defect rate is common knowledge. The buyer would pay \$1000 for a “good” refrigerator and \$900 for a “bad” one. Should the seller set a price, P , of \$1000 or \$900? (for the sake of exposition, ignore other possible prices). And, what would be the equilibrium action for the buyer: buy, B , or not buy, N ? This is a game of incomplete information, which can be depicted as in Fig. 2. Note that the seller's information set consists of the two nodes {1, 2} because he/she does not know whether Nature chose a good

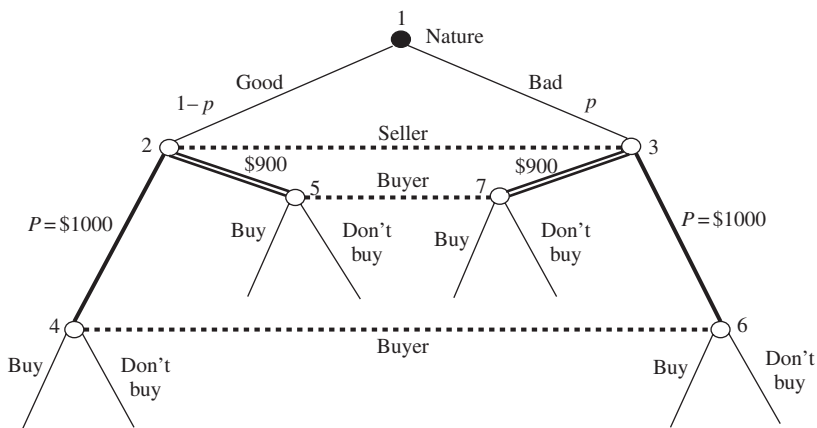

Figure 2 Game of incomplete, symmetric information. The dashed lines indicate the same information set.

refrigerator or a bad one. If the seller chooses a price of \$1000, the buyer is at the information set consisting of the two nodes {4, 6}, and if the seller chooses a price of \$900, the buyer is at {5, 7}. This game might be solved by invoking, for example, the expected value criterion. What is important to note here, though, is that in evaluating the best response based on expected value at an information set with multiple nodes, a decision maker must know the payoffs for any combination of node and action and must know the probability of being at a certain node conditioned on being at the information set. Figure 2 represents a game in which information is incomplete and symmetric, because neither seller nor buyer knows what Nature chose.

Now consider games of asymmetric information, which provide useful models for many interesting situations. Returning to the refrigerator example, suppose it can be one of two types with a defect rate of p_i , $i = 1, 2$, and $p_1 < p_2$. So, product 1 is good and product 2 is bad. Moreover, assume that buyers value a working refrigerator at \$1000 and a defective one at zero. Further, buyers are risk neutral, so they would pay $1000(1 - p)$ for a refrigerator with a known defect rate p . The cost to the seller of a type i refrigerator is assumed to be C_i . Thus, the profits from selling type i refrigerator, if buyers were informed of the type, is $1000(1 - p_i) - C_i$. Finally, assume that the probability that the seller has a good refrigerator is θ , and bad is $1 - \theta$. If consumers had no information on the type that the seller has, they would be willing to pay $1000[(1 - p_1)\theta + (1 - p_2)(1 - \theta)]$. Let P denote the price that the seller sets. Then, the buyer–seller interaction is depicted as a game of asymmetric information in Fig. 3. Here, as in Fig. 2, Nature picks the type of refrigerator at node 1, the seller picks a price at nodes 2 and 3, and the buyer makes a decision to buy or not at an information set consisting of nodes 4 and 5. The key point to note here is that the seller knows the node at which he/she is located but the buyer does not, resulting in asymmetric information. The more interesting question is what

the seller can do about it. There are two possibilities. One is for the seller to condition his/her equilibrium strategy on the node where he/she is located. This, in turn, would reveal information to the buyer, and so the buyer should revise his/her probability of a good refrigerator θ (being at 4 or 5) suitably, using Bayes' rule. The buyer's equilibrium strategy at the information set containing nodes 4 and 5 should then be arrived at using these revised probabilities. The second possibility is that the seller's equilibrium strategy is independent of the information he/she has, and so of the node where he/she is located. In this case, the buyer needs to make sense of an off-equilibrium outcome in stage 1. In particular, how should the buyer revise his/her probability of a good refrigerator? As will be seen, this has force in perfect Bayesian Nash equilibrium (PBNE), which extends the concept of subgame perfect Nash equilibrium to the case of asymmetric information.

Perfect Bayesian Nash Equilibrium

Perfect Bayesian Nash equilibrium is now illustrated to show how it applies in a simple signaling model. Revisit the refrigerator example with specific numerical values: $p_1 = 0.1$, $p_2 = 0.2$, $\theta = 0.5$, $C_1 = 845$, and $C_2 = 750$. Then, consider the following candidate PBNE:

Seller: $P = 1000[(1 - p_1)\theta + (1 - p_2)(1 - \theta)] = 850$.

Buyer: Buy.

Beliefs (off-equilibrium): $\Pr(\text{Good} | P \neq 850) = \theta$.

Given the strategies of the other, both the buyer and the seller are at their best response. However, for a subgame perfect equilibrium to this two-stage game, it should be specified what the buyer would do in stage 2 if the seller were to deviate from the equilibrium price of \$850 in stage 1. In a game of asymmetric information, it is specified how the buyer would revise his/her prior probability of a good refrigerator, θ , in this case as $\Pr(\text{Good} | P \neq 850) = \theta$. These are known as beliefs. The subject of what beliefs are appropriate has preoccupied game theorists considerably. In this case, what are known as passive conjectures have been proposed, so that on seeing an out-of-equilibrium outcome, the posterior is the same as the prior. Given this, it is easy to verify that this is indeed a PBNE. In this equilibrium, both types of sellers take the same equilibrium action, and so cannot be separated based on their actions. For this reason, the equilibrium is called a pooling equilibrium. Note that in this equilibrium, a bad product makes a large profit, $(850 - 750 = \$100)$, and a good one makes a small profit $(850 - 845 = \$5)$.

It might be conjectured that there are other equilibria in this case, because consumers would be willing to pay \$900 for a good refrigerator if there were no asymmetric information. In particular, is there an equilibrium in which the seller charges a high price in node 2 for

Figure 3 Game of incomplete, asymmetric information. The dashed lines indicate the same information set.

a good refrigerator and a low price in node 3 for a bad refrigerator? An equilibrium of this type that identifies the type of seller by the seller's actions is known as a separating equilibrium. It turns out that a separating equilibrium does not exist in this case. To see why, suppose it did. Then, on seeing a high price, the buyer would have to conclude that the refrigerator is good, and so be willing to pay a higher price. But then, why would a seller with a bad refrigerator not mimic the good type? Indeed, in this case, the seller would. Thus, for a separating equilibrium to exist, it must be that no type wants to mimic the other.

Next consider how the seller can profitably enforce a separating equilibrium by designing a contract before setting the price. This will make it not profitable for the bad type to mimic the good type. Specifically, suppose the seller can offer a money-back guarantee that costs \$25 to administer. Consider the following PBNE:

Seller: At node 2, offer a money-back guarantee, but not at node 3.

Seller: $P = 1000$ at node 2, \$800 at node 3.

Buyer: Buy.

Now, given the money-back guarantee, the buyer would pay \$1000 regardless of the defect rate. The buyer would certainly pay \$800 even for the bad product. So the buyer's strategy is a best response. For the seller, at nodes 2 and 3, profits are, respectively, $1000(0.9) - 25(0.1) - 845 = \52.5 , or $800 - 750 = \$50$. It is obvious that the good seller would not want to mimic the bad, but how about the other way around? If, at node 3, the seller were to offer the same terms as at node 2, his/her profits would be $1000(0.8) - 25(0.2) - 750 = \45 . It is clear that the seller would not want to mimic the action at 2. Thus, a way has been devised for the informed player, the seller, to communicate his/her private information to the buyer, the uninformed player. This was done by a signal of quality in this case. Interestingly, the signal alone did not affect quality. The signaling model as a way to offset asymmetric information is used in many contexts, including job market signaling, if worker's abilities are not known to employers; advertising, if product quality is known to seller but not buyer; and dividend payments, to convey information on a company's future prospects.

The Revelation Principle

A large class of problems in which there are two players, one informed and the other uninformed, has come to be known as principal-agent problems. A principal is one who designs a contract that an agent can accept or reject. From a game theoretic perspective, the key question is whether the informed or the uninformed player moves first. In the signaling model, the informed player moves first. In the particular example of the preceding section, the principal was informed. Signaling can also occur in

situations in which the agent is informed. Employers (principals) are uninformed of workers' (agents') abilities, but workers are informed. In this case, the employer designs the contract conditioned on a signal from the worker. Workers accept or reject the contract depending on their abilities.

Consider now situations in which the uninformed player must move first. In particular, assume that the principal is uninformed and must design a contract. There are many examples of this kind of situation. For example, insurance contracts are designed without knowing the driving characteristics of the insured. For illustrative purposes, consider a sales manager as the principal who must design a compensation plan (contract) for his/her salespersons, who are the agents. Assume that the agent in this model is informed. To what information might a salesperson, but not the manager, have access? It could be the salesperson's ability. In this case, the salesperson would be informed before accepting the contract. Another kind of information would be whether a customer the salesperson approached turned out to be easy or hard to sell to, because it would be difficult for the manager to observe this sales response. In this case, the salesperson becomes informed after accepting the contract but before putting in the effort to sell to the customer. Thus, the effort level of the agent depends on information that he/she, but not the principal, has. Finally, the manager would be uninformed about the effort put in by a salesperson. This would occur if sales have a random component to them, because knowing sales is not sufficient to infer the effort. More relevant, a manager, even if he/she could observe the salesperson, cannot write a contract that is conditioned on a salesperson's ability, the random customer response, or effort. Thus the type (of salesperson), the state of the world chosen by Nature, and effort are all not contractible, meaning that there would be no way for a third party, such as a court, to verify the claims of ability, customer response, and salesperson effort. And yet all of these factors would affect the sales generated by the salesperson. What the manager can do is to write an "optimal" contract conditional on sales. What are some properties that such optimal contracts must satisfy?

A contract based on sales (verifiable outcome) must satisfy three conditions to be practical. First, it must be acceptable to the salesperson. Usually, it must afford the agent expected utility that is not less than what the agent would obtain if he/she were to reject the contract. This is known as the individual rationality (IR) constraint. Second, it must take into account that the salesperson would take the contract as given and then choose effort to maximize his/her expected utility. In other words, the incentive structure in the contract would determine the effort level. This is known as the incentive compatibility (IC) constraint. Third, a contract that is optimal for the manager would maximize his/her expected utility subject

to the IR and IC constraints. This problem can be formulated as a constrained maximization problem.

The problem can also be viewed as a multistage game in which the principal first designs a mechanism, M , that specifies the terms of the contract. In particular, it says what the salesperson would have to sell, and what he/she would earn, both depending on what message he/she sends. After the mechanism has been designed, the salesperson accepts or rejects the contract. Suppose the salesperson accepts. Then, the information he/she has and the terms of the contract he/she chooses simultaneously send a costless message to the manager that will determine the salesperson's payoff. Thus, the principal chooses the mechanism and the agent chooses the message (and the effort), and the equilibrium in this game solves for the optimal contract. An important result in the theory of contracts is that the message can be restricted to be the information the agent has, and an optimal contract has the property that the agent would not have an incentive to report his/her information falsely. This is known as the revelation principle, because the optimal contract uncovers the information that the principal does not have. To see the intuition behind the revelation principle, suppose in the salesperson compensation problem that there are two salespersons with differing abilities, high (H) and low (L). Consider the (optimal) mechanism that offers $m(H)$ and $m(L)$, $m(H) \neq m(L)$, if salespersons report H and L , respectively. Suppose, contrary to the revelation principle, the mechanism induces H to lie, and to report L instead. Then, because the mechanism is optimal, the manager would have lost nothing by making $m(H) = m(L)$. This sort of reasoning can be established more rigorously. This is useful because it can restrict our attention to a subset of all possible contracts. In light of the revelation principle, the problem of optimal contracting can now be thought of as maximizing expected utility of the principal subject to three constraints: IR, IC, and truth telling.

Using the Game Theoretic Model

There are far too many interesting applications of game theory to cover here, but three examples with managerial implications will give the reader a feel for how the concepts developed in the preceding discussions can be used in modeling.

Auctions

Auctions play a major role in many spheres of economic activity, including e-commerce, government sale of communication frequencies, sale of state-owned assets to private firms, and, of course, art. Sellers are interested in maximizing their revenue and so analysis of equilibrium

under different auction rules for particular situations would be helpful. From a larger perspective, it would be desirable that the auctioned object goes to the person who values it most. Again, how this is affected by specific auction rules can be studied using game theory. At its core, an auction involves competitive bidding, with bidders taking turns. Bidders in an auction differ in their valuation for an object and their knowledge of the true value, so auctions can be viewed as games of asymmetric information. Here the Nash equilibrium strategies are characterized in the simple English and Dutch auctions. Consider a single object being auctioned to N potential bidders, indexed by i . Bidder i knows his/her valuation v_i of the object. Assume that $0 \leq v_i \leq V < \infty$, so that all bidders have a nonzero valuation and none has an infinite valuation. This type of auction is called a private value auction because each bidder knows with certainty his/her value, but not others' values. [In contrast, an auction in which all bidders have the same (common) value for the object, but each has an error-prone estimate of the common value, is usually called a common value auction. In this case, knowing others' estimates can help refine an individual bidder's estimate. The following discussion relates only to private value auctions.]

In a Dutch auction, the auctioneer starts off at a high price and decreases the price in small steps until a bidder steps in. The bidder wins at that price, but no information is generated about the valuations of the other potential bidders, except that they are lower than the winning bid. Because the bidder pays the highest price, and nothing is learned during the auction, a Dutch auction is equivalent to a first-price sealed-bid auction. In an English auction, the auctioneer cries out bids in incremental steps, and bidders stay in or opt out. When a single bidder remains, he/she wins the auction, and must pay the last bid at which the second highest bidder stayed in. During the course of the auction, information on the valuation of the other bidders becomes available from the price at which each dropped out, which could be useful, especially in common value auctions. In a private value auction, because nothing is learned during the auction, an English auction is equivalent to a second-price sealed-bid auction. Seminal work by William Vickrey in 1961 showed that both first-price and second-price auctions in a private value auctions yield the same expected revenue to the seller.

Second-Price Auction

In a second-price sealed-bid auction, the highest bidder wins but pays the second highest bid. Let B_i denote i 's bid. The payoff to bidder i is then

$$\pi_i(B_i, B_{-i}) = \begin{cases} v_i - \max(B_{-i}) & \text{if } B_i > \max(B_{-i}), \\ 0 & \text{else.} \end{cases} \quad (4)$$

The possibility of bids being tied is ignored. It is easy to see that a Nash equilibrium to this game is for each bidder to bid $B_i = v_i$. In the event that the bidder loses, this strategy is not dominated. In the event that the bidder wins, given other bidders' strategies, this is a best response. Thus, this strategy of bidding true valuation is a weakly dominant strategy, resulting in a Nash equilibrium because all players are at their best response.

The seller is interested in the equilibrium revenue to the seller, not the bids alone, and so would like to know what the revenues are when using a second-price rule. Revenue would depend on the distribution of values over bidders. Let $F(v)$ denote the cumulative distribution function of the v_i values. In other words, each bidder's value is a draw from this distribution. Assume that the draws are independent, and assume that F is differentiable and the values are in a closed interval. Given the Nash equilibrium strategies, a bidder with valuation v_i wins if all others have a valuation less than v_i , and this occurs, say, with probability $P(v_i)$. Of course, P depends on F . Knowing F , it is also possible to calculate the expected value of the second highest bid as the maximum of $(N - 1)$ independent draws from F conditioned on the maximum being less than v_i . Denote this by $M(v_i)$. Then, clearly the revenue to the seller conditioned on v_i is $P(v_i)M(v_i)$. The expected revenue can be obtained by unconditioning on v_i . In other words, expected revenue to the seller is simply $\int P(v)M(v) dF(v)$.

First-Price Auction

In a first-price auction, the Nash equilibrium strategies are slightly more complicated. Assume that bidders maximize their expected payoff. Suppose all bidders follow a strategy $s(v_i)$, with s monotonically increasing in v_i . Then, $s : v_i \rightarrow B_i$. It can be shown that a Nash equilibrium in this case is $s(v_i) = M(v_i) < v_i$. Thus, in a first-price auction, all bidders bid less than their true value. But, the revenue to the seller, computed, as before, by first conditioning on v_i and then taking expectations, is identical to that in the second-price auction. This is Vickrey's result. Thus, from the seller's point of view, the two types of auctions produce the same outcome. In both cases, the object goes to the person who values it most. The equivalence outcome under different auction rules does not always obtain. Indeed, many features of auctions, such as the use of reserve prices, auctions of multiple objects, common value auctions, and so on, would be part of a model, depending on the situation. Since the time of Vickrey's work, many game theoretic models have been developed to incorporate these features.

Government Procurement

How might the government design a contract for defense purchases? This is game of asymmetric information

because the (supplying) firm is likely to know more about its cost of supplying to the government than the knows about prices. Suppose the firm is one of two types, H and L , with abilities a_H and a_L , $a_H > a_L$, where cost of supplying the defense item is

$$c_i = c_0 - a_i - e_i, \quad i = H, L, \quad (5)$$

where e_i is the effort expended by firm i to control costs. The cost of the effort for the firm is $V(e)$, $V', V'' > 0$. Of course, the government cannot observe the effort level of a firm, but can observe the final cost. The government offers a contract that pays $t(c)$ if the firm's reported cost is c . The firm's objective is to maximize

$$\pi_i = t(c_i) - V(e_i). \quad (6)$$

The government cares about the cost, the social benefit B of the defense item, and the firm's profits. So it wants to maximize

$$\pi_G = B - c - V(e_i) - \lambda[c + t(c_i)]. \quad (7)$$

The last term represents the social cost of taxes that must be used to pay the firm. Although the government does not know which type the firm is, it is assumed to know the probability that the firm is type H or L , and it is common knowledge. This problem can be seen as one of mechanism design, with the government specifying a payment $s(H)$ and $s(L)$, and associated costs $s(H)$ and $s(L)$, corresponding to messages H and L . For realizations of other costs, the payment would be zero.

The solution to this problem yields a surprisingly simple incentive contract. The contract reimburses a high-cost firm for its effort e , but this effort is lower than what would be optimal if there were no information asymmetry and the government knew that it was dealing with a high-cost firm. On the other hand, with a low-cost firm, the government reimburses the cost of effort plus an additional amount that elicits truth telling by the low-cost firm. The effort level chosen by the low-cost firm is exactly what it would have been with no asymmetric information. When there are many types of firms, rather than two, and cost observation is noisy, this result generalizes to a contract in which a firm receives a fixed payment and a variable payment that reimburses a fraction of the observed cost. The fixed payment is higher for a lower cost firm whereas a higher fraction of the cost is reimbursed for a high-cost firm.

Retail Advertising and Pricing Practice

Supermarkets carry many products, and must decide which products they should price relatively low to induce customers to shop at their store, and also whether they

should advertise the price of such products. A game theoretic model can help answer such questions. Consider two retailers, indexed by j , A and B located at the ends of a straight line. Suppose that each carries two goods 1 and 2, indexed by i , and the price of good i at store j is P_{ij} . Consumers are willing to pay up to $\$R$ for either good. They are located on the line AB , are uniformly distributed, and are assumed to incur a cost to visit a store proportional to the distance of their location from the store. How might the competing stores price the products?

Peter Diamond has argued that, once at a store, a consumer would find it cheaper to buy at that store, even if the other store had a slightly higher price, because of the transportation cost. This would allow each store to price a little above the other, eventually to the monopoly price, in this case, R . This counterintuitive result of monopoly prices under competition has come to be known as the Diamond paradox. The question is how this would be affected if firms carrying multiple products could advertise prices of only a subset of products? This sort of question is relevant to supermarkets that carry many products but can advertise only a few. This can be modeled as a two-stage game in which firms advertise the price of one item (1 or 2) in the first stage, and then, after knowing the advertising strategies, set the price of the other item in the second stage. Of course, consumers would know the prices of advertised goods, but not the unadvertised ones. A Nash equilibrium to this game takes the following form:

Stage 1: Each firm advertises either item with probability 0.5, and chooses a price $P_a^* < R$ for it.

Stage 2: If both stores advertised the same item (1 or 2) in stage 1, they set the price of the unadvertised good at R . If they advertised different items, they set the price of the unadvertised good at $P_a^* + c < R$, where c is the incremental cost for a consumer located at the midpoint of route AB to visit an additional store.

In this equilibrium, consumers find it optimal to buy both items at the nearest store, even when the stores advertise different items, because, once they are at this store, it would not pay them to take advantage of a lower price on one of the items at the other store. When both stores advertise the same item, it is clearly optimal for consumers to shop at the nearest store.

The mixed-strategy equilibrium is consistent with casual observation of stores advertising both the same and different products on occasion, stores offering unadvertised price specials, and consumers content to make store choices without knowing all prices. It also shows that at least one item would always be below monopoly price R , while the expected price of the other item is also below R . The first effect is a consequence of permitting advertising, the second is a consequence of rational expectations on the part of consumers. Thus, a game theoretic model can provide insights into pricing practice.

Adapting the Game Theoretic Model

Repeated Games

An issue that has received a great deal of attention is the effect of players repeatedly playing a game such as the prisoners' dilemma. If played only once, the equilibrium is for both players to play their dominant strategy and to get a lower utility than what they would get with co-operation, but it can be conjectured that they could seek, and even obtain, some sort of cooperation if they encountered each other repeatedly, in turn leading to an outcome that is not a Nash equilibrium in a single play of the game. This line of thinking goes at least as far back as 1957, to the work of R. Duncan Luce and Howard Raiffa, who argued that "we feel that in most cases [of repetitions of Prisoners' Dilemma] an unarticulated collusion between the players will develop . . . this arises from the knowledge that . . . reprisals are possible." However, for some games, including the prisoners' dilemma, it can be shown that finite repetitions do not change the outcome, leading to what has come to be known as the chain-store paradox. Infinite repetitions are another matter, however. In this case, it is possible, under certain conditions, to support many payoff outcomes as a subgame perfect equilibrium, even if the outcome would not be a Nash equilibrium in a one-shot play of the game. Define, for each player, his/her security level or minmax value, m_{is} , as follows:

$$m_{is} = \min_{a-i} [\max_{a_i} \pi_i(a_i, a_{-i})]. \quad (8)$$

An individually rational payoff for player i is a payoff that is not less than m_{is} . Let players discount future payoffs by a factor δ , $0 < \delta < 1$. Let $G(\delta)$ denote an infinite repetition of a game G , with discount factor δ . Then, the result, called a folk theorem, holds for infinitely repeated games.

Folk Theorem

Any vector of individually rational payoffs in a game G can be supported as a subgame perfect Nash equilibrium in an infinitely repeated version of G for a sufficiently large δ . The folk theorem actually requires an additional technical condition that the set of payoffs that strictly pareto-dominate the individually rational payoffs be of dimension N . It is best to think of a desired level of payoffs to support in equilibrium as a desired outcome. When a player deviates from the desired outcome, the other players would punish him/her. Now, the intuitive condition that players should not discount the future too much allows players to inflict sufficient punishment to any deviant behavior by a player. This is the reprisal contemplated by Luce and Raiffa. The technical condition allows players to punish

a deviant player without punishing themselves. No punishment can lead to a player receiving a payoff lower than his/her minmax value. One of the consequences of the folk theorem is that sub-game perfect Nash equilibrium admits too many possible outcomes, calling into question the usefulness of the equilibrium concept as a modeling device. The challenge then is to model a situation carefully about what players can observe and how they can implement punishments. The main contribution of results such as the folk theorem is the reasonable way it offers to capture tacit understanding among players who interact repeatedly.

Experiments and Games

There has been a good bit of effort to see how good a model of human behavior game theory really is. Most of this work has consisted of laboratory experiments using human participants and creating environments that would correspond to typical game theoretic models of competitive interaction, whether it be auctions or price determination. In one study, it was reported that some predictions of game theory describe behavior well. In particular, games with unique Nash equilibrium are replicated well in the lab. On the other hand, in the presence of multiple equilibria, theoretical procedures to refine them do not find support in the lab. One of the concepts emphasized here is the subgame perfect equilibrium. However, participants in an experiment may have difficulty in implementing such a complicated computational procedure. In contrast, the concept of fairness seems to affect experimental outcomes, as do institutional structures (for example, the number of players).

An issue in real-world competition is how players learn. In game theoretic models, the usual way to model learning is to use some sort of Bayesian updating. This does not always accord well with experimental evidence. The capacity of individuals to learn in the course of auctions appears to be limited. Similar findings have been found in a large number of experiments. These considerations have led researchers to find ways of modeling learning, resulting in the growing area of evolutionary game theory. The goal of these efforts is to find a good way to incorporate learning in a game theoretic model. Some scholars who have explored this and related issues say there is little doubt that game theory has much to offer as a model, and alternatives are not nearly as attractive. Even so, one question remains: what is the best way to use and adapt game theory as a model of rational players?

Generalizability Theory

Richard J. Shavelson

Stanford University, Stanford, California, USA

Noreen M. Webb

University of California, Los Angeles, Los Angeles, California, USA

Glossary

condition The levels of a facet (e.g., task 1, task 2, . . . , task k).

decision (D) study A study that uses information from a G study to design a measurement procedure that minimizes error for a particular purpose.

facet A characteristic of a measurement procedure such as a task, occasion, or observer that is defined as a potential source of measurement error.

generalizability (G) study A study specifically designed to provide estimates of the variability of as many possible facets of measurement as economically and logistically feasible considering the various uses a test might be put to.

universe of admissible observations All possible observations that a test user would consider acceptable substitutes for the observation in hand.

universe of generalization The conditions of a facet to which a decision maker wants to generalize.

universe score The expected value of a person's observed scores over all observations in the universe of generalization (analogous to a person's true score in classical test theory); denoted μ_p .

variance component The variance of an effect in a G study.

Generalizability (G) theory, a statistical theory for evaluating the dependability (reliability) of behavioral measurements, grew from the recognition that the undifferentiated error in classical test theory provided too gross a characterization of the multiple sources of measurement error. Whereas in classical test theory, measurement error is random variation and the multiple error sources are undifferentiated, G theory considers both systematic and unsystematic sources of error variation and

disentangles them simultaneously. Moreover, in contrast to the classical parallel-test assumptions of equal means, variances, and covariances, G theory assumes only randomly parallel tests sampled from the same universe. These developments expanded the conceptions of error variability and reliability that can be applied to different kinds of decisions using behavioral measurements. In G theory a behavioral measurement (e.g., achievement test score) is conceived of as a sample from a universe of admissible observations, which consists of all possible observations that decision makers consider to be acceptable substitutes for the observation in hand. Each characteristic of the measurement situation (e.g., test form, item, or occasion) is called a facet and a universe of admissible observations is defined by all possible combinations of the levels of the facets. To estimate different sources of measurement error, G theory extends earlier analysis-of-variance approaches to reliability and focuses heavily on variance component estimation and interpretation to isolate different sources of variation in measurements and to describe the accuracy of generalizations made from the observed to the universe scores of individuals. In contrast to experimental studies, analysis of variance is not used to formally test hypotheses.

Generalizability Studies

In order to evaluate the dependability of behavioral measurements, a generalizability (G) study is designed to isolate particular sources of measurement error. The facets that the decision maker might want to generalize over (e.g., items or occasions) must be included.

Universe of Generalization

The universe of generalization is defined as the set of conditions to which a decision maker wants to generalize. A person's universe score (denoted μ_p) is defined as the expected value of his or her observed scores over all observations in the universe of generalization (analogous to a person's true score in classical test theory).

Decomposition of Observed Score

With data collected in a G study, an observed measurement can be decomposed into a component or effect for the universe score and one or more error components. Consider a random-effects two-facet crossed $p \times i \times o$ (person by item by occasion) design. The object of measurement, here people, is not a source of error and, therefore, is not a facet. In the $p \times i \times o$ design with generalization over all admissible test items and occasions taken from an indefinitely large universe, the observed score for a particular person (p) on a particular item (i) and occasion (o) is:

$$\begin{aligned}
 X_{pio} = & \mu && \text{grand mean} \\
 & + \mu_p - \mu && \text{person effect} \\
 & + \mu_i - \mu && \text{item effect} \\
 & + \mu_o - \mu && \text{occasion effect} \\
 & + \mu_{pi} - \mu_p - \mu_i + \mu && \text{person} \times \text{item effect} \\
 & + \mu_{po} - \mu_p - \mu_o + \mu && \text{person} \times \text{occasion effect} \\
 & + \mu_{io} - \mu_i - \mu_o + \mu && \text{item} \times \text{occasion effect} \\
 & + X_{pio} - \mu_p - \mu_i - \mu_o && \\
 & + \mu_{pi} + \mu_{po} + \mu_{io} - \mu && \text{residual}
 \end{aligned} \tag{1}$$

where $\mu = E_o E_i E_p X_{pio}$ and $\mu_p = E_o E_i X_{pio}$, and E means expectation. The other terms in (1) are defined analogously. Assuming a random-effects model, the distribution of each effect, except for the grand mean, has a mean of zero and a variance σ^2 (called the variance component). The variance of the person effect, $\sigma_p^2 = E_p(\mu_p - \mu)^2$, called universe-score variance, is analogous to the true-score variance of classical test theory. The variance components for the other effects are defined similarly. The residual variance component, $\sigma_{pio,e}^2$, indicates that the person \times item \times occasion interaction is confounded with residual error because there is one observation per cell. The collection of observed scores, X_{pio} , has a variance, $\sigma^2(X_{pio}) = E_o E_i E_p \times (X_{pio} - \mu)^2$, which equals the sum of the variance components:

$$\sigma^2(X_{pio}) = \sigma_p^2 + \sigma_i^2 + \sigma_o^2 + \sigma_{pi}^2 + \sigma_{po}^2 + \sigma_{io}^2 + \sigma_{pio,e}^2 \tag{2}$$

An estimate of each variance component can be obtained from a traditional analysis of variance (or other methods such as maximum likelihood). The relative magnitudes of the estimated variance components provide information about potential sources of error influencing a behavioral measurement. Statistical tests are not used in G theory; instead, standard errors for variance component estimates provide information about sampling variability of estimated variance components.

Decision Studies

G theory distinguishes a decision (D) study from a G study. The G study is associated with the development of a measurement procedure and the D study uses information from a G study to design a measurement that minimizes error for a particular purpose. In planning a D study, the decision maker defines the universe that he or wishes to generalize to, called the universe of generalization, which may contain some or all of the facets and conditions in the universe of admissible observations. In the D study, decisions usually are based on the mean over multiple observations rather than on a single observation. The mean score over a sample of n'_i items and n'_o occasions, for example, is denoted as X_{pIO} , in contrast to a score on a single item and occasion, X_{pio} . A two-facet, crossed D-study design in which decisions are to be made on the basis of X_{pIO} is, then, denoted as $p \times I \times O$.

Types of Decisions and Measurement Error

G theory recognizes that the decision maker might want to make two types of decisions based on a behavioral measurement: relative and absolute.

Measurement Error for Relative Decisions

A relative decision concerns the rank ordering of individuals (e.g., norm-referenced interpretations of test scores). For relative decisions, the error in a random-effects $p \times I \times O$ design is defined as:

$$\delta_{pIO} = (X_{pIO} - \mu_{IO}) - (\mu_p - \mu) \tag{3}$$

where $\mu_p = E_o E_i X_{pIO}$ and $\mu_{IO} = E_p X_{pIO}$. The variance of the errors for relative decisions is:

$$\begin{aligned}
 \sigma_\delta^2 &= E_p E_i E_o \delta_{pIO}^2 = \sigma_{pI}^2 + \sigma_{pO}^2 + \sigma_{pIO,e}^2 \\
 &= \frac{\sigma_{pi}^2}{n'_i} + \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{pio,e}^2}{n'_i n'_o}
 \end{aligned} \tag{4}$$

In order to reduce σ_δ^2 , n'_i and n'_o may be increased (analogous to the Spearman-Brown prophecy formula in classical test theory and the standard error of the mean in sampling theory).

Measurement Error for Absolute Decisions

An absolute decision focuses on the absolute level of an individual's performance independent of others' performance (cf. domain-referenced interpretations). For absolute decisions, the error in a random-effects $p \times I \times O$ design is defined as:

$$\Delta_{pIO} = X_{pIO} - \mu_p \quad (5)$$

and the variance of the errors is:

$$\begin{aligned} \sigma_{\Delta}^2 &= E_p E_I E_O \Delta_{pIO}^2 \\ &= \sigma_I^2 + \sigma_O^2 + \sigma_{pI}^2 + \sigma_{pO}^2 + \sigma_{IO}^2 + \sigma_{pIO,e}^2 \\ &= \frac{\sigma_i^2}{n_i'} + \frac{\sigma_o^2}{n_o'} + \frac{\sigma_{pi}^2}{n_i'} + \frac{\sigma_{po}^2}{n_o'} + \frac{\sigma_{io}^2}{n_i' n_o'} + \frac{\sigma_{pio,e}^2}{n_i' n_o'} \end{aligned} \quad (6)$$

Coefficients

Although G theory stresses the importance of variance components and measurement error, it provides summary coefficients that are analogous to the reliability coefficient in classical test theory (i.e., true-score variance divided by observed-score variance; an intraclass correlation). The theory distinguishes between a generalizability coefficient for relative decisions and an index of dependability for absolute decisions.

Generalizability Coefficient

The generalizability coefficient is analogous to classical test theory's reliability coefficient (the ratio of the universe-score variance to the expected observed-score variance; an intraclass correlation). For relative decisions and a $p \times I \times O$ random-effects design, the generalizability coefficient is:

$$E\rho^2(X_{pIO}, \mu_p) = E\rho^2 = \frac{E_p(\mu_p - \mu)^2}{E_O E_I E_p (X_{pIO} - \mu_{IO})^2} = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_{\Delta}^2} \quad (7)$$

Dependability Index

For absolute decisions with a $p \times I \times O$ random-effects design, the index of dependability is:

$$\Phi = \frac{\sigma_p^2}{\sigma_p^2 + \sigma_{\Delta}^2} \quad (8)$$

The right-hand side of Eqs. (7) and (8) are generic expressions that apply to any design and universe. For domain-referenced decisions involving a fixed cutting score λ (often called criterion-referenced measurements), and assuming that λ is a constant that is specified *a priori*, the error of measurement is:

$$\Delta_{pIO} = (X_{pIO} - \lambda) - (\mu_p - \lambda) = X_{pIO} - \mu_p \quad (9)$$

and the index of dependability is:

$$\Phi(\lambda) = \frac{E_p(\mu_p - \lambda)^2}{E_O E_I E_p (X_{pIO} - \lambda)^2} = \frac{\sigma_p^2 + (\mu - \lambda)^2}{\sigma_p^2 + (\mu - \lambda)^2 + \sigma_{\Delta}^2} \quad (10)$$

An unbiased estimator of $(\mu - \lambda)^2$ is $(\bar{X} - \lambda)^2 - \sigma^2(\bar{X})$, where \bar{X} is the observed grand mean over sampled objects of measurement and sampled conditions of measurement in a D-study design.

Generalizability- and Decision-Study Designs

G theory allows the decision maker to use different designs in the G and D studies. Although G studies should use crossed designs whenever possible to avoid confounding of effects, D studies may use nested designs for convenience or for increasing sample size, which typically reduces estimated error variance and, hence, increases estimated generalizability. For example, compare σ_{δ}^2 in a crossed $p \times I \times O$ design and a partially nested $p \times (I:O)$ design, where facet i is nested in facet o , and n' denotes the number of conditions of a facet under a decision maker's control:

$$\begin{aligned} \sigma_{\delta}^2 \text{ in a } p \times I \times O \text{ design} &= pI + \sigma_{pO}^2 + \sigma_{pIO}^2 \\ &= \frac{\sigma_{pi}^2}{n_i'} + \frac{\sigma_{po}^2}{n_o'} + \frac{\sigma_{pio,e}^2}{n_i' n_o'} \end{aligned} \quad (11)$$

$$\begin{aligned} \sigma_{\delta}^2 \text{ in a } p \times (I:O) \text{ design} &= \sigma_{pO}^2 + \sigma_{pI:O}^2 \\ &= \frac{\sigma_{po}^2}{n_o'} + \frac{\sigma_{pi,pio,e}^2}{n_i' n_o'} \end{aligned} \quad (12)$$

In Eqs. (11) and (12), σ_{pi}^2 , σ_{po}^2 , and $\sigma_{pio,e}^2$ are directly available from a G study with design $p \times xi \times o$ and $\sigma_{pi,pio,e}^2$ is the sum of σ_{pi}^2 and $\sigma_{pio,e}^2$. Moreover, given cost, logistics, and other considerations, n' can be manipulated to minimize error variance, trading off, in this example, items and occasions. Due to the difference in the designs, σ_{δ}^2 is smaller in Eq. (12) than in (11).

Random and Fixed Facets

Generalizability theory is essentially a random effects theory. Typically a random facet is created by randomly sampling conditions of a measurement procedure (e.g., tasks from a job in observations of job performance). When the conditions of a facet have not been sampled randomly from the universe of admissible observations but the intended universe of generalization is infinitely large, the concept of exchangeability may be invoked to consider the facet as random.

A fixed facet (cf. fixed factor in analysis of variance) arises when (1) the decision maker purposely selects certain conditions and is not interested in generalizing beyond them, (2) it is unreasonable to generalize beyond conditions, or (3) the entire universe of conditions is small and all conditions are included in the measurement design. G theory typically treats fixed facets by averaging over the conditions of the fixed facet and examining the generalizability of the average over the random facets. When it does not make conceptual sense to average over the conditions of a fixed facet, a separate G study may be conducted within each condition of the fixed facet or a full multivariate analysis may be performed.

G theory recognizes that the universe of admissible observations encompassed by a G study may be broader than the universe to which a decision maker wishes to generalize in a D study, the universe of generalization. The decision maker may reduce the levels of a facet (creating a fixed facet), select (and thereby control) one level of a facet, or ignore a facet. A facet is fixed in a D study when $n' = N'$, where n' is the number of conditions for a facet in the D study and N' is the total number of conditions for a facet in the universe of generalization. From a random-effects G study with design $p \times i \times o$ in which the universe of admissible observations is defined by facets i and o of infinite size, fixing facet i in the D study and averaging over the n_i conditions of facet i in the G study ($n_i = n'_i$) yields the following estimated universe-score variance:

$$\sigma_\tau^2 = \sigma_p^2 + \sigma_{pI}^2 = \sigma_p^2 + \frac{\sigma_{pi}^2}{n'_i} \quad (13)$$

where σ_τ^2 denotes estimated universe-score variance in generic terms. σ_τ^2 in Eq. (13) is an unbiased estimator of universe-score variance for the mixed model only when

the same levels of facet i are used in the G and D studies. Estimates of relative and absolute error variance, respectively, are:

$$\sigma_\delta^2 = \sigma_{pO}^2 + \sigma_{pIO}^2 = \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{pio,e}^2}{n'_i n'_o} \quad (14)$$

$$\begin{aligned} \sigma_\Delta^2 &= \sigma_O^2 + \sigma_{pO}^2 + \sigma_{IO}^2 + \sigma_{pIO}^2 \\ &= \frac{\sigma_o^2}{n'_o} + \frac{\sigma_{po}^2}{n'_o} + \frac{\sigma_{io}^2}{n'_i n'_o} + \frac{\sigma_{pio,e}^2}{n'_i n'_o} \end{aligned} \quad (15)$$

Numerical Example

As an example, consider the following 1998 G study, by Webb, Nemer, Chizhik, and Sugrue, of science achievement test scores. In this study, 33 eighth-grade students completed a six-item test on knowledge of concepts in electricity on two occasions, 3 weeks apart. The test required students to assemble electric circuits so that the bulb in one circuit was brighter than the bulb in another circuit and to answer questions about the circuits. Students' scores on each item ranged from 0 to 1, based on the accuracy of their judgment and the quality of their explanation about which circuit, for example, had higher voltage. The design was considered fully random.

Table I gives the estimated variance components from the G study. σ_p^2 (0.03862) is fairly large compared to the other components (27% of the total variation). This shows that, averaging over items and occasions, students in the sample differed in their science knowledge. Because people constitute the object of measurement, not error, this variability represents systematic individual differences in achievement. The other large estimated variance components concern the item facet more than the occasion facet.

Table I Generalizability Study and Alternative Decision Studies for the Measurement of Science Achievement

Source of variation	σ^2	<i>G study</i>		<i>Alternative D studies</i>				
		$n'_i = 1$ $n'_o = 1$	$n'_i =$ $n'_i =$	6 1	6 2	8 3	12 1	12 2
Person	σ_p^2	0.03862	σ_p^2	0.03862	0.03862	0.03862	0.03862	0.03862
Item	σ_i^2	0.00689	σ_I^2	0.00115	0.00115	0.00086	0.00057	0.00057
Occasion	σ_o^2	0.00136	σ_O^2	0.00136	0.00068	0.00045	0.00136	0.00068
<i>pi</i>	σ_{pi}^2	0.03257	σ_{pI}^2	0.00543	0.00543	0.00407	0.00271	0.00271
<i>po</i>	σ_{po}^2	0.00924	σ_{pO}^2	0.00924	0.00462	0.00308	0.00924	0.00462
<i>io</i>	σ_{io}^2	0 ^a	σ_{IO}^2	0	0	0	0	0
<i>pio,e</i>	$\sigma_{pio,e}^2$	0.05657	$\sigma_{pIO,e}^2$	0.00943	0.00471	0.00236	0.00471	0.00236
	σ_δ^2	0.09838		0.02410	0.01476	0.00951	0.01667	0.00969
	σ_Δ^2	0.10663		0.02661	0.01659	0.01082	0.01860	0.01095
	ρ^2	0.28		0.62	0.72	0.80	0.70	0.80
	Φ	0.27		0.59	0.70	0.78	0.67	0.78

^a Negative estimated variance component (−0.00093) set to zero.

The nonnegligible σ_i^2 (5% of the total variation) shows that items varied somewhat in difficulty level. The large σ_{pi}^2 (22%) reflects different relative standings of people across items. The small σ_o^2 (1% of the total variation) indicates that performance was stable across occasions, averaging over students and items. The nonnegligible σ_{po}^2 (6%) shows that the relative standing of students differed somewhat across occasions. The zero σ_{io}^2 indicates that the rank ordering of item difficulty was the same across occasions. Finally, the large $\sigma_{pio,e}^2$ (39%) reflects the varying relative standing of people across occasions and items and/or other sources of error not systematically incorporated into the G study.

Table I also presents the estimated variance components, error variances, and generalizability coefficients for several decision studies varying in the number of items and occasions. Because more of the variability in achievement scores came from items than from occasions, changing the number of items has a larger effect on the estimated variance components and coefficients than does changing the number of occasions. The optimal number of items and occasions is not clear; for a fixed number of observations per student, different combinations of numbers of items and occasions give rise to similar levels of estimated generalizability. Choosing the optimal number of conditions of each facet in the D study involves logistical and cost considerations as well as issues of generalizability (reliability). Because administering more items on fewer occasions is usually less expensive than administering fewer items on more occasions, a decision maker will probably choose a 12-item test administered twice over an eight-item test administered three times. No feasible test length will produce a comparable level of generalizability for a single administration, however—even administering 50 items on one occasion yields an estimated generalizability coefficient of less than 0.80.

The optimal D study design need not be fully crossed. In this example, administering different items on each occasion (*i:o*) yields slightly higher estimated generalizability than does the fully crossed design; for example, for 12 items and two occasions, $\rho^2 = 0.82$ and $\phi = 0.80$. The larger values of ρ^2 and ϕ for the partially nested design than for the fully crossed design are solely attributable to the difference between Eqs. (11) and (12).

Multivariate Generalizability

For behavioral measurements involving multiple scores describing individuals' aptitudes or skills, multivariate generalizability can be used to (1) estimate the reliability of difference scores, observable correlations, or universe-score and error correlations for various D study designs and sample sizes; (2) estimate the reliability of a profile of scores using multiple regression of universe scores

on the observed scores in the profile; or (3) produce a composite of scores with maximum generalizability. For all these purposes, multivariate G theory decomposes both variances and covariances into components. In a two-facet, crossed $p \times i \times o$ design with two dependent variables, the observed scores for the two variables for person p observed under conditions i and o can be denoted as ${}_1X_{pio}$ and ${}_2X_{pio}$, respectively. The variances of observed scores, $\sigma^2({}_1X_{pio})$ and $\sigma^2({}_2X_{pio})$, are decomposed as in Eq. (2).

The covariance, $\sigma({}_1X_{pio}, {}_2X_{pio})$, is decomposed in analogous fashion:

$$\begin{aligned}\sigma({}_1X_{pio}, {}_2X_{pio}) = & \sigma({}_1p, {}_2p) + \sigma({}_1i, {}_2i) + \sigma({}_1o, {}_2o) \\ & + \sigma({}_1pi, {}_2pi) + \sigma({}_1po, {}_2po) \\ & + \sigma({}_1io, {}_2io) + \sigma({}_1pio,e, {}_2pio,e)\end{aligned}\quad (16)$$

In Eq. (16) the term $\sigma({}_1p, {}_2p)$ is the covariance between universe scores on variables 1 and 2, say, ratings on two aspects of writing: organization and coherence. The remaining terms in Eq. (16) are error covariance components. The term $\sigma({}_1i, {}_2i)$, for example, is the covariance between scores on the two variables due to the conditions of observation for facet i .

An important aspect of the development of multivariate G theory is the distinction between linked and unlinked conditions. The expected values of error covariance components are zero when conditions for observing different variables are unlinked, that is, selected independently (e.g., the items used to obtain scores on one variable in a profile, writing organization, are selected independently of the items used to obtain scores on another variable, writing coherence). The expected values of error covariance components are nonzero when conditions are linked or jointly sampled (e.g., scores on two variables in a profile, organization and coherence, come from the same items).

In 1976, Joe and Woodward presented a G coefficient for a multivariate composite that maximizes the ratio of universe-score variation to the universe score plus error variation. Alternatives to using canonical weights that maximize the reliability of a composite are to determine variable weights on the basis of expert judgment or to use weights derived from a confirmatory factor analysis.

Issues in the Estimation of Variance Components

Given the emphasis on estimated variance components in G theory, any fallibility of their estimates is a concern. One issue is the sampling variability of estimated variance components; a second is how to estimate variance components, especially in unbalanced designs.

Sampling Variability of Variance Component Estimates

Assuming that mean squares are independent and score effects have a multivariate normal distribution, the sampling variance of an estimated variance component (σ^2) is:

$$\sigma^2(\sigma^2) = \frac{2}{c^2} \sum_q \frac{E(MS_q)^2}{df_q} \quad (17)$$

where c is the constant associated with the estimated variance component; $E(MS_q)$ is the expected value of the mean square, MS_q ; and df_q is the degrees of freedom associated with the MS_q . In the $p \times i \times o$ design, for example, σ_p^2 is estimated by $(MS_p - MS_{pi} - MS_{po} + MS_{pio,e})/(n_i * n_o)$. Using Eq. (17) to estimate the variance of σ_p^2 , c refers to $n_i * n_o$, and MS_q refers to MS_p , MS_{pi} , MS_{po} , and $MS_{pio,e}$. The more mean squares that are involved in estimating variance components, the larger the estimated variances are likely to be (e.g., compare standard errors $\sigma(\sigma_p^2) = 0.01360$ and $\sigma(\sigma_{pio,e}^2) = 0.00632$ for the results in Table I). Furthermore, the variances of estimated variance components will be larger with smaller numbers of observations per person (reflected in smaller df_q). Although exact confidence intervals for variance components are generally unavailable (due to the inability to derive exact distributions for variance component estimates), approximate confidence intervals are available, as are resampling techniques such as bootstrapping.

Estimates of Variance Components

Although analysis-of-variance methods for estimating variance components is straightforward when applied to balanced data and has the advantages of requiring few distributional assumptions and producing unbiased estimators, problems arise with unbalanced data. They include many different decompositions of the total sums of squares without an obvious basis for choosing among them (which leads to a variety of ways in which mean squares can be adjusted for other effects in the model), biased estimation in mixed models (not a problem in G theory because G theory averages over fixed facets in a mixed model and estimates only variances of random effects, or mixed models can be handled via multivariate G theory), and algebraically and computationally complex rules for deriving expected values of mean squares.

In 1987, Searle reviewed several alternative methods of estimating variance components that do not have the drawbacks of analysis-of-variance methods. Maximum likelihood (ML) and restricted maximum likelihood (REML) methods of estimation produce estimators that are normally distributed and have known sampling

variances at least under large-sample conditions. Minimum norm quadratic unbiased estimation (MINQUE) and minimum variance quadratic unbiased estimation (MIVQUE), unlike ML and REML, do not assume normality and do not involve iterative estimation, thus reducing computational complexity. However, MINQUE and MIVQUE can produce different estimators from the same data set, and estimates may be negative and are usually biased. In 2001, Brennan described two resampling techniques, bootstrap and jackknife, that can be used to estimate variance components and standard errors. Drawing on Wiley's 2001 dissertation, bootstrap now appears to be potentially applicable to estimating variance components and their standard errors and confidence intervals when the assumption of normality is suspect.

Another concern with variance component estimation is when a negative estimate arises because of sampling errors or because of model misspecification. Possible solutions when negative estimates are small in relative magnitude are to (1) substitute zero for the negative estimate and carry through the zero in other expected mean square equations from the analysis of variance, which produces biased estimates; (2) set negative estimates to zero but use the negative estimates in expected mean square equations for other components; (3) use a Bayesian approach that sets a lower bound of zero on the estimated variance component; and (4) use ML or REML methods, which preclude negative estimates.

University of California, Santa Barbara, California, USA

Glossary

datum Basis for measurement of position on the Earth's surface.

discrete object view Conceptualization of geographic phenomena as analogous to a tabletop littered with countable, possibly movable objects.

ecological fallacy The fallacy of making inferences about individuals from aggregated data.

field view Conceptualization of geographic phenomena as a set of functions over geographic space.

geocoding Conversion of addresses, place names, or other geographic references to coordinates, such as latitude and longitude.

modifiable areal unit problem The dependence of analysis of aggregate data on the precise reporting zones used for aggregation.

polyline Representation of a line as a sequence of points connected by straight segments.

spatial analysis A method of analysis whose results depend on the locations of the objects being analyzed.

street centerline data set Representation of a street network as a collection of lines approximately centered along each street.

A geographic information system is designed to capture, store, display, communicate, transform, analyze, and archive georeferenced information, that is, information tied to specific locations on the Earth's surface. Geographic information systems enhance and to some extent replace the traditional role played by maps, but are also capable of handling information in the form of satellite images of the Earth's surface, as well as information from surveys and administrative records that have been georeferenced. They are increasingly used in the social sciences to support research based on cross-sectional data or studies for which geographic location and context are important and useful.

Introduction

The origins of geographic information systems (GISs) can be traced to the mid-1960s. Early computers were designed primarily for numerical processing, following the lead of Babbage and others. But by 1965, other applications had begun to appear, supported in part by the development of specialized peripherals, notably pen plotters and map digitizers. About this time, the Canada Land Inventory faced a massive problem of map data processing: how to take the very large number of maps created to document Canada's underutilized land resource and to produce tables of the amounts of land available for various types of development and use. Measurement of area from maps had always been time-consuming, tedious, and inaccurate when performed by hand. But if the maps could be converted to digital form, simple algorithms would allow areas to be measured and tabulated electronically. The Canada Geographic Information System (CGIS) was thus a response to a well-defined need.

By the 1980s, commercial GISs had begun to appear, offering a wide range of functions that in various ways were too complex, tedious, inaccurate, or expensive for humans to perform by hand. These included simple measurement of area and length, transformations needed to alter data formats, simple statistical analyses such as the calculation of means and standard deviations, and a host of more complex and sophisticated methods generally termed spatial analysis. In addition, GISs were provided with advanced capabilities for data display, including mapping and various forms of data visualization (see Fig. 1). The scientific community was quick to recognize the potential of GIS, and through the 1980s and 1990s GIS emerged as an indispensable tool for research in any discipline dealing with the surface of the Earth or the near-surface. In the social sciences, some of the first applications were in archaeology, but political scientists, criminologists,

Figure 1 A GIS-generated map showing the locations of polluting industrial plants (black dots, from the Environmental Protection Agency's Toxic Release Inventory) and average income by census tract (white denotes lowest average income) for Los Angeles County. The map shows a clear association between pollution and low income. Reprinted from Burke (1993), with permission.

demographers, and epidemiologists were also prominent early adopters. For extensive bibliographies covering applications of GIS and spatial analysis in the social sciences, as well as information on sources of tools, data, and other resources, see the Web site of the Center for Spatially Integrated Social Science (<http://www.csiss.org>).

GIS has undergone significant transformation, as applications have emerged that go well beyond the early notion of a digital assistant performing tasks that humans find difficult. The advent of the Internet and the World Wide Web had by 1995 induced a sharp change of perspective, in which GIS was viewed as a means for sharing information between people, in addition to its more traditional role. Many Web sites were created, offering to supply visitors with geographic data sets, or to create maps on demand, or to perform simple GIS services to user specifications, using data provided by the user or by the site. Maps are compelling ways of presenting information and spatial analysis has been reinterpreted as a set of

methods by which one person adds value to information, by making visible what might otherwise be invisible to another person, thus strengthening the message.

Advances in technology have brought the promise of GIS that is no longer confined to the office, but carried into the field in the form of portable and wearable devices. Wireless communication is available to download and upload data to and from Internet sites and sufficient power is available in portable devices to support virtually any GIS operation. The advent of field GIS offers to revolutionize the nature and practice of field work, in social surveys and other field-based social science.

Representation

At the heart of a GIS is a system of representation, by which features in the real world are coded in the binary alphabet of the digital computer. GIS representations

typically include three aspects of real-world features: their locations on the Earth's surface, using a convenient coordinate system such as latitude and longitude; their attributes, or the things that are known about them; and any relationships of importance between them. Examples of relationships include adjacency, such as the adjacency that might exist between two neighborhoods, and connectivity, such as the connections that might exist between parts of a street network.

Attributes provide much of the richness of a GIS representation, especially in the social sciences. Reporting zones such as census tracts might carry large numbers of descriptive attributes, created from the summary tables provided by the census, such as average income or percentage unemployed. Points representing the locations of individuals in a sample survey might carry as attributes the information collected in the survey from each individual.

Underlying the representation of geographic variation are two distinct conceptualizations. In the first, the features on the Earth's surface are discrete objects, much as a tabletop might be littered by books, pens, or coffee mugs. Discrete objects can overlap and empty space can exist between them. This discrete object view is particularly appropriate in the representation of moving or persistent objects, such as individual people or vehicles. Objects can be represented as points, lines, or areas depending on their size in relation to the geographic extent of the representation. Areas are represented as sequences of points connected by straight lines (polygons) and lines are similarly represented (polylines).

The second is the field view. In this conceptualization, geographic variation is characterized by the continuous variation of a number of variables, each a function of position. Elevation is of this nature, since it can be determined at every point on the surface of the planet, and so is population density. Note that a field of population density is a generalization of a discrete object view, in which each person is a point, surrounded by empty space. This process of generalization is termed density estimation and is an important function of a GIS.

Somewhat confusingly, representations of fields must also be built from points, polylines, and polygons, using one of six recognized methods (see Fig. 2). A field can be represented by values at sample points, distributed either irregularly, or regularly on a grid. It may be represented by a set of nonoverlapping polygons that collectively exhaust the space, each having the mean value or the integral of the field over the area as an attribute (e.g., mean population density or total population). Polyines can also be used, if the isolines (contours) of the field variable are digitized. Finally, a field can be represented as a mesh of nonoverlapping triangles, with values of the field associated with each triangle vertex, and linear variation within each triangle, in the model known as the triangulated irregular network.

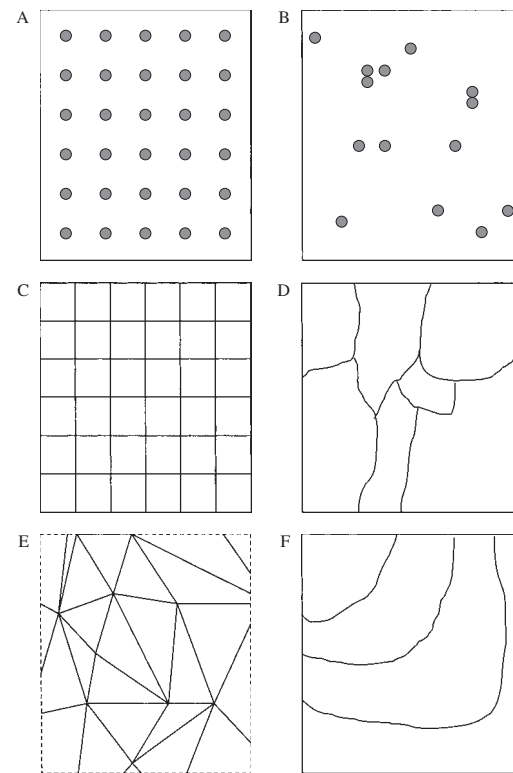

Figure 2 The six alternative representations of a field used in GIS. (A) Regularly spaced sample points. (B) Irregularly spaced sample points. (C) Rectangular cells. (D) Irregularly shaped polygons. (E) Irregular network of triangles, with linear variation over each triangle (the triangulated irregular network or TIN model; the bounding box is shown dashed in this case because the unshown portions of complete triangles extend outside it). (F) Polyines representing contours.

Social scientists are likely to use both discrete object and field conceptualizations. Individual crimes, archaeological artifacts, or deaths from a disease are viewed as discrete objects. But aggregate variables, such as those available in census summary statistics, are more likely to be viewed in terms of fields that have been averaged within reporting zones, which must behave according to the rules of a polygon-based field representation: polygons may not overlap and must collectively exhaust the space. Other phenomena likely to be conceptualized as fields include crowding, ambient noise, or topographic slope.

Georeferencing

Measuring Location

A system for accurately identifying location on the surface of the Earth is an essential component of any GIS representation. The Meridian Conference of 1884 established latitude and longitude as the universal standard for georeferencing, based on measurements from the Greenwich

Meridian and the Equator. Unfortunately, the Earth is not a perfect sphere and has been approximated by a variety of mathematical functions over time and in different parts of the world, each of which potentially leads to a slightly different latitude and longitude. The system or datum of choice in North America is the North American Datums of 1983 (NAD83), but other data may be encountered, such as the earlier NAD27, and the data used in other countries. All of this means that it is impossible to determine location exactly and variations of as much as 200 m on the ground may exist between determinations of latitude and longitude using different data. Modern GIS software makes it possible to convert easily from one datum to another, but nevertheless social scientists will occasionally encounter datum differences.

In addition to latitude and longitude, georeferencing often makes use of methods for projecting the Earth's curved surface onto a plane and associated planar coordinate systems. These include the universal transverse mercator (UTM) system, the NATO standard widely used by national mapping agencies. UTM consists of 60 distinct map projections and coordinate systems, each designed to provide accuracy within a 6° zone of longitude (for example, Zone 11 runs from 120° West to 114° West). U.S. users of GIS may also encounter the State Plane Coordinate systems, adopted by each state for high-accuracy survey; U.K. users may be familiar with the National Grid and many other countries also have national grids.

The use of map projections and the practice of flattening the Earth were essential in the era of paper maps, but are somewhat paradoxical in a technology based on digital representation, since nothing in a digital computer requires flattening. But paper maps are still a very important product of GIS, as well as an important source of input. Moreover, most social science research is conducted over small areas, where the distortions introduced by flattening the Earth are small and where the benefits of being able to work in a simple rectangular coordinate system are compelling. Distance and area are comparatively difficult to compute from latitude and longitude and much easier from planar coordinates expressed in meters.

Street Addresses and Place Names

Although latitude and longitude and planar coordinate systems are convenient, they are essentially inaccessible to the average person, who is more likely to remember and report location in more familiar ways, such as through the use of place names or street addresses. GIS techniques have been developed for easy recognition and conversion, in effect providing an interface between the vague world of human discourse and the precise world of georeferencing. These processes are known by a variety of terms, including geocoding and address matching.

Consider, for example, a survey conducted with a sample of households, in which each household is identified by street address. In order to map the results of the survey, it is necessary to identify the coordinates corresponding to each address. This can be accomplished by making use of one of a number of available street centerline data sets, which represent streets as polylines and include the ranges of addresses on each side of each street segment (the stretch of a street between two adjacent intersections). The first street centerline data sets for the United States were developed in conjunction with the census and distributed free to interested users. The TIGER (Topologically Integrated Geographic Encoding and Referencing) data set, which was first developed for the 1980 census, stimulated a substantial industry concerned with adding value and exploiting the applications of TIGER.

Unfortunately, geocoding is not as simple as it sounds. Specific addresses must be interpolated between the addresses of the end-points of each segment (e.g., 951 would be placed just over halfway between 901 and 999 in the 900 block), which is a dubious assumption in rural areas, where street addresses may not even exist, and in condominium complexes and townhouse developments. In Japan, houses are often numbered by date of construction rather than order along a street. Spelling variations, the lack of a standard syntax, and other problems typically result in success rates of less than 80% for automated geocoding and require expensive human intervention, even in urban areas of the United States.

Place names also provide the basis for a second method of geocoding, although at much coarser scale. An index providing the basis for translation between place names and coordinates is known as a gazetteer and there has been much interest in these data sets, in conjunction with information retrieval. Suppose, for example, that one wants to conduct a study of a particular city and to collect and assess any data that may be available. Many large archives of GIS data, such as the Geography Network (www.geographynetwork.com), developed and maintained by Environmental Systems Research Institute (a major vendor of GIS software), or the Alexandria Digital Library (www.alexandria.ucsb.edu), an online map and imagery library developed by the University of California, Santa Barbara, allow users to search for data within the archive by starting with a place name and using the services of a gazetteer to translate it into a latitude and longitude reference. This reference is then used, along with other user-supplied criteria, to search the archive for suitable data, which can then be retrieved, examined, and downloaded. Other services based on gazetteers have also emerged; geoparsing, for example, allows large masses of text to be searched for place names, which are then used to establish geographic context.

Visualization

GIS is an inherently visual technology, inviting its users to take advantage of the power and effectiveness of data when rendered visually. Maps are the traditional way of visualizing geographic information and GIS owes much to the legacy of cartography, the science and art of mapmaking, and to successful efforts by cartographers to systematize the discipline. Summary or aggregate data associated with polygons are often displayed in the form of choropleth maps, using shading and other forms of polygon fill to distinguish values of the variable of interest. Point data are typically displayed as symbols, again with color or symbol size used to distinguish attribute values. Commercial GIS software supports a vast array of possible mapping techniques, including contour or isopleth maps of fields, and cosmetic features such as legends, north arrows, annotation, and scale bars.

It is important, however, to recognize the fundamental differences between GIS displays and paper maps and the advantages that the digital technology provides over traditional methods. First, GIS has changed mapmaking from an expensive and slow process carried out by a few highly trained cartographers to a fast and cheap process available to all. Anyone armed with a computer, data, and simple software can produce compelling maps (and also misleading maps).

Second, GIS displays are inherently dynamic and interactive, whereas paper maps are essentially immutable once created. GIS displays can portray changes through time or allow users to zoom and pan to expose new areas or greater detail. More than one display can be created simultaneously on a single screen. Maps can also be displayed beside other forms of presentation, such as tables, and tables and maps can be linked in interesting ways (e.g., clicking on a polygon in a map display can highlight the corresponding row in a table). The term “exploratory spatial data analysis” has been coined to describe the interactive exploration of GIS data through maps and other forms of presentation.

Spatial Analysis

Although the display of geographic information in the form of maps can be powerful, the true power of GIS lies in its ability to analyze, either inductively in searching for patterns and anomalies or deductively in attempts to confirm or deny hypotheses based on theory. The techniques of analysis available in GIS are collectively described as spatial analysis, reflecting the importance of location. More precisely, spatial analysis can be defined as a set of techniques whose results depend on the locations of the objects of analysis. This test of locational dependence

clearly distinguishes techniques of spatial analysis from more familiar statistical techniques, such as regression, that are invariant under relocation of the objects of analysis. Thus, GIS can be understood as a technology facilitating methods of spatial analysis, just as the familiar statistical packages facilitate methods of statistical analysis or word processors facilitate the process of writing.

Since about the 1950s, a vast array of methods of spatial analysis have been devised for the detection of patterns and anomalies and the testing of hypotheses. Many texts, such as that by Bailey and Gatrell, organize spatial analysis according to the types of data for which they are designed: techniques for the analysis of point patterns, or polygon data, for example. In 2001, Longley *et al.* used a somewhat different approach based on the objectives of analysis and that approach is followed here in a brief review. Interested readers are referred to the more detailed discussion in that source.

Query

Interactive displays allow users to determine answers to simple queries, such as “What are the attributes of this object?” or “Where are the objects with this attribute value?” Some queries are best answered by interacting with a map view, by pointing to objects of interest. Other queries are better answered by interacting with a table view, by searching the table for objects whose attributes satisfy particular requirements. A histogram view is useful for finding objects whose attribute values lie within ranges of interest and a scatterplot view allows objects to be selected based on comparisons of pairs of attributes. Finally, a catalog view allows the user to explore the contents of the many data sets that might constitute a complete GIS project.

Measurement

Earlier discussion of the origins of GIS emphasized the importance of area measurement in the development of CGIS. Many other simple measurements are supported by GIS, including distance, length, terrain slope and aspect, and polygon shape. Measurements are typically returned as additional attributes of objects and can then be summarized or used as input to more complex forms of analysis.

Transformation

Many techniques of spatial analysis exist for the purpose of transforming objects, creating new objects with new attributes or relationships. The buffer operation creates new polygons containing areas lying within a specified distance of existing objects and is used in the analysis of spatial proximity. The point in polygon operation

determines which of a set of polygons contains each of a set of points and is used to summarize point data by area, in the analysis of crime or disease (e.g., Fig. 1). Polygon overlay determines the areas of overlap between polygons and is often used by social scientists to estimate summary statistics for new areas that do not coincide with reporting zones (e.g., to estimate populations of communities whose boundaries do not respect census zone boundaries). Density estimation also falls into this category, since it transforms point data sets into representations of continuous fields.

Summary Statistics

Search for pattern is often conducted by computing statistics that summarize various interesting properties of GIS data sets. The center of a point data set is a useful two-dimensional equivalent to the mean and dispersion is a useful equivalent to the standard deviation. Measures of spatial dependence are used to determine the degree of order in the spatial arrangement of high and low values of an attribute. For example, rates of unemployment by census tract might be highly clustered, with adjacent tracts tending to have similarly high or similarly low values, or they might be arranged essentially independently, or adjacent tracts might be found to have values that are more different than expected in a random arrangement.

Optimization

A large number of methods have been devised to search for solutions that optimize specific objectives. These include methods for finding point locations for services such as libraries or retail stores, for finding optimum routes through street networks that minimize time or cost, for locating power lines or highways across terrain, or for planning optimal arrangements of land use. These methods are often embedded in spatial-decision support systems and underpinned by GIS software.

Hypothesis Testing

The sixth class consists of methods that apply the concepts of statistical inference, in reasoning from a sample to the characteristics of some larger population. Inference is well established in science and it is common to subject numerical results to significance tests, in order to determine whether differences or effects could have arisen by chance because of limited sample size or are truly indicative of effects in the population as a whole.

It is tempting to adopt statistical inference in dealing with geographic information, but several problems stand in the way. First, geographic data sets are often formed from *all* of the information available in an area of interest and it is therefore difficult to believe that the data are

representative of some larger universe and that results can be generalized. Instead, one tends to believe in spatial heterogeneity or the variation of conditions from place to place; in this context, it is difficult to regard a study area as representative of any larger area. Second, geographic data sets typically exhibit spatial dependence, which means that one object's attributes are unlikely to be truly independent of the attributes of its neighboring objects. The endemic presence of spatial dependence in geographic data has been called the First Law of Geography and is often attributed to Waldo Tobler.

There are several possible solutions to this dilemma. First, objects might be chosen sufficiently far apart, allowing the assumption of independence to be acceptable, but this results in discarding data. Second, one might limit analysis to a description of the data and area of study and avoid any suggestion of inference about larger areas or other data sets, but this flies in the face of scientific tradition and the norms of peer review. Third, one might assume that the universe consists of all possible spatial arrangements of the data, in a form of randomization, particularly if the actual spatial arrangement of the data is the issue of interest. But this approach, though attractive, does not support inference in areas not covered by the data.

Issues

As will be obvious from the previous section, the use of GIS raises numerous issues concerning the nature of geographic information and inference from cross-sectional data. It is generally accepted that cross-sectional data cannot be used to confirm hypotheses about process, but they can certainly be used to reject certain false hypotheses and to explore data in the interests of hypothesis generation. Although GIS has evolved from the static view inherent in paper maps, there is much interest in adding dynamics and in developing methods of spatiotemporal analysis.

Uncertainty is a pervasive issue in GIS. It is impossible to measure location on the Earth's surface exactly and other forms of uncertainty are common also. For example, summary statistics for reporting zones are means or totals and clearly cannot be assumed to apply uniformly within zones, despite efforts to ensure that census tracts are approximately homogenous in socioeconomic characteristics. Results of analysis of aggregated data are dependent on the boundaries used to aggregate (the modifiable areal unit problem) and inferences from aggregated data regarding individuals are subject to the ecological fallacy.

Nevertheless, the outcomes of the widespread adoption of GIS in the social sciences since the 1980s are impressive. It is clear that GIS has brought new power to the analysis of cross-sectional data and the integration

of diverse data sets. It has also shifted the ground of social science to some degree, by increasing the emphasis on local data, geographic variation, and highly disaggregated analysis, in contrast to the pervasive nomethetic approach of earlier decades.

Geography

James O. Wheeler

University of Georgia, Athens, Georgia, USA

We cannot talk any better than our ancestors...cannot figure any better than the best mathematicians of old, but we have not only thousands of tricks that have been gathered through the years, but machinery which enables a rather simple-minded person to get calculations done accurately and quickly.

Benjamin C. Gruenberg,
Biology and Human Life, 1925

Glossary

gravity model A model that compares the volume of flow, or spatial interaction, between two or more places based on the mass (population) of these places and the distance between the places.

index of dissimilarity A measure that compares the proportions of different occupational types within the study area.

index of segregation A measure that provides a single statistic summarizing the spatial distribution between a subcategory and the category as a whole.

information gain statistic A statistic indicating the overall spatial relationship. It is also used as a goodness-of-fit statistic comparing two spatial distributions, P_i and Q_i ; the smaller the fit between the two distributions, the lower the value of I .

location quotient A ratio of ratios used to measure and map relative distributions or relative concentrations of a subarea to the area as a whole.

principal components analysis A data transformation technique that measures the degree to which n variables in a data set are intercorrelated. The technique uses unities in the $m \times n$ correlation matrix, where m refers to places or areas, and transforms the n variable into a smaller number of independent components, with each component accounting for a decreasing proportion of the total variance.

social area analysis The application of factor analysis to socioeconomic and demographic data for a number of

places (often census tracts) to identify the major dimensions (characteristics) of residential areas of a city.

Human geography is a social science that focuses on the location, spatial distribution, and spatial interaction of human beings and their social, economic, cultural, and political activities. The interest is in places and geographic spaces. The term spatial interaction entails the volume or intensity of linkages between and among two or more places, such as the number of work trips originating in a particular neighborhood and terminating in various office complexes or industrial districts within a metropolitan area. This essay provides a general overview of the quantitative methods used in contemporary geography. Particular attention is given to locational or spatial statistics, the gravity model, and factor and principal components analysis.

Introduction and Background

Although some examples of the use of quantitative methods—primarily statistics—appeared in geographic research prior to the mid- to late 1950s, the full introduction of quantitative modeling and statistical analysis did not occur until the early 1960s, building strength throughout that decade. The quantitative approach to human geography has continued powerfully into twenty-first century, although many other competitive nonquantitative advances have also been made, beginning in the early 1970s. Currently, quantitative statistical approaches represent only one of several different competing ways of conducting research in human geography. Some of these competing research styles, such as postmodernism, are frankly antagonistic to numerical analysis.

Whereas social sciences such as psychology and economics embraced quantitative statistical analysis long

before geography adopted these methods, other fields such as anthropology, and especially history, were much slower to accept the value of enumerative procedures in research. Human geography's acknowledgment of the advantages of statistical analysis and mathematical modeling fell somewhere near the middle of the acceptance trajectory within the social sciences and was a major factor in placing human geography squarely within the social sciences.

The Origin and Expansion of Quantitative Methodology in American Geography

In the mid- to late 1950s, a number of exceptionally bright and highly motivated graduate students joined the Department of Geography at the University of Washington in Seattle, then and now one of the leading geography programs in the United States and Canada. Many of these students chose to study at University of Washington in order to work with Professor Edward L. Ullman, one of the most prominent geographers in North America, who in 1951 had moved from Harvard University to the University of Washington. As Doug Eyre wrote in 1978:

by a stroke of fortune, there was assembled not only a fine group of able young faculty but also a group of outstanding graduate students, a truly vintage assemblage whose members were to play a leading role in the profession. Chief among these was Brian Berry, who with young Dr. William Garrison pioneered the path that led to the "quantitative revolution" in geography across the country after the mid-1950s. It was a period of unusual intellectual ferment that moved the Seattle department to a position of national leadership. The ferment was not always positive or reasoned—there were unavoidable, sometimes acrimonious, clashes in the department between the traditionalist and the Young Turks who were intent upon sweeping reforms. Ed was an early supporter of the latter's emphasis upon theory-building and quantitation, but he became gradually disenchanted with their extreme positions and dogmatic excesses. In turn, they reciprocated by ignoring or undervaluing his scholarly output.

Those who were attracted to Seattle by Ullman—including Brian Berry, with his undergraduate degree from University College, University of London—instead chose William Garrison as their mentor. Garrison had just returned from a year's leave of absence in the newly formed Regional Science program at the University of Pennsylvania, headed by Walter Isard, where Garrison had immersed himself in statistics, mathematical modeling, and theory development and hypotheses testing procedures. Many graduate students were attracted to Garrison and his new geography, emphasizing the use of statistical

methods, theory development, and hypothesis testing. These students included, in addition to Berry, William Bunge, Michael Dacey, Art Getis, David Huff, Duane Marble, Richard Morrill, John Nystuen, and Waldo Tobler. As Berry wrote in 1993, "Within five years of beginning of their graduate studies, the initial cohort had positions in leading centers of geographic education."

In a 1967 study, LaValle, McConnell, and Brown mapped the spread of quantitative methods courses offered in Ph.D.-granting programs. The first to offer such a course was Bill Garrison at the University of Washington, then Edwin N. Thomas at the University of Iowa (under the leadership of Harold H. McCarty), Brian J. L. Berry at the University of Chicago, Edward J. Taaffe at Northwestern University, and James Barnes at the University of Georgia—a total of only five departments as of 1958 (Fig. 1A). By 1965, 24 of the 32 Ph.D.-granting geography departments in the United States offered a quantitative geography course (Fig. 1B). The then-new approach, sometimes dubbed the quantitative revolution, was quickly and widely adopted in geography. Programs in the Midwest and, somewhat later, on the East Coast were especially responsive, swiftly and vigorously embracing the quantitative approach to geographic research.

Locational Indices in Geography

Because human geography is primarily interested in the location of people and their activities, it follows that certain basic descriptive quantitative measures are commonly used in data analysis. Those indices discussed here are the location quotient, the index of dissimilarity, the index of segregation, and the information gain statistic.

Location Quotient

The location quotient, a ratio of ratios, is a widely used geographic index. It is used to measure and map relative distributions or relative concentrations of a subarea to the area as a whole. An example of its use might be to measure the residential distribution of scientists within a metropolitan area compared to total workers. The formula is:

$$LQ = \frac{X_i / \sum X_i}{N_i / \sum N_i} \cdot 100$$

where LQ is the location quotient, X_i is the value of a variable (scientists) in area i , $\sum X_i$ is the value of the variable (scientists) in all the subareas combined (metropolitan area), N_i is the total of workers in each subarea of the metropolitan area, and $\sum N_i$ is the total number of workers in the metropolitan area (Tables I and II). Thus, the location quotient varies in our example with the proportion of scientists in a given subarea to the total number of

Figure 1 Ph.D.-granting geography departments offering quantitative methods courses, (A) 1958 and (B) 1965. After LaValle, McConnell, and Brown (1967) with permission.

Table I Sample Data for Computing Locational Quotient

Subarea	Scientists, X_i	Total workers, N_i
1	5	100
2	10	50
3	20	50
4	20	200
5	50	600
Total	100	1000

Table II Computing the Locational Quotient

Subarea	$X_i / \sum X_i$	$N_i / \sum N_i$	LQ
1	0.05	0.10	50
2	0.10	0.05	200
3	0.20	0.05	400
4	0.20	0.20	100
5	0.50	0.60	83

Table III Location Quotient for Help-Supply Service Workers in the U.S. South by Metropolitan-Area Population Size Categories, 1999

<i>Metropolitan hierarchy</i>	<i>Location quotient</i>
2.5 million and above	1.14
1 million to 2,499,999	1.22
250,000 to 999,999	1.04
100,000 to 249,999	0.73
Less than 100,000	0.58

Source: Hongmian Gong (2002, 54).

workers in that subarea. A value of 100 indicates that there is the same proportion of scientists as total workers. In areas 1 and 5 in Table II, the values less than 100 shows that there are fewer scientists than “expected” compared to the total number of workers. In contrast, values greater than 100 indicate that there is a higher proportion of scientists than “expected” living in the subareas 2 and 3 compared to the total number of workers.

The 2002 study by Gong provides an illustration. Her interest is in measuring the relative metropolitan concentration of employees in help-supply services in the U.S. South. Help-supply services provide temporary workers to other businesses on a fee basis. Here the focus is on how the number of help-supply service employees vary among metropolitan areas of different sizes compared to the total number of workers. Table III shows a clear hierarchical distribution; the larger the metropolitan area, the higher the location quotient (except for metropolitan areas with more than 2.5 million in population). Gong’s results indicate that larger metropolitan areas tend to have a greater need for temporary workers compared to total workers.

Index of Dissimilarity

The index of dissimilarity compares the proportional distribution of two subcategories, in contrast to the location quotient, which compares the relative distribution of a subcategory within a larger category. If, for example, we wish to compare the number of help-supply service workers with the number of manufacturing workers, the index of dissimilarity is the appropriate measure.

$$ID = \sum_{i=1}^N \frac{|(X_i / \sum X_i) - (Y_i / \sum Y_i)|}{2} \cdot 100$$

where ID is the index of dissimilarity, X_i is the value of one subcategory (help-supply service workers) and Y_i is the value of another subcategory (manufacturing workers), and i represents observations or areas such as census tracts or counties. For every area i , the absolute value of the difference of the two subcategory

Table IV Residential Dissimilarity between Chinese Americans and Selected Racial and Ethnic Groups in Four Counties in the Atlanta Metropolitan Area, 1990

<i>County</i>	<i>Index of dissimilarity</i>			
	<i>Whites</i>	<i>Blacks</i>	<i>Hispanic</i>	<i>Asian Indians</i>
Cobb	53	62	51	62
DeKalb	38	74	46	46
Fulton	51	89	52	62
Gwinnett	44	44	35	41
Average	47	67	46	53

Source: Zhang (1998, 132).

proportions $|(X_i / \sum x_i - Y_i / \sum y_i)|$ is taken. These absolute differences are summed for all areas i and divided by two to avoid double counting. The index is multiplied by 100 in order to express the index in whole numbers. Its value ranges from 0 to 100, where 0 reflects identical proportional distributions between the two subcategories and 100 indicates a totally opposite spatial distribution.

The 1998 study by Zhang provides a useful example of the application of the index of dissimilarity. His study was of the residential locations of racial and ethnic groups in four counties of the Atlanta metropolitan area (Table IV). His findings show that Chinese Americans in Atlanta had residential patterns that were most similar to Hispanics and Whites, least similar to Blacks, and in an intermediate position with respect to Asian Indians. The index of dissimilarity here is interpreted as the percentage of Chinese Americans that would have to change census tracts within a county in order for their residential locations to be identical with another racial or ethnic group. Thus, 89% of Chinese Americans would have to shift census tracts in Fulton County to achieve an even spatial distribution with Blacks, representing the highest level of dissimilarity in Table IV.

Index of Segregation

The index of segregation is related to the index of dissimilarity. The difference is that the index of segregation provides a single statistic that summarizes the proportional spatial distribution between a subgroup and the group as a whole:

$$IS = \sum_{i=1}^N \frac{|(X_i / \sum X_i) - (N_i / \sum N_i)|}{2} \cdot 100$$

Its value ranges from 0 to 100, with the same interpretation as the index of dissimilarity.

Boelhouwer, in his 2002 study, used the index of segregation to represent the levels of residential segregation in the four largest cities in the Netherlands (Table V).

He found that the percentage of minorities (Turks, Moroccans, southern Europeans, Surinamese, and Antilleans) was approximately 30% in 1995 for Amsterdam, Rotterdam, and The Hague, but only 21% for Utrecht. Boelhouwer confirmed that, despite a significant growth in minority populations in these four largest cities, the index of segregation has stayed more or less the same and, in fact, dropped somewhat in Rotterdam and The Hague.

The Information Gain Statistic

The information gain statistic has been used by geographers in a variety of ways. It is a goodness-of-fit model that has the advantage over correlation-regression analysis in that it does not assume that the data are normally distributed. The information gain statistic allows the comparison of two variables at a time, such as actual population scores versus predicted population numbers for, say, counties in North Georgia. Conceptually, information is gained from a set of N messages that transform a set of N *a priori* probabilities (Q_i) into a set of N *a posteriori* probabilities (P_i). Thus, there is an initial message (Q_i) and a subsequent message (P_i). At issue is whether the subsequent message improves the information beyond the initial message.

The information gain statistic (I_i) is calculated as follows:

$$I_i = P_i \ln \left(\frac{P_i}{Q_i} \right) \quad (1)$$

Table V Index of Segregation of Minorities in the Four Largest Cities in the Netherlands, 1980–1995

City	1980 ^a	1987 ^a	1995 ^a
Amsterdam	30	32	31
Rotterdam	47	43	43
The Hague	56	53	51
Utrecht	37	33	33

Source: Boelhouwer (2002, 568).

^aTurks, Moroccans, southern Europeans, Surinamese, and Antilleans.

Note that the natural logarithm (\ln), not the common logarithm, is used. Thus, if, for example, $Q_i = 0.25$ and $P_i = 0.25$, no additional information is gained and $I_i = 0$. If $P_i > Q_i$, I_i is positive, reflecting a gain in information. If, however, $Q_i > P_i$, I_i is negative, indicating a loss of information. For example:

$$I_i = P_i \ln \left(\frac{P_i}{Q_i} \right) = 0.36 \ln \left(\frac{0.36}{0.20} \right) = 0.2116$$

We can compute not only the *a priori* and *a posteriori* probabilities for each observation (where i = counties, for example), but we can also sum over all observations to obtain a single summary statistic for the entire data set:

$$I_1 = \sum_{i=1}^N P_i \ln \left(\frac{P_i}{Q_i} \right) \quad (2)$$

The poorer the fit between the two sets of probabilities, the larger the value of I_1 , the summary statistic.

Table VI shows a hypothetical computational example of the use of the information gain statistic. The first step is to take the absolute data (corporate assets and population totals) and convert them into probabilities, Q_i and P_i , respectively. Carrying out the operations of Eq. (1) provides the individual city probabilities that allow the determination of I_i . When these city values of I_i are summed, following Eq. (2), we find $I_1 = 0.08$ in this example has a positive value.

The information gain statistic can be used to compare actual population totals with projected population, where the latter is the *a posteriori* probability, or to compare two distributions within a region, for example, manufacturing employment and service employment. It can be used, in fact, to compare any two spatial distributions or more than two distributions. In the latter case, the *a priori* probability acts as a kind of dependent variable, with which a set of *a posteriori* probabilities, acting as independent variables, is compared. Here, the summary statistic (I_1) is of prime interest.

Table VI Hypothetical Computational Example of the Information Gain Statistic

Metropolitan area	Corporate assets	Q_i	Population size	P_i	I_i^a
Houston	103.4	0.3427	2905	0.2306	−0.0914
Dallas	84.7	0.2805	2975	0.2362	−0.0406
Washington	69.4	0.2299	3061	0.2430	0.0135

Total	301.8	1.0	12,597	1.0	

^a $I_1 = 0.08$.

Spatial Interaction Modeling

Geographers not only are interested in describing and interpreting the characteristics of places but are also intent on understanding how places are linked or connected with one another. In fact, to comprehend the nature of a place we need to know the linkage structure of that place with other places. Linkages among places may be measured on a binary scale, link or no link. A binary measure leads to measures of accessibility. More commonly, however, linkages among places are calibrated on an interval scale to measure the volume of interaction among places. Because this interaction takes place over space, the term spatial interaction is normally used by geographers. Spatial interaction models have been used, for example, to understand human migration among cities and regions, commuting within metropolitan areas, customer and expenditure flows from residential areas to stores and shopping destinations, and commodity flows among cities and regions.

The Gravity Model

The gravity model is the most common example of spatial interaction modeling. The gravity model uses two variables to predict or estimate the volume of spatial interaction between or among places, be they cities, counties, or regions. These are (1) population totals of the places and (2) the distance separating these places or the time or cost of overcoming distance. The expectation is that there will be a positive association between flow volume and population size; that is, when two places have large populations we expect the volume of migrants or commuters to be large, but when places are separated by a great distance we expect that the effect of distance, as mediated by distance, cost, or travel time, will reduce the level of interaction. Thus, whereas population size leads to a positive relationship, distance leads to an inverse correlation (the volume of spatial interaction decreases as distance separation increases). The gravity model is written as follows:

$$I_{ij} = k \left(\frac{P_i \cdot P_j}{D_{ij}^b} \right)$$

where I_{ij} is the estimate of the volume of spatial interaction between place of origin i and place of destination j , k is a constant, D_{ij} is the distance between i and j , b is the exponent of distance, and P_i and P_j represent the population sizes of the places of origin and destination. The values of k and b vary depending on the specific data set.

Applications of the Gravity Model

We provide two examples of the application of the gravity model. The first is from a 1999 study by Wheeler and measures the extent to which small metropolitan areas are linked to the regional and national metropolitan economies. The specific case study used the numbers of overnight letters, packages, and boxes sent via FedEx from Athens, Georgia (population in 2000 of approximately 150,000) to 42 large U.S. metropolitan areas. The gravity model took the following form:

$$\log \text{FedEx} = \log k (\log P_j - \log D_{ij})$$

where the model is calibrated in log form, P_j is the population of metropolitan area j , and D_{ij} is the distance between Athens (i) and destination j . P_i need not enter the equation because it is the population of Athens. The model is solved by using ordinary least squares regression.

The results are of interest. First, the R^2 for the equation is 0.65, reflecting a moderately strong relationship between FedEx flow volume and the population size of the 42 metropolitan destinations and the airline distance separating them from Athens, Georgia. The standardized parameter estimates for population and distance were, respectively, 0.83 and 0.37. Thus, the population size of the 48 metropolitan areas to which FedEx letters, packages, and boxes were sent from Athens was a very strong indicator of the volume of packages sent. In contrast, the distance separating Athens from the high-volume destinations was only a weak measure of the FedEx flow magnitude—a -0.37 parameter shows only a modest decline in volume with increasing distance. In fact, the five leading metropolitan destinations for FedEx shipments from Athens were Atlanta, New York, Chicago, Dallas-Fort Worth, and Los Angeles, in that order. From this listing it is obvious that population size was of paramount importance, not distance. For FedEx shipments, which take on something of a perishable nature or may be said to be information-based, how far they are sent is less important than where they are sent.

The second gravity model application, from a 1990 study by Wheeler, examines the links between major corporate headquarters in New York City and the U.S. location of subsidiaries under their control. We know that New York is the preeminent location for major corporate headquarters in the United States. The question is in which metropolitan areas do these New York-based corporations locate their subsidiaries. Again, what is the role of metropolitan population size and of distance separation? In the study, the approximately 550 New York parent companies had nearly 2000 subsidiaries in the United States, 93% of which were in 129 metropolitan areas. The eight leading metropolitan locations of the subsidiaries were Chicago, Los Angeles, Newark, Boston, Houston, Philadelphia, St. Louis, and Hartford.

The model is:

$$\log OL = \log a_1 + a_2 \log(P_j) - a_3 \log(D_{ij})$$

where OL is the number of ownership links, P_j the population of the 129 U.S. metropolitan areas having at least one subsidiary with its headquarters in New York City, D_{ij} is the airline distance from New York to the subsidiary metropolitan area, and a_1 is a constant and a_2 and a_3 are parameter estimates. As before, the model is solved using ordinary least squares. Table VII reports the results of the gravity model application. A modestly strong R^2 is found (0.66). The population size of the metropolitan areas is a strong predictor of where the subsidiaries are located; New York parent firms prefer to locate their subsidiaries in large metropolitan areas. All states except Montana and North Dakota have subsidiaries of the New York parent companies. Distance shows an extremely weak inverse relationship, although the parameter estimate (-0.24) is negative as expected. Thus, distance is negatively associated with subsidiary location, with slightly more subsidiaries near New York City.

Geographic Application of Factor and Principal Components Analysis

In his classic book *Applied Factor Analysis*, R. J. Rummel considered factor analysis to be “A Calculus of Social Science.” Most applications of factor analysis by human geographers have followed the typical social science methodological applications and procedures. The unique contribution by geographers, however, has been that the observation inputs to factor analysis have involved areal units or locational points. As do other social scientists, geographers have typically used factor analysis as a data reduction technique whereby N attributes measured over M areal units (observations) result in a number of factors or components considerably smaller than N . Geographers are not only interested in the composition of the factors but also the geographic pattern of the factor scores. In

Table VII Model of Subsidiary Linkages with New York Parent Firms

Variables	Standardized parameters
Population	0.79
Distance	-0.24
$N = 129$

Source: Wheeler (1990) with permission of the American Geographical Society; Dun and Bradstreet data.

fact, the factor scores for each observation (areal units) can be displayed on maps, providing a rich basis for geographic interpretation. Factor analysis and principal components analysis are both types of factorial analysis. Factor and component scores are often used as independent variables in regression analysis and cluster analysis. Because the scores are independent of one another, they are ideal inputs for these multivariate techniques.

Social Area Analysis

One of the most common examples of the use factor analysis in geography is known as social area analysis (also known as factorial ecology). In these applications to various U.S. cities, a considerable number of variables (sometimes up to 50) are inputted for an even larger number of census tracts, defined by the U.S. Census Bureau. The purpose of this use of factor analysis is to measure and map the social space in the city and to break the large number of variables down into a small number of social factors.

Analyses of several U.S. cities have yielded remarkably similar results. Whether the number of variables used is 20 or 50, three basic factors have emerged in virtually all of these studies. (To be considered a factor, the potential factor must have an eigenvalue greater than unity.) Table VIII lists the generalized variables typically employed to measure social areas in the city and the three factors that commonly result from social area analysis.

The socioeconomic status factor is usually the strongest indicator of the various social areas in the city. Census tracts fall into high, medium, and low on the factor scores, and, as indicated earlier, these can be mapped. The socioeconomic factor, as indicated by factor scores for the census tracts, take on sectoral patterns, radiating away from the center of the city and expanding into the

Table VIII Typical Factors and Variables Used in Social Area Analysis

Factors	Variables
Socioeconomic status	Income
	Occupation
	Education
	Housing value
Family status	Marital status
	Fertility
	Family size
	Age of adults
Ethnic status	Black population
	Hispanic population
	Asian population
	Linguistic groups

suburban areas. Thus, high-income sectors or wedges extend from the inner city into suburban space and medium-income sectors and low-income sectors have their own corresponding social spaces. Although factor analysis provides a quantitative index to the differentiated socioeconomic characteristics of neighborhoods, even a casual observer driving through the various neighborhoods in a city can see and experience the different socioeconomic levels. Such observations are usually based merely on housing indicators, such as the size and age of the house, lot size, and landscaping quality.

The second factor identified in social area analysis is family status, sometimes termed the life-cycle stage or urbanization index. This factor largely measures the demographic characteristics of census tracts. From mapping factor scores, the family status factor displays a pattern of concentric circles.

The third factor measures minority or ethnic status and is sometimes referred to as the segregation index. Here the social areas of the city are clumped into different racial, language, and accent groups and often on the basis of level of poverty and unemployment.

Because these three identified factors are derived by the use of factor analysis, the three factors are independent of one another. It is the composite of these three factors that gives rise to the social structure of the city.

Principal Components Analysis and Origin-Destination Matrixes

Another distinctive geographic application of a data reduction technique is the use of principal components analysis to understand complex origin-destination (O-D) matrixes. Principal components analysis uses unities on the diagonal rather than communalities, where communalities reflect the extent to which a particular variable enters into the factors. In O-D matrixes, the rows represent the origins and the columns are the destinations. The O-D matrix may measure work trips among census tracts or planning areas within a city, migration flows among the 50 U.S. states, or the movement of container freight from one U.S. port to a state or metropolitan destination. The basic questions being asked is how do the origins differ from one another in their spatial pattern of destinations? The same questions may be asked of destinations with respect to origins. Do inner-city areas differ notably from suburban areas? Again, factor scores may be mapped.

Table IX shows a hypothetical set of factor loadings for three factors, based on Varimax rotations of destinations (columns). Each destination is correlated (zero-order correlation coefficients) with one another to show common patterns of origins. The correlation matrix is then

subjected to principal components analysis and then rotated. Factor I accounts for just more than 30% of the variance in the matrix, and the three factors combined show a cumulative sum of more than 67%. The highest loadings for the three factors show that they are largely concentrated among contiguous traffic zones.

Summary Comments

Because simple and multiple linear correlation and regression are commonly used throughout the social sciences, including geography, no attempt has been made here to introduce these techniques. Suffice it to say, that geographers typically use places or areas as the observational units. Geographers, as do other social scientists,

Table X Other Common Statistical Techniques Used by Geographers

select a dependent variable as the primary feature to be understood and correlate it with one or more independent variables, with all variables representing points, places, or areas. [Table X](#) lists other statistical techniques commonly used by geographers. The treatment of these techniques lies beyond the scope of this article.

One final issue is worth noting. Over the past 15–20 years, there has been a decline in the use of quantitative techniques in geography and a gradual rise in the application of qualitative methods. There has also been a notable rise in the narrative approach in journal articles in the field, in which no numerical data are introduced at all. This narrative approach to presenting geography has also led to a reduced reliance on the use of maps by geographers. Moreover, there is a small minority of geographers who embrace postmodernism and are antiscientific and antiquantitative. Geography became a recognized social science primarily during the 1960s, when the discipline began using many of the basic quantitative methods common throughout the social sciences, adapting them to spatial analysis and developing various additional locational techniques. Whereas, in the 1960s, graduate programs in geography required at least one quantitative methods course, today almost no graduate department in geography requires such a course, though quantitative courses continue to be taught. Commonly, however, courses in qualitative techniques and GIS (geographic information science) are offered and eagerly sought out by graduate students.

Geolibraries

Peter Keenan

University College, Dublin, Ireland

Glossary

digital library An integrated and cataloged collection of data stored in electronic format.

gazetteer A list of named places together with a geographic reference for identifying locations.

Geographic Information System (GIS) A computer system for storing, manipulating, and displaying geographically referenced information.

geolibrary A digital library that stores information in a format searchable by geographic location in addition to traditional search methods.

georeferenced information Data indexed by location with a distinct geographic footprint.

metadata Information about data, used to facilitate the building of large data sets of diverse information.

spatial data Information about the location and shape of, and relationships between, geographic features.

The digital indexing of library content has greatly facilitated social research, making the searching and cross-referencing of research material much easier than with paper formats. The digital format allows the easy search of a variety of data types in addition to traditional text content. Geographic (or spatial) data are becoming increasingly available in digital form, which allows searching the data by geographic location. Digital search techniques, applied in geolibraries, may be of considerable value to researchers as an extension of traditional paper libraries or nonspatial digital libraries. Digital geolibraries provide a comprehensive collection of all forms of data related to place, suitably indexed and cataloged to allow easy access by researchers. Use of geolibraries is optimized by understanding their potential advantages and some of the problems that exist in building comprehensive geolibraries.

Introduction to Geolibraries

Digital Data Sources

Social researchers are accustomed to using libraries and other sources of secondary information. These sources have traditionally been indexed in paper format by author, date of publication, title, or keyword. Traditional research approaches exploited paper-based indexes and catalogs to locate material in paper-based libraries. Information technology has enhanced research in two major ways via enhancement of library operations: digital techniques can be used for indexing library content and for storage of that content. In particular, the use of database techniques for library catalogs allows easier searching and cross-referencing of material (though the material need not necessarily be digital in nature). The digital Social Science Citation Index, for example, is much more powerful and convenient to use than its traditional paper-based equivalent. Though the digital indexing of offline resources is useful, additional cross-referencing becomes possible when the source material is stored in digital form, and in recent years large databases of computerized text and numerical data have been compiled. In addition to the advantages resulting from easier searching, the use of digital data representation eliminates or reduces traditional problems of bulky physical storage, restricted accessibility, limited portability, and concurrent use.

These advantages mean that digital libraries have much to offer for traditional library content, and researchers are already accustomed to using digital data in this form. However, conventional text-based material represents only a small part of the total data that may be of interest to researchers. The contribution of other formats, such as spatial, audio, or pictorial material, may be overlooked if they are not properly associated with related text-based content. Consequently, the full potential of

the new digital technologies can be realized only if a greater range of information sources can be searched and if new relationships can be identified in data.

Geolibraries

A geolibrary is a digital library that, in addition to being searchable by traditional methods, stores information in a format searchable by geographic location; such data are thus georeferenced. In principle, a geolibrary need not use online techniques for indexing or storage of content, and paper-based map collections with appropriate catalogs have existed in libraries for many years. However, geographic location-based indexing is very difficult to implement using paper-based approaches, and comprehensive indexes of this form are not common in traditional libraries. Computerized techniques have now made comprehensive spatial indexing feasible and this will lead to spatial referencing becoming increasingly important in the future. Just as database management techniques made possible the development of digital library catalogs for traditional content, the development of the Geographic Information Systems (GIS) facilitated digital indexing of geographically referenced information. These techniques are especially valuable for the indexing of inherently spatial data that might be used for further processing by a GIS, but geographical referencing also has a major contribution to make for other forms of content across a wide range of social science disciplines.

A traditional index might identify resources associated with a particular author or date of publication; potentially this could also include multimedia formats, such as a piece of music by a particular composer. A georeferenced catalog will store material connected with a particular place. For instance, a geolibrary might store pictures of an urban street or sound recordings of traffic noise at that location. Another example is the combination of geographic data with pictorial records to produce three-dimensional representations of urban environments. Though these multimedia formats have great potential, the seamless integration of these diverse data poses difficulties in all digital libraries and the coherent georeferencing of multimedia content poses a distinct challenge in a geolibrary.

The concept of a geolibrary originated in the 1990s, and the Alexandria Digital Library at the University of California in Santa Barbara is generally regarded as the first major prototype geolibrary. The geolibrary model was further defined within the GIS community by the Workshop on Distributed Geolibraries: Spatial Information Resources, convened by the Mapping Science Committee of the U.S. National Research Council in June 1998. The idea of a geolibrary is therefore a relatively new one, and the data-intensive nature of geographic information has meant that geolibraries have inevitably

lagged behind the construction of digital resources for simpler forms of data, such as text or statistics. The concept of a geolibrary is likely to evolve further as potential users become aware of the contribution of geolibraries and as sophisticated real systems become available.

Comprehensive georeferencing of digital library content requires the availability of digital spatial data for the geographic areas concerned. By the end of the 20th century, large amounts of digital spatial data had already been collected in most developed countries, and this may form the basis for the georeferencing of library content. One obstacle to building geolibraries arises because spatial data resources are somewhat fragmented and thus difficult to assemble for applications that require the synthesis of data originating in different organizations. Improved spatial processing techniques and comprehensive geographic databases mean that spatial data relationships are potentially of interest to a much wider audience than those in the traditional geographic disciplines, for whom the data were initially collected. Existing spatial data collections are often designed for the particular needs of specific user communities and it is difficult to integrate these together. Currently, the wider potential user community lacks the training and experience to make full use of the latent potential provided by the spatial association of information. The introduction of properly organized and cataloged geolibraries can make a major contribution to extending the use of spatial information and techniques to a broader community.

In many respects, geolibraries have both the problems and advantages of other types of databases. Data are collected for particular purposes by organizations that have a good understanding of the nature and immediate applications of the specific data. Nevertheless, once data have been collected and organized, their use can be justified for further downstream applications. The increasing availability of conventional digital libraries has already allowed social researchers exploit these resources for research purposes, using data in ways that were not envisaged by the original users and collectors. Such an integrated database of georeferenced data, properly indexed and cataloged in the form of a geolibrary, will also allow researchers investigate new geographic relationships that may have been difficult to research using traditional libraries.

Geolibrary Applications

Geolibrary Software

For any digital data, accessibility is largely determined by the availability of appropriate tools. A geolibrary will comprise both georeferenced data and the tools to access the data. Michael Goodchild, the most prominent researcher in geolibraries, has identified a number of

key components of a geolibrary; these include a geolibrary browser, a basemap, a gazetteer, and search facilities. The geolibrary browser is a specialized software application running on the user's computer and providing access to the geolibrary via a computer network. In a sense, the many existing Internet-based mapping applications with zoom functionality offer an immature example of how such a system might operate (for example, the link to maps at <http://www.mapquest.com>).

The basemap provides an image of Earth, allowing the user to identify the area of interest and to display the results of a geolibrary search. Goodchild has also identified the need to search across geolibraries containing distributed information. In principle, a single geolibrary should exist for the whole planet Earth, but in practice, geolibraries will combine resources located in different databases. The large volume of data in geolibraries means that transmission of the data requires high-capacity network links. The locations containing the component parts of the geolibrary can be connected by high-speed connections, but the absence of universal high-speed network connections poses problems for user access to large volumes of geographic data. One suggestion is to distribute common geographic data (basemaps) by compact disk with read-only memory (CD-ROM) or digital videodisk (DVD), allowing the browser software to concentrate on the downloading of specialized data sets from the geolibrary. If the user had the basic geographic data in place on their machine, additional layers or attribute data could be obtained as required from the geolibrary.

A gazetteer is a list of named places together with geographic coordinates identifying locations. Gazetteers were traditionally found in printed atlases; the *Times Atlas of the World*, for instance, contains over 200,000 items in its gazetteer. The Geographic Names Information Service of the U.S. Geological survey (<http://mapping.usgs.gov>) is one digital equivalent of the atlas gazetteer. Traditional gazetteers have a number of problems from a geolibrary perspective. First, official gazetteers tend to concentrate on place names with some legal use or definition, and other widely used informal place names may not be included. There may be no clear definition of commonly used terms such as the "Midwest" of the United States or "Western Europe." Second, traditional gazetteers tended to give only a point location for a place name, but many place names refer to regions or districts rather than single points. Because point locations lack an extent, data could not be used to establish the geographic footprint associated with the name. A gazetteer could define the extent of a geographic region by indicating its component parts; for example, Iberia could be defined as Spain and Portugal together. A geographic region may also be defined by delineating its boundaries. The latter approach is data intensive and is infrequently used by traditional gazetteers, but is required for an effective geolibrary.

Limitations of Traditional Techniques

Traditional library content is organized into a few discrete objects for indexing purposes; common examples include books, sections in books, journals, and articles in journals. In contrast, georeferenced data relate to part of a continuum of space, with a geographic footprint that characterizes each piece of data. Such footprints can be precise, for example, when a unique identifier refers to a legally defined area. Other footprints are fuzzy in nature, when the limits of the area are unclear. Imprecise footprints can arise with physical objects; the boundaries of a valley or a mountain may be vaguely defined. More often, fuzzy footprints arise when there is no clear definition of commonly used terms. Though what these expressions mean in context is generally understandable, they lack the type of clear definition required for straightforward computer processing.

Traditional digital databases make it possible to search for an attribute value. This could include data with a geographic element; for example, the search could be for all people whose address is in a certain town or who share the same postal code. However, though this approach is widely used, it has several limitations. First, the same name may refer to differently defined spatial regions. For example, a variety of organizations may have an administrative center based in a town; the exact region served by these offices may differ from one body to another. A city may have an urban administration covering only part of the greater urban area; for research purposes, this limited definition of the urban area may not be of interest. In many cases, a county or state may share the same name as a town or city. Furthermore, the same place name may occur in different locations; for instance, Washington State may be confused with Washington, D.C. A web search engine search for "Dublin" may return information on Ireland's capital city or on Dublin, Ohio in the United States. A third problem is that place names may be used to label non-spatial information. A search for "Dublin" may also return information on data standards developed in Dublin, California. This is an instance of a geographic location being used as a label for something not in itself of a spatial nature (other examples include the Treaty of Rome and food-stuffs such as Brussels sprouts, Parma ham, or Peking duck). Consequently, the frequent confusion of different entities with a similar name is a major obstacle to the use of conventional text-based approaches for searching for establishing spatial associations.

Geolibrary Operations

A geolibrary should allow the user to overcome these problems by providing tools and data to answer questions related to geographic entities of interest, in addition to the

standard units used by standard digital databases. For instance, demographic data is collected in small districts, which are combined into larger regions for reporting purposes. This can present a problem if these larger regions are not identical to the region of interest to the researcher. A geolibrary with detailed data would allow the combination of that data into any larger unit, to allow definition of a footprint to correspond exactly with the focus of the research (Fig. 1). Other types of analysis may not be based on administrative districts, but may be concerned with the regions served by shopping facilities or regions where commuting takes place to a large urban center.

Digital data processing is most powerful when it allows different sources of data to be synthesized together. Consequently, geolibraries provide a spatial indexing structure that facilitates the combination of different spatial data sets; for example, a digital library catalog allows searching for both keyword and author. In a similar way, a geolibrary search can identify whether spatial features overlap with the footprints of other spatial objects. For example, a search might identify the administrative districts that lie along a river, allowing the discovery of content relating to these regions. Another use of these techniques would be to identify the regions close to a political boundary, i.e., suburbs of a city or other fringe

areas. In addition to using overlay operations to identify where footprints overlap, spatial operations can be used to identify which lines or points lie within specific areas. For instance, it would be possible to identify the modern towns lying within the boundary of a historic political entity, such as a province of the Roman Empire. Other spatial processing techniques include network analysis, which can be used to calculate travel times on road networks. These techniques are probably less important in a geolibrary context, but could be used to identify information associated with travel to work regions and other spatial patterns not reflected in administrative boundaries.

Geolibrary Example

A number of geolibrary prototype systems exist, although these presently fall some way short of the ultimate potential of a geolibrary, they are constantly evolving to include more information. Examples of current systems available over the World Wide Web include the Alexandria Digital Library web client (<http://webclient.alexandria.ucsb.edu/>) located at the University of California in Santa Barbara and the Geography Network (<http://www.geographynetwork.com>) hosted by ESRI Corporation. Because of the limitations of the software commonly used on the web, these provide a relatively unsophisticated geolibrary browser access to georeferenced material and a gazetteer.

Using the Alexandria web client as an example, the user is initially presented with a screen with an interactive map in one window and the ability to enter text commands. User interaction through the map browser or text dialogue boxes can change the bounding box that determines the footprint being examined. The interface allows different shapes of bounding box to be selected and the user can zoom in to the level of detail required (Fig. 2). The object of a search is to identify information in the database with a geographic footprint that overlaps in some way with the footprint of the region of interest to the user. The user can request information with a georeferenced footprint that lies entirely inside the selected region, footprints that overlap with it, or indeed footprints that are entirely outside the region. The library will return the results of such a search as database entries with the required footprint. These might include gazetteer entries for towns in the area selected, details of relevant offline information such as books, and links to online information such as digital maps and aerial photographs of the region.

In their present immature state, geolibrary services inevitably lack much potentially useful information that will be added in such resources in the future. The limitations of web technology mean that the interfaces are not as easy to use as they might be, and dedicated geographic browser software may be needed to address this

Figure 1 Use of a bounding box for aggregation of data from subdistricts into a new area of interest.

Figure 2 Defining a more detailed bounding box.

problem. Nevertheless, these prototypes demonstrate the potential power of the geolibrary model and can advance to provide a fuller implementation of the concept.

Issues in Geolibraries

Difficulties in Using Spatial Techniques

Social science researchers have become accustomed to using digital tools such as database queries and statistics. Though these tools are widely used, not every user makes full use of their potential, in part because of a lack of understanding of the techniques involved. Modern statistical analysis packages provide a range of powerful statistical techniques, but the limitations of these may not be fully comprehended by a user whose primary domain is not statistics. Spatial techniques are even more complex and the development of appropriate interfaces to make these approaches accessible to the nonspecialist user is an important challenge for geolibrary designers. Geographic interfaces often assume user familiarity with specialist geographic terminology; this assumption is unlikely to hold true for a broader user community. Training can offer one solution to this lack of experience with spatial techniques, but it is always likely to be the case that the desire of social researchers to use geolibraries exceeds their willingness to undergo long training courses. There is a danger that inexperienced users may fail to use a geolibrary to its full potential, owing to ignorance of many of its capabilities. The geolibrary tools need to make access as convenient as possible, while preventing inexperienced users from using the system inappropriately.

Geolibrary interfaces need to address a number of issues: the formulation of the problem, the identification

of relevant data, the correct spatial association of the data, the performance of any spatial operations required on the data, and the presentation of the results in a format comprehensible to a nonspecialist user. Problem formulation is made more difficult by differences of terminology and nomenclature between different disciplines. One strategy for resolving this difficulty is to provide a direct manipulation interface that provides a visual interactive description of the operation required. Using this approach, the user might specify the region to be processed by drawing a boundary on an onscreen map. Successful geolibrary initiatives are likely to offer more sophisticated interfaces, including this type of functionality, exploiting artificial intelligence and visual interactive modeling techniques to interpret user requirements and facilitate presentation of output in customized formats.

Metadata

Identification of the relevant data for a specific problem requires that the contents of the geolibrary be comprehensively spatially indexed. As the volume of spatially referenced data continues to grow, indexing of these data resources plays a vital role in facilitating the wider use of spatial techniques. The correct spatial association between spatial entities is complicated by the use of different spatial units for the aggregation. This is a problem faced by other forms of digital data storage, and techniques such as data dictionaries are used to facilitate the organization of digital databases. The spatial equivalent of these approaches is needed to facilitate the use of geolibraries. A variety of spatial directories exist; for example, in the All Fields Postcode Directory in the United Kingdom, these relate spatial units such as postal codes to other spatial representations. However, to document spatial relations comprehensively,

metadata, or data (information) about data, are needed. As the building of geolibraries requires the synthesis of different spatial data sets, metadata have a major role to play in clarifying any ambiguities in the definition of spatial data. The objective of metadata is to facilitate the discovery of data, their suitability and their availability, and to identify any technical parameters required for their use.

To fulfill these requirements, metadata must be quite complex, and consequently are not likely to be understood by potential geolibrary users. Raw metadata are likely to be used mainly by librarians and other professionals rather than end users. Less experienced users will use the geolibrary through its interaction tools; this software will use the metadata to structure user access to data. Much of the data imported into a geolibrary will be geographically referenced in the form of traditional database fields. For example, attribute data will be associated in a database table with "east region" or "Smallville urban area." A metadata description is needed to identify exactly what is meant by these terms, because other data sets in the geolibrary may deal with other regions known as "east" and other regions based on the "Smallville area." The definitions of these regions may change over time; for instance, the regions used in one census may differ from those used in subsequent censuses. A metadata definition of a data set will clarify any ambiguities in these definitions.

Traditional library metadata approaches have concentrated on documents and these need to be extended to take account of spatial databases. Various national and regional initiatives exist; one example is the U.S. initiative on the Content Standard for Digital Geospatial Metadata (CSDGM). More than 30 countries are coordinating their standards to be compatible with an international standard, IS 19115. This provides a schema for describing digital geographic data sets using a comprehensive set of mandatory and conditional metadata elements. The challenge is for geolibrary builders to integrate the various metadata approaches successfully, in a way that is largely seamless to the user.

Economics of Geolibraries

A geolibrary is a combination of various data sources, collected by different organizations, often at considerable cost. If spatially related data are to become freely available for inclusion in geolibraries, then the question of the funding of these libraries arises. One approach is for geolibraries to be regarded as a public benefit that should be funded by the government. Many spatial data are of public interest, and a large volume of spatial data originates with government agencies such as traditional cartographic agencies (e.g., the Ordnance Survey in the United Kingdom, or the Bundesamt für Kartographie und

Geodäsie in Germany) and local government bodies. However, differing approaches are taken internationally to the distribution of these data. In the United States, government policy is to make basic geographic data collected with taxpayers' money freely available to citizens; this has led to initiatives such as the National Spatial Data Infrastructure (NSDI) and the funding in 1994 of the Alexandria Digital Library by the U.S. National Science Foundation. There have also been geolibrary-type initiatives at the state and local level in the United States (for instance, the Idaho Geospatial Data Center). In contrast, in most European countries, government policy is to seek to recover some or all of the cost of spatial data collection from those who use it, thus posing a major challenge to the builders of geolibraries. Then again, the comprehensive nature of a geolibrary raises the question of a charging model even in the more favorable public sector environment found in the United States. First, when a geolibrary integrates data from private and public sector sources, the economic rationale for these data providers is different. Second, digital data may be readily copied, so the traditional library model of a loan for a restricted period may not be relevant.

This problem of building digital databases from multiple private sector sources is one faced by other sectors; for example, the music industry has experienced great difficulty in establishing a working model for the download of copyright music. In electronic commerce generally, copyright issues remain problematic and proposed solutions such as micropayment mechanisms have had only limited success. A geolibrary might operate by allowing access to the database only through tools provided by the library, thereby enforcing economic restrictions on user access to the data. However, these types of restrictions inhibit access to the data, compromising the objective of the geolibrary. The design of an appropriate charging structure for geolibraries is likely to prove as big an obstacle to their widespread use as any technical problems with data storage or transmission.

Conclusion

Digital indexing and storage of data allow many extended possibilities for social research. These partly arise from the convenience of the digital format, but also because new types of data and data relationships can be exploited. One such opportunity exists for exploiting spatial relationships; this requires the georeferencing of data, which has been greatly facilitated by digital processing. For this form of data to be easily used, the traditional library needs to be extended in the form of a geolibrary. This would provide a comprehensive collection of all forms of data related to any one place, indexed and cataloged to

allow spatial operations on different combinations of data in the geolibrary.

Though the potential of geolibraries is clear, their development poses many problems. Social researchers are typically not familiar with either the power or the limitations of spatial techniques. The geolibrary must make these accessible to researchers in all domains; this requirement poses a strong challenge for the designers of geolibraries and their interfaces. Geolibraries will be at their most successful if they contain a wide range of georeferenced data. However, georeferencing requires the availability of digital spatial data, which are usually expensive to collect and which typically originate from different sources. Consequently, it is difficult to devise an appropriate economic model for geolibraries that provides an appropriate return to the data providers. This problem is likely to prove even more difficult than the purely technical obstacles to geolibrary development. Despite these difficulties, the research potential for the use of spatial data is so great that geolibraries will play an important and growing role in research work in the social sciences in the future.

Giddings, Franklin Henry

Stephen P. Turner

University of South Florida, Tampa, Florida, USA

Glossary

ballistic relations Causal associations that are probabilistic in the sense of being better depicted as a joint statistical distribution than as a deterministic law.

concerted volition The sum of the distinctive responses made by individuals subjected to common stimuli and interstimulation that produced similar behavior, such as cooperation or competition.

consciousness of kind Sympathy, especially through the recognition of similarity or common membership in a category, usually with social consequences, for example, group identity.

index numbers Numbers derived typically by adding heterogeneous items that are assigned predetermined numerical values.

profit-sharing A method by which workers are rewarded a fraction of the net profit of an enterprise.

Franklin H. Giddings was the founder of sociology at Columbia University, and, with Lester F. Ward, William Graham Sumner, and Albion Small, one of the four founders of American sociology. Through his writings and his students, he played a pivotal role in establishing mainstream quantitative sociology in the United States. Among his prominent students were William Fielding Ogburn, Howard W. Odum, and F. Stuart Chapin. In *Inductive Sociology* (1901) and *The Scientific Study of Human Society* (1924) he outlined an account of the relation of social theory and quantification in a way that broke with the nineteenth-century tradition of sociological commentary on tabular material and provided an alternative model more closely resembling the model of statistical hypothesis testing characteristic of twentieth-century social science. Giddings was also a theorist, who developed the idea of “consciousness of kind” and applied

models from early population genetics to the question of the development of social types.

Background and Career

Giddings, born in Sherman, Connecticut, was the son of a Congregational minister and came from a distinguished Massachusetts family that had arrived on the Mayflower and provided generals in the Revolutionary War. Rebelling against his father's Calvinism, he entered Union College in 1873 to study civil engineering, but was forced to drop out after 2 years as a result of his father's death. He took up a career in journalism, working for the *Springfield Republican* and other newspapers during a period of intense debate over labor and monetary issues. He also became involved with the Connecticut Valley Economic Association and the cooperative movement and played a role in the early history of the American Economic Association (AEA), editing its book series. His interest in the social sciences appears in his early journalistic work, which included an effort at the quantification of inflation using a price index. Giddings's earliest writing included an empirical, although not statistical, study of cooperative labor and profit-sharing published in 1886 by the Massachusetts Bureau of Labor Statistics under the name of its director, Carroll Wright. Giddings received a B. A. from Union College in 1888 as a member of the class of 1877.

Although cooperativist ideas were central to his thought, they took various forms throughout his career. At the time, state offices concerned with the solution of the labor problem collected labor statistics and routinely printed studies analyzing cases of profit-sharing and cooperation. Giddings had a strong interest in the theoretical implications of cooperation and founded an organization called the American Sociologic Association,

about which little is known other than its statement of principles, which prefigured his later analysis of concerted volition and his support for the League of Nations. Eventually, however, his empirical work undermined his commitment to cooperativism as a solution to the labor question; he found participants in successful cooperative adventures typically aspired to having their own business and used the experiences of cooperative labor as a means of learning the business.

Academic Career

Giddings's academic career began when he was appointed to Bryn Mawr in 1888, taking over the position that Woodrow Wilson vacated for Princeton. He continued to write essays, notably an 1898 essay "Imperialism" (collected in *Democracy and Empire*, 1900) that responded to William Graham Sumner's attack on the emergence of American imperialism in the wake of the Spanish-American War, in which he argued that empires could be social aggregations founded on positive common ideals. At Bryn Mawr, he taught economics, history, and politics and introduced sociology. At the beginning of his career, he was active in the AEA, holding several positions in the association. He published various articles on economics, two of which were included in *The Modern Distributive Process*, which he produced with his mentor, the economist John Bates Clark, in 1888. His first-published discussion of sociology appeared in 1890, but he had presented a paper on "The Sociological Character of Political Economy" to the AEA in 1887. In 1891, he published an article on "Sociology as a University Subject" and engaged in a series of exchanges on the general theme of the relation between sociology and economics and the other social sciences. He also began in 1892 to travel to New York to lecture at the rapidly developing faculty of social and political science at Columbia University. Statistics in this Columbia faculty was then taught by the economic and social statistician Richmond Mayo-Smith, who represented the tabular tradition in statistics and directed the first American social science dissertation on a recognizably sociological topic, Walter Willcox's 1891 study of divorce. Giddings was appointed Professor of Sociology at Columbia in 1894 (the first sociology professorship in an American college, established through the efforts of active social reformer Seth Low). In 1906, Giddings held both the chair in Sociology and the newly established chair in the History of Civilization as the Carpentier Professor of Sociology and the History of Civilization, a position he held until 1928. He was awarded a D.L.D. by Columbia in 1929.

Giddings published his key theoretical work, *The Principles of Sociology*, in 1896, and it was promptly and widely translated; his key early methodological work, *Inductive Sociology*, was published in 1901. His

subsequent work mostly consisted of essays, which were either published as short books or collected as books. His most important later books were *Studies in the Theory of Human Society* (1922) and his final methodological book *The Scientific Study of Human Society* (1924), based on a series of articles published in *Social Forces*. During the war years Giddings wrote *The Responsible State: A Re-examination of the Fundamental Political Doctrines in the Light of World War and the Menace of Anarchism*, published in 1918, but the war prevented him from carrying out some major planned projects, including one on the history of civilization and an extensive empirical study of working men's time and leisure.

Public Intellectual

Giddings was a public intellectual and served as a member of the school board; various commissions; the Committee of One Hundred, which was organized to choose a non-partisan candidate for Mayor of New York City; and on the board of the Charity Organization Society. He continued to produce for the press throughout his career, notably for Hamilton Holt's *Independent*, to which for many years he contributed an editorial a week, as well as writing regularly for *Van Nordens* and the *New York Times Magazine*. Never one to shy from controversy, he spoke regularly at the Rand School, a center for radical and socialist lectures, often antagonizing his audience. He was, in general, a defender of the middle class and a skeptic about social amelioration, considering many of the ills to which reform was addressed to be better understood as costs of progress. He was an early supporter of the American entry into World War I and was one of the principal speakers at Carnegie Hall at the Lusitania dinner. He later toured the country for the national Security League in support of the war and was an officer of the League to Enforce Peace. His outspoken position embroiled him in controversy at Columbia, which was the site of conflict over the war (and of a famous academic freedom issue involving James McKeen Cattell, which divided the faculty from the administration), and at the end of his career he was seen by the administration and funding agencies to be an obstacle to the development of sociology at Columbia.

Giddings's Influence

Although his early years at Columbia were occupied with the problems of training social workers and meeting the demand for lectures on social reform topics, he quickly established general sociology, particularly theory and method, as his primary concern, publishing his *Principles of Sociology* in 1896 and in it staking a claim to the scientific approach to the field. Columbia at the time required training in several fields for its social science graduates, so Giddings was presented with the peculiar

situation of having to define the field not only for students of sociology but also for the students of other social science fields. Many of the students he taught sociology to, such as Robert Merriam, became influential figures in their own disciplines. His own students were themselves trained in economics as well as sociology and statistics, and several of them, including, William Fielding Ogburn and F. Stuart Chapin, were in the early years of their careers identified as economists as well as sociologists in their writings and took up such topics as municipal socialism.

The *Principles* was concerned with a problem that appears in various forms in the thinking of each of the early sociologists, but which is nowadays rarely mentioned, although it appears today in evolutionary approaches to social life. The issue was social causation, which was a concern to identify the basic forces that contributed to the making of social life and produced its various forms. Giddings's central concept of consciousness of kind, although it was later applied to a variety of topics, arose in connection with this concern for identifying the basic motivating forces relevant to social life. In a later book, *A Theory of Socialization* (1897), his concern was with the processes by which individuals were made social by being brought into contact with others. He continued to reformulate his position on these issues throughout his career, but never made a major statement of his theoretical position. However, it evolved from its original emphasis on the physical conditions of social life that produced different social forms to an emphasis on the idea that the effects even of physical conditions of life operate through a social medium that is itself produced by past conditions. Thus, he recognized the significance of tradition. Like several of his contemporaries, however, Giddings was careful not to treat society as a teleological object but was concerned with what he called the analysis and correlation of moral and social forces, which included the problem of social reaction on individual character and the reverse problem of the social effect of individual will; this concern for processes informs his methodological thought.

His first major work in the area of methodology, *Inductive Sociology*, was little read, but nevertheless was a pivotal text in the history of American sociology. In this book, Giddings listed dozens of concepts and provided numerical measures for them or in many cases merely definitions that allowed for counting. This was very primitive as measurement, but the radical significance of this project was apparent. Giddings did not simply take over the categories of official statistics but attempted to construct a systematic scheme of concepts that was susceptible of precise definition or measurement. Although Giddings was aware of currents in contemporary French sociology, particularly the work of Gabriel Tarde, which may have provided some distant inspiration for this

project, there is no contemporary example of a comparable large-scale effort to find quantifiable versions of social concepts.

Giddings conveyed this conception to his students, encouraging them to make the steps toward verification that he himself did not take. In this school-building effort he was extremely successful. With the help of Mayo-Smith, the first Columbia economist; the celebrated anthropologist Franz Boas; who developed and applied them to physical anthropology; and Henry L. Moore, a proto-econometrician—each of whom taught statistics—and later two other young social statisticians, Robert Chaddock and Frank A. Ross, sometime members of Giddings's department, Giddings created at Columbia an intellectual setting dominated by questions of statistical method. He personally reinforced the association by holding a kind of salon called the (Franklin H. Giddings) Club, which one of his students, F. S. Chapin, recalled as “a small group of graduate students and past students of Professor Giddings who met regularly at his house and enjoyed his hospitality and the rare stimulus of intimate association with him,” during which, as another student, Charles Gehlke, reminisced, “we discussed the universe very thoroughly” before the evening “wound up with beer or gingerale and pretzels and cakes.” Index numbers continued to interest Giddings throughout his career and the interest continued in his students, such as Chapin, whose famous living-room scale of social class was an index number.

In the first decade of the twentieth century, Giddings attempted, with the help of his students, to revise and update *Inductive Sociology*. Although no revision ever appeared, the group of students that worked with Giddings during this period, including Ogburn, Howard W. Odum, and Chapin, continued to further work out the implications of Giddings's own basic ideas. They went on to become not only leading figures in American social science in statistics, the most important practitioners of statistical empirical sociology in the interwar period, but also dominated the discipline—one-third of the presidents of the American Sociological Association from 1920 to 1940 were his students. By the late 1920s, their methodological ideas, which had been acquired during their time with Giddings, became the basis of textbook methodology in sociology. Giddings himself was the author of the first widely used methodology textbook, *The Scientific Study of Human Society*.

A central theme in Giddings's theoretical work was biological and social evolution from diversity into stable types, an issue identified by British biometrician Karl Pearson. Giddings's student William Ogburn, for example, studied the creation of culture by a process of selection in which environmental forces, including social pressure, eliminated deviations. This was an application of Giddings's idea of “concerted volition” as a product of

a process of interstimulation. In his doctoral thesis, Ogburn had examined the transformation of diverse state labor laws into standard form. In *Social Change* (1922), the book for which he was best known, Ogburn coined the term cultural lag to describe how, in response to selective forces, material conditions change before a culture does and different parts of cultures themselves change at different rates. These processes Giddings termed “ballistic,” that is, probabilistic rather than machinelike.

The Problem of Social Science Theory and Statistical Verification

Giddings learned his methodology from Mill and Jevons, and later from Mach and Pearson, and among the founding figures of American sociology was the only one who concerned himself in any detail with methodological questions and with the questions of whether the theories of sociology could be made into science and whether the empirical material was available to the sociologist to test them. Giddings can be credited with inventing the account of this problem, which became dominant in American sociology. He was eager to apply the methodological lessons being retailed by contemporary scientists to the question of what empirical inquiry can warrant in the way of theory. From Mach, Giddings took the idea that mechanics is nothing more than description and concluded that “no other branch of knowledge can claim to be more.” This prepared him for Pearson’s similar but even more extreme message that not only was developed science no more than description but that the laws of physics themselves were not, properly speaking, descriptions but rather idealization of relationships that involved variation. In *The Grammar of Science* (1892) Pearson included a figure of a scattergram of data points that showed the data points arranged in a typical pattern of random error variation around a curve to which a line could be fitted. Inserted into this scattergram was a blown-up section of the pattern, which of course appeared as a high level of variation. Pearson’s point was that physics was based on correlations no less than other areas of knowledge and that variation was built into nature itself. Like Comte before him, Pearson regarded the idea of cause as intellectually retrograde, a step backward toward animism; Giddings followed Pearson and Comte in this respect, regarding causation as a metaphysical notion and explanation itself as a suspect concept.

Giddings’s embrace of these Pearsonian and Machian doctrines created obvious difficulties for him as a theorist. But he resolved these by placing sociological theory within what he called the three normal stages of the scientific method: guesswork, deduction, and verification. The

three stages are a modification of Pearson’s stages of ideological, observational, and metrical, which Giddings quoted in his lectures and which themselves were a modification of Comte’s three stages. In 1920, Giddings gave the following formulation:

Science cannot, as a distinguished scientific thinker said the other day, even get on without guessing, and one of its most useful functions is to displace bad and fruitless guessing by the good guessing that ultimately leads to the demonstration of new truth. Strictly speaking, all true induction is guessing; it is a swift intuitive glance at a mass of facts to see if they mean anything, while exact scientific demonstration is a complex process of deducing conclusions by the observations of more facts.

His own work, he hoped, would enable his readers “to see that much sociology is as yet nothing more than careful and suggestive guesswork; that some of it is deductive; and that a little of it, enough to encourage us to continue our researches, is verified knowledge.” The solution to the puzzle of the relation between statistical sociology and sociological theory this suggests is that speculative social theory is a source from which the sociologist may take basic concepts to see if statistical data “mean anything,” then deduce conclusions from strict formulations of these guesses, and test them on more facts, thus gradually adding to the stock of verified knowledge that thus consists of the accumulation of statistical results that serve, if not to answer theoretical questions, to replace theoretical answers with metrical descriptions of relations.

Measurement

Statistics and Sociology (1895) by Giddings’s Columbia colleague Richmond Mayo-Smith remained squarely in the nineteenth-century tradition of moral statistics. In it, Mayo-Smith commented, with a sociological purpose, on material of the sort collected by state bureaus, such as tables of vital statistics. In his *Inductive Sociology* and his articles, such as “The Measurement of Social Pressure” (1908), Giddings attempted something quite different—the measurement of magnitudes that derive either from sociological theories or from social concepts such as labor unrest. The data he proposed to use were not very different from the sort discussed by Mayo-Smith, but they were conceived in a distinctly new fashion.

The key difference was how the problem arose. Giddings was concerned with a theoretical question, with the constraints on political evolution (especially the achievement of democracy) that result from conflicts with primordial ties such as kinship and from the inadequate psychological and characterological evolution of personalities. His approach to this problem is indicative of his approach to sociology. We might investigate this kind of problem impressionistically by deciding if some

group has some characteristic, such as “forcefulness” (one of Giddings’s four basic psychological types), that is pertinent to the theoretical question of their capacity for sustaining particular forms of political association. But only systematic quantitative evidence in the form of magnitudes can enable the precise determination of correlations. So in *Inductive Sociology* he constructs a magnitude:

Suppose that we desire to know whether the men of Montana represent a type of character that might be described as forceful, but that we find no testimony, no record of personal observations, directly bearing on our inquiry. We know, however, that by the general consent of mankind, men who follow adventurous and daring occupations are described as forceful. Turning, then, to the census, we learn that a majority of men in Montana follow adventurous and daring occupations.

Accordingly, by substitution, we affirm that a majority of the men of Montana are of the forceful type of character.

The explicit idea of measurement “by substitution” warranted by “the general consent of mankind” (or “face validity” in later parlance) represented a genuine innovation that allowed him to extend the concept of magnitude to other social concepts.

The primary inspiration for Giddings’s innovation here was the problem of race, one of the defining issues for Columbia at the time. Giddings’s student, Frank H. Hankins, makes the point in *Introduction to the Study of Society* (1929) that “all the customary indices of racial difference, viz., stature, cephalic index, hair color, eye color, skin color, nasal index, hair form, alveolar index, etc. in fact extensively overlap one another.”

Norwegians are obviously taller on an average than Japanese, but some Japanese are taller than many Norwegians. White and Negro cannot be distinguished by stature; nor by cephalic index; even as regards skin color and hair form the border areas of distribution overlap. It is this overlapping that makes it necessary to think of a race as a group set apart by a complex of traits inherited together within a limited range of variability. Since tall stature shades into short, long head into round, and dark complexion into light, it must be shown that with tall stature are found also a certain head form, eye color, shape of hair, etc.

The underlying idea here that a race is not definable by a single criterion but by correlated statistical distributions of several properties, and this justifies the practice of using a wide variety of measures, each of which can be plausibly used as a surrogate for the variable of interest.

If we consider only Giddings’s early attempts at using distributions, for example, of the number of people in daring occupations as imperfect indicators of the preponderance of psychological types, such as “forceful,” his achievement may appear to be rather trivial, even

preposterous. Certainly it is questionable whether these “traits” are traits and whether this sort of substitution is properly regarded as a form of measurement. But it was very difficult to pass from the abstract ideal of metricizing social theory to the actual creation of metrical substitutes for theoretical concepts. Before Giddings, there were some abstract discussions of measuring happiness (the felicific calculus), and, at the other extreme, a body of data collected for a wide variety of official purposes such as vital statistics, suicide statistics, and crime statistics. There were also some rudimentary data on opinions and attitudes. Opinion data collected by the Bureau of Labor Statistics took the form of queries to officials or people presumed to be knowledgeable regarding the causes of a phenomenon of interest, which could be classified by these causes. This was very far from Giddings’s goal, to be algebraic, or concerned with magnitude, rather than arithmetic, or concerned only with counting items in the social world.

In this effort, he was a genuine pioneer in creating a quantitative sociology organized around the measurement of variables and the determinations of the correlations between them. The existing theoretical discussions of measuring belief and desire were far removed from data collection, and the concepts used by theorists were not readily measured. Giddings closed this gap. He reconceptualized commonly used concepts, such as “the unsocial,” “the degraded,” and “the immoral,” which he specified in terms of what moral statisticians had termed drunkenness, begging, and the like. He also defined measures of various social phenomena, such as “domestic peace and order,” which he specified in terms of “the number of insurrections and riots experienced,” and devised measures of equity in the distribution of wealth. This huge enterprise of identifying measures had a limited direct impact on research, but prepared students for a revolution in research practice.

Yet, in *Inductive Sociology*, Giddings did produce some influential models of analysis, including what may be the first example of statistical hypothesis testing in sociology. The speculative concept “consciousness of kind” suggested the following deduction: “Concerted volition” of forms of political association depend on sympathy or consciousness of kind. Hence, there should be a relationship (which he spelled out at length, discursively, on the theoretical level) between the degree of social sympathy and what we might call political culture. He tested this hypothesis by constructing an index number corresponding to a weighted formula based on the addition of these fractions: the proportion of the numbers of native born of native parents; the proportion of native born of native parents and native born of foreign parents to foreign born; and this proportion to the proportion of colored. The number was understood to correspond to the degree of homogeneity in the population. After

calculating this number for each state of the union, he constructed three categories based on the scores. The relationship was verified by examining the lists of states falling into each category. In the highest index number category, he said, "it will be observed that the states which are distinguished for a rather pronounced 'Americanism' in politics and legislation are chiefly found, as might be expected." In those states where the population was "neither perfectly homogeneous nor excessively heterogeneous," signifying the existence of more intellectual ties as distinct from primordial group feelings, are to be found the highest degree of "progress and social leadership."

The statistical association between the metricized concept of heterogeneity and the nonmetricized concept of progressiveness provides a kind of paradigmatic example of the kind of social research that became conventional in sociology by 1935. It was motivated by some theoretical ideas about the political effects of heterogeneity. Heterogeneity was an abstract variable measured indirectly. The association was imperfect, but it confirmed and metricized a theoretical idea. In time, Giddings's suggestions about measurement became far more clever. In his 1924 textbook, he gave an example that might be used today—to measure "discriminative reaction to nationalities," he gave 70 people a list of 2 dozen nationalities and asked each of them to distribute places for 100 hypothetical immigrants among them. He used a similar method to measure interest in causes, asking his respondents to distribute \$100 among up to 20 possible causes, such as scientific research, the suppression of vice, and so forth.

Causation

Giddings and his students also struggled with the relationship between correlation and cause. In the 1911 edition of *The Grammar of Science*, Pearson treated the difference between cause and correlation as merely a matter of degree; the difference between the laws of physics and the relations between parental and adult children's stature, for example, is the quantitative fact of degree of variation, and even observations in physics do not perfectly match up with the idealized laws of physics. Accordingly, he urged the abandonment of the distinction between laws and correlations. Almost everything is correlated with everything else, Pearson insisted. Analogously, as Giddings explained, "every manifestation of energy is associated with other manifestations, every condition with other conditions, every known mode of behavior with other modes." Giddings and his students attempted, as did their biometric colleagues, to find a proper middle ground between collapsing cause into correlation and adhering to the traditional notions of cause and law while searching for an adequate formulation of the compromise.

Giddings made several striking contributions to what was to be the ultimate resolution of the problem in sociology. In *Inductive Sociology*, he corrected the deficiencies of Mill's purism by redefining the task of social science. Although "it is not always possible perfectly to isolate our phenomena [f]or example, in Mill's familiar example of the effect of a protective tariff, we may nevertheless be certain that we have found the only one commensurate with results." The paradigmatic means of establishing this result is "systematic observations of the resemblances and differences of occurrence in a series, and of magnitude," meaning correlational analysis. The terminology of resemblances is Mill's and John Venn's (in his *Logic of Chance*, 1876); the idea of the mathematical expression of a comparison between "classes or series of figures," or the notion that a correlation coefficient is "always equivalent to a generalization or law" is taken from Pearson, but is also exemplified by Edward Tylor's much simpler diagrammatic method in an 1889 study of the relation between matrilineality and matrifocal residence patterns.

Yet Giddings's comment on Mill in *Inductive Sociology* posed a dilemma. To the extent that we retain the possibility of isolating sufficient antecedents or major causes, it is not sufficient to point to correlations, however high. As Giddings explained in his methodology textbook of 1924, "If, in a large number of cases, we find a high correlation of the occurrence of frequencies of our experimental factor with the occurrence frequencies of the result attributed to it, the presumption of causal nexus is strong." Giddings conceded that there was no rule that distinguished causal associations from merely statistical associations, but he identified a key indicator—a high correlation "points to the major causal nexus" when it persists, "while other factors and correlations come and go." He thought of these relations as similar to those captured by the notion of constants in physical science and suggested that social science also pursued constants but that these could never be as precisely determined. The intuition that a correlation can be presumed not to be a mere arithmetical accident when the hypothesis of a common cause can be excluded and where there are no highly correlated causes that may be confounded with the putative cause pointed to issues that were to concern statistical sociology for much of the century.

Goal-Based vs. Goal-Free Evaluation

Michael Quinn Patton

Union Institute University, Minneapolis, Minnesota, USA

Glossary

external evaluation Inquiries aimed at judging the merit, worth, quality, and effectiveness of an intervention conducted by independent evaluators.

goal-based evaluation Program evaluation that assesses the degree and nature of goal attainment.

goal-free evaluation Program evaluation that assesses the extent to which and ways in which the real needs of participants are met by the program without regard to the program's stated goals.

internal evaluation Evaluative inquiries undertaken by staff within a program or organization.

needs assessment Determining those things that are essential and requisite for a particular population that are lacking, the degree to which they are lacking, and the barriers to their being provided or met.

program evaluation The systematic collection of information about the activities, characteristics, and outcomes of programs to make judgments about the program, improve program effectiveness, and/or inform decisions about future programming.

program goals The desired and targeted outcomes or results of program activities.

Goal-based versus goal-free evaluation involves a debate among evaluators about the degree to which measuring goal attainment ought to be the central focus of program evaluations. The alternative to the traditional and still-predominant goal-based approach is goal-free evaluation, which proposes to replace measuring goal attainment with assessing the extent to which and ways in which *the real needs* of participants are met by the program without regard to the program's stated goals.

The Centrality of Goals in Evaluation

Traditionally, evaluation has been synonymous with measuring goal attainment. Evaluation textbooks have typically taken the position that a program must have clearly stated goals in order to be evaluated and that the primary purpose of evaluation is to assess goal attainment. Conversely, a program that does not have clearly specified goals cannot be evaluated. This perspective took on the status of being a truism. For example, evaluators have long been fond of citing the Cheshire Cat's witty reply to Alice in Wonderland that if you don't know where you're going, any road will get you there. A widely disseminated evaluation cartoon shows an archer shooting an arrow into a wall and then drawing a circle around wherever the arrow lodged and proclaiming, "I hit the target dead center," a way of poking fun at the seemingly absurd notion that one could take credit for hitting a target (attaining a goal) without having a bull's-eye to aim at in advance (stating a targeted goal in advance). In short, early definitions of evaluation viewed the purpose of evaluation as assessing a program's goal attainment.

Clear, Specific, and Measurable Goals

The trinity of goal-based evaluation is clarity, specificity, and measurability. Thus, an evaluable goal is one that is clear, specific, and measurable. However, evaluators have frequently found that, on starting to conduct an evaluation, they must begin by refining the program's goal statements because the goals are fuzzy, vague, and immeasurable. The process of refining goals can be difficult and conflict-laden.

The Goals Clarification Challenge

Fuzzy and Vague Goals

When evaluators work with program staff to clarify goals and attain clarity, specificity, and measurability, the program's goals may not just get clarified, they may also get changed. In some cases, changing the goals is helpful and appropriate. In other cases, however, program staff may feel forced to adopt goals they do not believe in and are not committed to in order to come up with goal statements that have the virtues of clarity, specificity, and measurability. If staff and evaluators do not know how to measure goal attainment, they may adopt goals that are unsuitable and inappropriate to meet the evaluation criteria of a "good" goal.

Multiple Goals

Another challenge in conducting goal-based evaluations involves prioritizing goals. Few programs have only one primary goal. For example, the Headstart program aims to prepare preschool children for success in school, but it also includes health assessment goals, nutrition goals, parenting goals, and sometimes even employment or community organizing goals. Evaluation priorities must be set to determine which goals get evaluated and how scarce resources should be allocated to evaluating different goals.

Conflicts over Goals

Another barrier to goals clarification and goal-based evaluation is conflict over priorities. Conflict among different stakeholder groups over program goals is common. For example, in criminal justice programs, battles are waged over whether the purpose of a program is punitive (punish criminal offenders for wrongdoing), custodial (keep criminal offenders off the streets), or rehabilitative (return offenders to society after treatment). In education and training programs, conflicts often emerge over whether the priority goal is attitude change or behavior change. In welfare agencies, disagreements can be found over whether the primary purpose is to get clients off welfare or out of poverty and whether the focus should be long-term change or short-term crisis intervention. In health settings, staff dissension may emerge over the relative emphasis to be placed on preventive versus curative medical practice. Chemical dependency programs are often enmeshed in controversy over whether the desired outcome is sobriety or responsible use. Even police and fire departments can get caught in controversy about the purposes and actual effects of sirens, with critics arguing that there are more a nuisance than a help. Virtually any time that a group of people assemble to determine

program goals, conflict can emerge resulting in a lengthy, frustrating, and inconclusive meeting.

Evaluation of school busing programs to achieve racial balance offers an example rich with conflict. By what criteria ought busing programs be evaluated? Changed racial attitudes? Changed interracial behaviors? Improved student achievement? Degree of parent involvement? Access to educational resources? All are candidates for the honor of primary program goal. Is school busing supposed to achieve desegregation (representative proportions of minority students in all schools) or integration (positive interracial attitudes, cooperation, and interaction)? Many communities, school boards, and school staffs are in open warfare over these issues. Central to the battles fought are basic disagreements about what evaluation criteria to apply and how to assess results.

Goal-Free Evaluation

Philosopher and evaluator Michael Scriven has been a strong critic of goal-based evaluation and, as an alternative, an advocate of what he has called "goal-free evaluation." Goal-free evaluation involves gathering data on a broad array of *actual effects* and evaluating the importance of these effects in meeting demonstrated needs. The evaluator makes a deliberate attempt to avoid all rhetoric related to program goals. No discussion about goals is held with staff and no program brochures or proposals are read; only the program's actual outcomes and measurable effects are studied and these are judged on the extent to which they meet *demonstrated participant needs*.

Reasons for Shifting to Goal-Free Evaluation

Scriven has offered four reasons for doing goal-free/needs-based evaluations:

- (1) to avoid the risk of narrowly studying stated program objectives and thereby missing important unanticipated outcomes;
- (2) to remove the negative connotations attached to the discovery of unanticipated effects, side effects, or secondary effects;
- (3) to eliminate the perceptual biases introduced into an evaluation by knowledge of goals; and
- (4) to maintain evaluator objectivity and independence through goal-free conditions.

Avoiding the Tunnel Vision of Goals

Scriven has argued that focusing on goals in evaluation is unnecessary. To the contrary, too much attention to goals can distort an evaluation and lead to tunnel-vision. The

less an external evaluator hears about the goals of the project, the less tunnel-vision will develop and the more attention will be paid to *looking for actual effects* (rather than checking on *alleged effects*), including attention to side effects and unanticipated consequences of program activities.

Avoiding Grandiosity and Unrealistic Goals

By reducing the emphasis on goals, goal-free evaluation strives to reduce the tendency in programs to overpromise what they can achieve in order to obtain funding. Unrealistic goals contribute to negative evaluation findings. Even if a program is achieving significant results, that finding may be disguised and lead to negative judgments when goals were unrealistic from the outset.

Avoiding the Problem of Real Goals versus Alleged Goals

Organizational theorists, such as Argyris and Schon, have long distinguished between rhetorical goals (what a program says it aims to accomplish) and real goals (what staff actually care about and work toward). The problem of distinguishing real from alleged goals is avoided in goal-free evaluation.

Goal Clarification Becomes Unnecessary

Goal-free evaluation also removes the evaluator from playing the role of facilitating a staff exercise in goals clarification in a search for clear, specific, and measurable goals. In this way, the evaluator avoids becoming caught in goals conflicts among competing stakeholder groups. The problems of multiple goals and changing goals (shifting goals in the middle of a project) are also avoided.

The Focus of Goal-Free Evaluation

Needs Fulfillment versus Goal Attainment

Goal-free evaluation is *needs-based instead of goal-based*; that is, it focuses on assessing the extent to which the real needs of the program's clients or recipients are being met by the program. Thus, the evaluation does not focus on measuring the goals of the people in the program and goal-free evaluators never need to know the stated goals and should not even look at them. The outcome of a goal-free evaluation is an assessment of the merit of the program, not goal attainment.

Determining Priority Needs of Participants

Scriven has argued that determining priority needs is typically as obvious as the difference between soap and cancer. People need a cure for cancer more than they need soap. Hungry people need food more than they need books or self-esteem enhancement. Conducting a careful and rigorous needs assessment provides the baseline for goal-free evaluation.

Internal and External Evaluation Combinations

Scriven's ideal goal-free proposal assumes both internal and external evaluators. Under this ideal, the external evaluators can ignore program staff and local project goals because the internal evaluator takes care of measuring goal attainment and providing feedback to managers and staff. Scriven has acknowledged that planning and production require goals and formulating them in testable terms is necessary for the manager as well as the internal evaluator who keeps the manager informed. This frees external evaluators to assess whether priority needs are being met rather than repeating the internal work of measuring goal attainment.

Criticisms of Goal-Free Evaluation

Goal-free evaluation was derived from a critique of goal-based evaluation, especially the problem of possibly missing side effects when measuring goal attainment and the entanglement of evaluators in stakeholder politics when trying to clarify vague, general, and immeasurable goals. But goal-based evaluators have countered with what they perceive as weaknesses in goal-free evaluation.

Who Determines Goals (and Needs)?

Critics argue that the issue is whose goals will be evaluated. The goal-free model keeps program staff from determining and controlling the focus of an evaluation (stated goals), but in so doing it directs data away from the stated concerns of the people who run the program, thereby reducing the evaluation's usefulness to those closest to the program participants and in the best position to use evaluation findings. Goal-free evaluation typically addresses the concerns of an external audience, such as legislative or philanthropic funders. But, in as much as these audiences are often ill-defined and lack organization, the standards an evaluator applies in determining real needs in a goal-free evaluation may turn out to be none other than the evaluator's very own preferences about what program effects are appropriate and of priority interest. Goal-free evaluation carries the danger of

substituting the evaluator's preferred program goals for those of the program staff.

Accuracy of the Name "Goal-Free"

Evaluation theorist Marv Alkin has argued that the term "goal-free evaluation" is not to be taken literally. Goal-free evaluation *does* recognize goals, but they are wider context, socially inferred goals rather than the specific stated objectives of the program. This, Alkin argues, means that goal-free evaluation is not really goal-free at all but rather is an approach that frees the evaluator to focus on the goals of different and usually more distant decision makers and audiences. The question is whether such distant decision audiences ought to be given the highest priority.

The Problem of Defining Needs

Goal-free evaluation recommends focusing on assessing real program effects and judging those effects in relation to real needs. The third area of criticism concerns this focus on needs in goal-free evaluation. This critique has both conceptual and methodological dimensions. What is a "need" and how is it measured? In addition to the challenge of distinguishing needs from wants, there is the challenge of making explicit the values and assumptions that undergird needs assessments. Does a battered woman need motivational counseling, therapy to deal with childhood abuse, shelter to escape the abuser, higher self-esteem, financial support to escape the abuser, community support, religion, or some other form of assistance?

Status of Goal-Based and Goal-Free Evaluation

Goal-Based Evaluation Remains Dominant in Evaluation

Most evaluation designs focus on assessing goal attainment and goals clarification remains a major task undertaken by evaluators early in the evaluation design process. Goal-free evaluation has not resonated much either with evaluators or with those who commission and use evaluations. Relatively few goal-free evaluations have been reported in the literature. A few comprehensive evaluations include hybrid designs in which a goal-free evaluator works parallel to a goal-based evaluator, but such efforts are expensive and, accordingly, rare.

Beyond the Rhetoric of Goal-Free Evaluation

Scriven's original goal-free proposal provoked considerable controversy and stimulated professionals in the

field of evaluation to examine more closely both theory and practice with regard to goals. In particular, goal-free evaluation has directed more attention to the need for measuring a program's real effects, side effects, and unanticipated consequences in addition to measuring goal attainment. Emphasizing and calling attention to the importance of looking beyond narrow goal attainment measures has been the real and lasting contribution of goal-free evaluation, but the term itself—goal-free evaluation—has proven to be no more than a rhetorical thrust that provoked controversy, as intended. The notion that an evaluation can and ought to be goal-free has not been taken seriously by many as a viable primary approach to actually conducting evaluations.

Diverse Options Now Available for Conducting Evaluations

The idea of performing goal-free evaluation also helped bring attention to other ways of focusing evaluations besides measuring goal attainment, including designing evaluations to improve programs, illuminate important issues, answer the questions of primary decision makers, and support dialogue about future programming directions. Evaluation has become a field rich with options for focusing designs, only two of which are goal-based and goal-free evaluations.

Graded Response Model

Fumiko Samejima

University of Tennessee, Knoxville, Tennessee, USA

Glossary

continuous response model The analysis of continuous responses, for example, marking a range between “Totally disagree” and “Totally agree.”

dichotomous response model The analysis of dichotomous responses, for example, a choice between “True” and “False.”

graded response model The analysis of graded responses, for example, a choice among five responses, “Strongly disagree,” “Disagree,” “Neutral,” “Agree,” “Strongly agree.”

For several decades item response theory dealt with solely dichotomous responses, such as correct/incorrect, true/false, and so on. In 1969, the general graded response model was proposed. This model represents a family of mathematical models that deal with ordered polytomous responses in general. This entry introduces graded response models and considers their relationships with dichotomous and continuous response models. Although the example here are simple, graded response models have many innovative applications, and for future research it has a big potential.

Introduction

Psychometrics, or mathematical psychology, distinguishes itself from the general statistics in two ways: (1) Psychology has its own goal of understanding the behavior of individuals rather than dealing with them as mass products and (2) psychometrics includes measurement of hypothetical constructs, such as ability, attitude, etc. Item response theory (IRT) started as modern mental test theory in psychological measurement and as latent structure analysis in social attitude measurement. In its

early days, IRT was called latent trait theory, a term that is still used in latent trait models, which represent mathematical models in IRT.

For several decades IRT dealt with solely dichotomous responses such as correct/incorrect, true/false, and so on. In 1969, the general graded response model was proposed by Samejima. This model represents a family of mathematical models that deal with ordered polytomous responses in general. To understand the need for the graded response model, the following example may be useful. Suppose that included in a questionnaire measuring social attitudes toward the war is the statement: “A war is necessary to protect our own country.” Figure 1 presents examples of three possible types of answer formats. Figure 1A shows a dichotomous response that allows the subject choose one of the two categories: “Disagree” and “Agree.” Figure 1B shows a graded response that allows the subject to select one of the five response categories: “Strongly

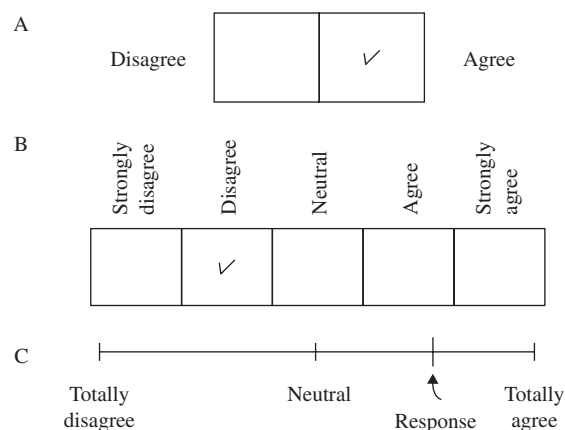

Figure 1 The three response formats. (A) Dichotomous response format. (B) Graded response format. (C) Continuous response format.

disagree,” “Disagree,” “Neutral,” “Agree,” and “Strongly agree.” Figure 1C shows a continuous response that allows the subject choose any position on the line segment ranging from “Totally disagree” to “Totally agree.” The general graded response model uses the second format, the graded response, which makes use of more abundant information from the subject’s reaction than the general dichotomous response model. Note that the number of response categories can be any positive integer and that the number of categories can be different for each item (statements, questions, X-ray films, etc.). The example in Figure 1 is one of the simplest, most straightforward applications of the graded response model. However, the graded response model has many innovative applications, and for future research it has a big potential.

The expansion of dichotomous response models to graded response models resulted in a substantial enhancement of the applicability of IRT for various areas of social and natural science measurements. The graded response model is applicable whenever we measure a hypothetical construct based on the subject’s graded responses to items or whenever each item response is evaluated and a graded score is given. Examples of the use of the graded response model are the Likert-type attitude measurement and the skeletal maturity scale in medical science. In the latter example, expert medical scientists evaluate and grade the maturity level of a knee joint (graded responses) on X-ray films (items) taken from various angles and, on the basis of the sequence of graded responses (response pattern), the patient’s skeletal maturity level is estimated following a specified graded response model. The skeletal maturity scale is especially useful for young patients because there is no one-to-one correspondence between a patient’s chronological age and skeletal maturity and the optimal time for a specific surgery will depend on his or her skeletal maturity, not chronological age.

General Graded Response Model

Let θ be the unidimensional latent trait that represents the target hypothetical construct to measure and that is assumed to take on any real number. Let g denote an item, which is the smallest unit of manifest entity in observable data (e.g., “[3/11] – [12/5] = ” in an arithmetic test); X_g ($= 0, 1, \dots, m_g$) denote a graded item score to item g ; and x_g be its realization. Note that, unlike dichotomous responses, the values of m_g can be different for separate items, the feature that makes the graded response model more widely applicable to different types of data. The dichotomous response model is included in the graded response model as a special case where $m_g = 1$.

The operating characteristic, $P_{x_g}(\theta)$, of the graded item score x_g is defined by:

$$P_{x_g}(\theta) \equiv \text{prob.}[X_g = x_g | \theta]. \quad (1)$$

The general graded response model is represented by:

$$P_{x_g}(\theta) = \left[\prod_{u \leq x_g} M_u(\theta) \right] [1 - M_{(x_g+1)}(\theta)] \quad (2)$$

where $M_{x_g}(\theta)$ is called the processing function, which is strictly increasing in θ except:

$$M_{x_g}(\theta) = \begin{cases} 1 & \text{for } x_g = 0 \\ 0 & \text{for } x_g = m_g + 1 \end{cases} \quad (3)$$

Let $P_{x_g}^*(\theta)$ be the cumulative operating characteristic of the graded item score, $X_g = x_g$, defined by:

$$P_{x_g}^*(\theta) = \prod_{u \leq x_g} M_u(\theta). \quad (4)$$

From Eqs. (2) and (4), the operating characteristic $P_{x_g}(\theta)$ can be written as:

$$P_{x_g}(\theta) = P_{x_g}^*(\theta) - P_{(x_g+1)}^*(\theta) \quad (5)$$

for $x_g = 0, 1, 2, \dots, m_g$. The operating characteristic $P_{x_g}(\theta)$ is the sole basis of the graded response model, and all other functions such as various types of information functions, the basic function for each of $m_g + 1$ grades, and the bias function of the maximum likelihood estimate of θ (MLE bias function) of a test are derived from $P_{x_g}(\theta)$. Note from Eqs. (2), (3), (4), and (5), however, that any specific mathematical model can be represented by either $M_{x_g}(\theta)$ or $P_{x_g}^*(\theta)$ also.

Homogeneous and Heterogeneous Cases

Let $U_g (= 0, 1)$ denote a binary score for dichotomous responses. The item characteristic function (ICF) is defined by:

$$P_g(\theta) \equiv \text{prob.}[U_g = 1 | \theta]. \quad (6)$$

This is a special case of Eq. (1), which is obtainable by replacing the graded item score X_g by the dichotomous item score U_g , and by replacing its realization x_g by a specific value, 1. It is noted that, when $m_g > 1$, the $m_g + 1$ graded response categories can be redichotomized by choosing one of the m_g borderlines between any pair of adjacent graded response categories and creating two binary categories, as is done when the letter grades A, B, and C are categorized into “Pass” and D and F into “Fail.” When the borderline was set between the categories $(x_g - 1)$ and x_g , the cumulative operating characteristic $P_{x_g}^*(\theta)$, defined by the right-hand-side of

Eq. (4), equals the ICF given by Eq. (6). If these m_g ICFs are identical except for the positions alongside the θ dimension, the model is said to be homogeneous; otherwise it is heterogeneous.

A homogeneous model can be represented by:

$$P_{x_g}^*(\theta) = \int_{-\infty}^{a_g(\theta - b_{x_g})} \psi(t) dt \quad (7)$$

where $\psi(\cdot)$ denotes a four times differentiable density function with $\lim_{t \rightarrow -\infty} \psi(t) = 0$ (which is required for obtaining other functions from the operating characteristics $P_{x_g}(\theta)$, including the MLE bias function), and the item response parameter b_{x_g} satisfies:

$$-\infty = b_0 < b_1 < b_2 \cdots < b_{m_g} < b_{m_g+1} = \infty. \quad (8)$$

Models that are homogeneous imply that each and every graded response boundary has the same discrimination power, a principle that may fit categorical judgment data. If in Eq. (7) $\psi(t)$ is replaced by the standard normal density function,

$$\frac{1}{\sqrt{2\pi}} \exp \left[-\frac{t^2}{2} \right]$$

for example, it will provide the cumulative operating characteristic in the normal ogive model for graded responses. Another widely used homogeneous model is the logistic model, expanded from the model for dichotomous responses proposed by Birnbaum in 1968.

Examples of heterogeneous models are those derived from Bock's 1972 nominal response model, Samejima's 1995 acceleration model, and Samejima's 2003 logistic positive exponent model; the last is a graded response model expanded from Samejima's 2000 logistic positive exponent family (LPEF) of models for dichotomous responses in which the item parameter $\xi_g > 0$ controls the principle incorporated in ordering the MLE of θ . To be more precise, when $0 < \xi_g < 1$ the principle is to penalize the failure to answer an easy item correctly, and when $\xi_g > 1$ it is to give credit to the success in answering a difficult question correctly, with the logistic model ($\xi_g = 1$) as their transition, which is not affected by either of the two principles. Let $\Psi_g(\theta)$ be such that:

$$\Psi_g(\theta) = \frac{1}{1 + \exp[-Da_g(\theta - b_g)]} \quad (9)$$

which equals the logistic ICF for dichotomous responses with $a_g (>0)$ and b_g as the discrimination and difficulty parameters, respectively. The cumulative operating characteristic in this model is given by:

$$P_{x_g}^*(\theta) = [\Psi_g(\theta)]^{\xi_{x_g}} \quad (10)$$

where the acceleration parameter ξ_{x_g} satisfies:

$$0 = \xi_0 < \xi_1 < \cdots < \xi_{m_g} < \xi_{m_g+1} = \infty. \quad (11)$$

The operating characteristic in this model is obtained by substituting the right-hand-side of Eq. (10) into Eq. (5) for the graded scores x_g and $(x_g + 1)$. The processing function in this model can be written as:

$$M_{x_g}(\theta) = [\Psi_g(\theta)]^{\xi_{x_g} - \xi_{x_g-1}} \quad \text{for } x_g = 1, 2, \dots, m_g. \quad (12)$$

The 1995 acceleration model was proposed by Samejima for cognitive diagnosis such as problem solving. Let $\Psi_g(\theta)$ in Eq. (9) be replaced by $\Psi_{x_g}(\theta)$, with the item parameters a_g and b_g changed to the item response parameters a_{x_g} and b_{x_g} , respectively, and $\Psi_g(\theta)$ in Eq. (10) be replaced by $\Psi_{x_g}(\theta)$. Setting the step acceleration parameter $\xi_{x_g}^* = \xi_{x_g} - \xi_{x_g-1}$, if this parameter is used in Eq. (12) and $\Psi_g(\theta)$ is replaced by $\Psi_{x_g}(\theta)$, the formula will become the processing function of the acceleration model, although in this model $\Psi_{x_g}(\theta)$ is not restricted to the logistic function. Figure 2 presents a set of seven $P_{x_g}(\theta)$ of a graded response item following the acceleration model, with $m_g = 6$ and the item response parameters: $a_{x_g} = 1.0$ for all x_g ; $b_{x_g} = -1.0$ for $x_g = 1, 2, 3$; and $b_{x_g} = 1.0$ for $x_g = 4, 5, 6$; with $\xi_{x_g}^* = 0.5$ for $x_g = 1, 4$; $\xi_{x_g}^* = 1.0$ for $x_g = 2, 5$; and $\xi_{x_g}^* = 1.5$ for $x_g = 3, 6$.

In general, $P_{x_g}(\theta)$ for $x_g = 1, 2, \dots, m_g - 1$ are not symmetric in a model that is heterogeneous, as illustrated in Figure 2. They are symmetric and unimodal in homogeneous cases, however, if the model provides point-symmetric $P_{x_g}^*(\theta)$, as is the case with the normal ogive and logistic models. The modal points of $P_{x_g}(\theta)$ are ordered in accordance with the graded item score x_g in the logistic positive exponent model and in models derived from Bock's nominal model, as well as in the normal ogive and logistic models. In the acceleration model, however, this is not rigorously true, although it does hold in most practical situations, as in Figure 2.

Relationship with Continuous Response Models

We can categorize the family of general graded response model into (1) models that can be naturally expanded to continuous response models and (2) those that are discrete in nature. Most models in category 1 also have additivity in the sense that:

1. If two or more adjacent graded response categories (e.g., grades A, B, and C) are combined into one new category (e.g., "Pass"), the operating characteristic of the resulting new category, which is the sum total of the original separate operating characteristics, also belongs to the original model.
2. If we divide a graded response category (e.g., "Agree") into two or more graded categories (e.g.,

Figure 2 Example of a set of operating characteristics of graded responses. Acceleration model with seven graded scores, 0 through 6.

“Strongly agree” and “Moderately agree”), the operating characteristics of these new categories can be found in the original mathematical model.

In the acceleration model, however, the first kind of additivity does not rigorously hold, although it does hold in most practical situations. It can be said that models in category 1 are less restrictive and have a broader range of applicability because of their additivity.

Models That Can Be Naturally Expanded to Continuous Response Models

Let Z_g be a continuous item score that assumes any real number between 0 and 1 and z_g denote its realization. An example of a response format in social psychological measurement for which a continuous response model is used is given in Figure 1C. In this example, $Z_g = 0$ is assigned to the end point labeled “Totally disagree,” and $Z_g = 1$ to the other end point labeled “Totally agree.” To every other point on the line segment, the value between zero and unity that is proportional to the length from the left end point (i.e., where $Z_g = 0$) is assigned as z_g , when the statement is phrased positively. (If it is phrased negatively, the positions of $Z_g = 0$ and $Z_g = 1$ are reversed.)

When a specific graded response model is expandable to a continuous response model, the operating density characteristic, denoted by $H_{z_g}(\theta)$, is defined by:

$$H_{z_g}(\theta) = \lim_{\Delta z_g \rightarrow 0} \frac{P_{z_g}^*(\theta) - P_{(z_g + \Delta z_g)}^*(\theta)}{\Delta z_g} = - \frac{\partial}{\partial z_g} P_{z_g}^*(\theta) \quad (13)$$

where $P_{z_g}^*(\theta)$ is analogous to $P_{x_g}^*(\theta)$ in Eq. (7) for the graded response $X_g = x_g$. In homogeneous cases, the operating density characteristic for a continuous response is given by, from Eqs. (7) and (13):

$$H_{z_g}(\theta) = a_g \psi_g \{a_g(\theta - b_{z_g})\} \left[\frac{\partial}{\partial z_g} b_{z_g} \right] \quad (14)$$

provided that b_{z_g} is a strictly increasing and differentiable function of z_g . Samejima proposed in 1973 and 1974 the normal ogive and logistic models for continuous responses expanded from those for graded responses; they are specific cases of the general outcome given by Eq. (14). Additivity holds in these models in the homogeneous case, as can be seen in Eqs. (5), (7), and (8).

Whereas generally graded response models that are homogeneous can be naturally expanded to continuous response models, models that are heterogeneous are more diverse, namely some belonging to category 1 and others to category 2—that is, they are discrete in nature. The logistic positive exponent model for graded responses is a good example of a graded response model that can be naturally expanded to a continuous response model. The operating density characteristic of the resulting continuous response model is obtained from Eqs. (10) and (13):

$$H_{z_g}(\theta) = - [\Psi_g(\theta)]^{\xi_{z_g}} \log \Psi_g(\theta) \left[\frac{\partial}{\partial z_g} \xi_{z_g} \right] \quad (15)$$

provided that ξ_{z_g} is a nonnegative, strictly increasing, and differentiable function of z_g . It is also obvious from Eqs. (5), (10), and (11) that additivity holds for the logistic positive exponent model.

Models that are Discrete in Nature

A typical example of models that are discrete and cannot be naturally expanded to continuous response models is a model that is derived from Bock's 1972 nominal response model, which is represented by:

$$P_{k_g}(\theta) = \frac{\exp[\alpha_{k_g}\theta + \beta_{k_g}]}{\sum_{u \in K_g} \exp[\alpha_u\theta + \beta_u]} \quad (16)$$

where K_g denotes a nominal response to item g , and k_g is its realization, and $\alpha_{k_g} (>0)$ and β_{k_g} are item response parameters. Samejima (1972) pointed out that Bock's nominal model can be considered as a heterogeneous graded response model with the replacement of K_g in Eq. (16) by X_g and k_g by x_g and with the ordering:

$$\alpha_0 \leq \alpha_1 \leq \alpha_2 \leq \dots \leq \alpha_{m_g} \quad (17)$$

where a strict inequality should hold at least at one place. When two or more adjacent parameters, say, α_{x_g} and α_{x_g+1} , are equal, the operating characteristics of these adjacent graded responses share the same modal point, and this enables the model to deal with multiple correct answers and multiple incorrect answers. Thissen and Steinberg called this family of models, which includes Masters's 1982 partial credit model and Muraki's 1992 generalized partial credit model, the divided-by-total model. The processing function $M_{x_g}(\theta)$ in this model can be written:

$$M_{x_g}(\theta) = \frac{\sum_{u=x_g}^{m_g} \exp[\alpha_u\theta + \beta_u]}{\sum_{u=x_{g-1}}^{m_g} \exp[\alpha_u\theta + \beta_u]} \quad \text{for } x_g = 1, 2, \dots, m_g \quad (18)$$

in addition to Eq. (3) for $x_g = 0$ and $x_g = m_g + 1$.

It can be seen in Eq. (16) that the conditional ratio, given θ , of the operating characteristics of any two responses, k_g and h_g , equals the ratio of the numerators of the respective operating characteristics, each of which consists solely of its own item response parameters and θ . This means that the ratio is unchanged regardless of the other elements of the set K_g ; a similar assumption is used by Luce's 1959 individual choice behavior. This principle makes the model discrete and provides an excellent model for nominal responses. As models for graded responses, however, this principle of the invariance of the conditional ratio, given θ , between the operating characteristics of any pair of discrete item responses to the same item g is rather restrictive. For example, for the category obtained by combining the responses k_g and h_g , the operating characteristic becomes:

$$P_{k_g}(\theta) + P_{h_g}(\theta) = \frac{\exp[\alpha_{k_g}\theta + \beta_{k_g}] + \exp[\alpha_{h_g}\theta + \beta_{h_g}]}{\sum_{u \in K_g} \exp[\alpha_u\theta + \beta_u]} \quad (19)$$

which does not belong to the model represented by Eq. (16); that is, first type of additivity does not hold.

Estimation of the Operating Characteristics

Methods for estimating the operating characteristics of graded item responses can be categorized as (1) nonparametric methods and (2) parametric methods. Nonparametric approaches are characterized by the discovery of the true shapes of the operating characteristics directly from the data, without assuming any mathematical form for $P_{x_g}(\theta)$. In contrast, parametric approaches assume a specific mathematical form for the operating characteristic, and the estimation of $P_{x_g}(\theta)$ is replaced by that of item parameters incorporated in the specific mathematical model.

For any scientific research, it is advisable to first use a nonparametric method to discover the shapes of the operating characteristics and then parameterize them by selecting a model that suits the nature of the data and that also fits the shapes of the $P_{x_g}(\theta)$ uncovered by the nonparametric estimation method. Note that a good fit of the ICF provided by a specific model to the uncovered curve is not sufficient because many mathematical models with completely different rationale can produce almost identical sets of $P_{x_g}(\theta)$ values.

Well-developed nonparametric estimation methods include the Levine's 1984 multilinear formula score theory, Ramsay's 1991 kernel smoothing approaches, and Samejima's 1998 conditional probability density function (pdf) approach. Computer software for parametric estimation methods has been developed mainly for Samejima's logistic model for graded responses and models based on Bock's nominal response model, using the marginal likelihood method and expectation-maximization (EM) algorithm. In particular, Thissen's Multilog (1991) and Muraki and Bock's Parscale (1993) have been used by many researchers.

Operating Characteristic of a Response Pattern

Let V denote the response pattern, which represents the individual's performance for n graded response items by a sequence of graded item score X_g for n items, and let v be its realization. Thus,

$$v = \{x_g\}' \quad \text{for } g = 1, 2, \dots, n. \quad (20)$$

It is assumed the local independence, or conditional independence, of item scores holds, so that the conditional distributions of n item scores are independent of

one another, given θ . Thus, the likelihood function for $V=v$ is given as the operating characteristic of the response patterns, $P_v(\theta)$:

$$L(v | \theta) = P_v(\theta) \equiv \text{prob.}[V = v | \theta] = \prod_{x_g \in v} P_{x_g}(\theta). \quad (21)$$

Information Functions

Samejima proposed the item response information function for a general discrete item response. For a graded response x_g , it is denoted by $I_{x_g}(\theta)$ and defined by:

$$\begin{aligned} I_{x_g}(\theta) &\equiv -\frac{\partial^2}{\partial \theta^2} \log P_{x_g}(\theta) \\ &= \left[\frac{(\partial/\partial \theta) P_{x_g}(\theta)}{P_{x_g}(\theta)} \right]^2 - \frac{(\partial^2/\partial \theta^2) P_{x_g}(\theta)}{P_{x_g}(\theta)} \end{aligned} \quad (22)$$

She also defined the item information function for general discrete responses as the conditional expectation of the item response information function, given θ . For a graded response x_g , this function can be written:

$$\begin{aligned} I_g(\theta) &\equiv E[I_{x_g}(\theta) | \theta] = \sum_{x_g} I_{x_g}(\theta) P_{x_g}(\theta) \\ &= \sum_{x_g} \left[\frac{(\partial/\partial \theta) P_{x_g}(\theta)}{P_{x_g}(\theta)} \right]^2. \end{aligned} \quad (23)$$

Note that Eq. (23) includes Birnbaum's 1968 item information function for the dichotomous item, which is based on a somewhat different rationale, as a special case.

Samejima also proposed the response pattern information function, $I_v(\theta)$. For graded responses, it is given by:

$$I_v(\theta) \equiv -\frac{\partial^2}{\partial \theta^2} \log P_v(\theta) = \sum_{x_g \in v} I_{x_g}(\theta) \quad (24)$$

and the test information function, $I(\theta)$, as the conditional expectation of $I_v(\theta)$, given θ , which, from Eqs. (22), (23), and (24), can be written as

$$\begin{aligned} I(\theta) &\equiv E[I_v(\theta) | \theta] = \sum_v I_v(\theta) P_v(\theta) \\ &= -\sum_v \left[\frac{\partial^2}{\partial \theta^2} \log P_v(\theta) \right] P_v(\theta) = \sum_{g=1}^n I_g(\theta). \end{aligned} \quad (25)$$

The outcome of Eq. (25) also includes Birnbaum's 1968 test information function for dichotomous responses as a special case.

In general, the amount of test information is larger for graded response items than for dichotomous response items, and more importantly, it is substantially larger for a wider range of θ . In computerized adaptive testing

(CAT), we construct a set of several hundred or more appropriate questions (items), called an item pool. These items have already been calibrated, and we let the computer select an optimal subset of items to a given examinee based on his or her performance on the previously presented question(s), so that an individual's ability level (individual parameter) can be estimated accurately without presenting too many questions to each examinee.

CAT is now widely used for the administration of the Graduate Record Examinations (GRE) and other large-scale tests, and dichotomous response items are used in the item pool in most cases because of the ease of writing items (questions). However, if we include several items that can be graded polytomously, presenting them to the examinee in the initial stage of CAT and analyzing the examinee's performance using a graded response model, CAT becomes more efficient because these graded response items direct the examinee closer to his or her true position on the latent trait scale with higher probabilities.

Figure 3 illustrates the shift of $\hat{\theta}_v$, the MLE of the individual parameter θ , in CAT after the presentation of each selected item, using simulated data for each of two hypothetical examinees who have the same (true) ability level, $\theta = 54.8$. The hypothetical item pool consists of dichotomous response items following the normal ogive model whose ICF, defined by Eq. (6), is identical with the cumulative operating characteristic, $P_{x_g}^*(\theta)$, in the normal ogive model for graded responses provided by Eq. (7), with the replacement of the item response difficulty parameter b_{x_g} by the item difficulty parameter b_g and of the density function ψ by the standard normal density function. For the first examinee (hollow circles), six to nine items were needed before $\hat{\theta}_v$ converged to the true θ , whereas for the second examinee (black square) as many as thirteen or more items were needed before $\hat{\theta}_v$ reached this stage. Note that with dichotomous items, after the examinee has answered the first question in CAT the current $\hat{\theta}_v$ is either negative infinity or positive infinity, depending on whether the answer is incorrect or correct. Although for the first examinee in Figure 3 this happened solely after the first item presentation, for the second examinee

Figure 3 Shifts of the maximum likelihood estimate of ability after each dichotomous response item has been presented and responded to, for two hypothetical examinees with equal ability levels, 54.8.

the item score continued to be zero up to the fourth item, and thus the corresponding $\hat{\theta}_v$ were uniformly negative infinity, which cannot be plotted in the figure. It is expected that, if graded response items are presented on the initial stage of CAT instead of dichotomous response items, the convergence of $\hat{\theta}_v$ to the true θ will be facilitated and that the slow convergence with substantial discrepancies between the current $\hat{\theta}_v$ and the true θ illustrated by the second examinee in Figure (3) will be substantially less likely to happen.

Very few researchers have paid attention to the fact that the amount of test information can be reduced unless the estimation of θ is done directly from the response pattern. Let T be any aggregate (union) of response patterns, and t denote its realization. Because the response patterns are disjoint, the operating characteristic of $T = t$ becomes:

$$P_t(\theta) = \sum_{v \in t} P_v(\theta). \quad (26)$$

Let $I^*(\theta)$ denote the test information function based on such an aggregate t instead of each response pattern v . This is obtained by replacing $P_v(\theta)$ in the fourth expression of Eq. (25) by $P_t(\theta)$, given by Eq. (26). For these two test information functions, there exists the relationship:

$$I(\theta) \geq I^*(\theta). \quad (27)$$

Eq. (27) has an important implication because the reduction in the amount of test information leads to the inaccuracy of the estimation of θ . A good example of the aggregate T is the test score, which is the sum total of the $n x_g$ values in $V = v$. Because the reciprocal of the square root of the test information function can be used as an approximate local standard error of estimation, it is obvious from Eq. (27) that the accuracy of the estimation of the latent trait θ will be reduced if the test score is used as the intervening variable. Thus, it is essential that θ be estimated directly from the response pattern, not from the test score.

It should also be noted that the item response information function $I_{x_g}(\theta)$ and the response pattern information function $I_v(\theta)$, which are defined by Eqs. (22) and (24), respectively, have important roles in the estimation of the latent trait θ based on the subject's response pattern v . For example, even if $I_{x_g}(\theta)$ of one or more x_g that belong to the response pattern v assumes negative values for some interval(s) of θ , the item information function $I_g(\theta)$ that is defined by Eq. (23) will still assume non-negative values for the same interval(s), as is obvious from the far right-hand-side expression in the equation. The consideration of this fact is especially necessary in programming CAT to select an item to present to an individual subject when the three-parameter logistic model is adopted for multiple-choice test items in the item pool.

These information functions and observations can be considered extensions of Fisher information functions. In most of the statistics literature, however, the discussion and theorizing concern a restricted situation in which all observations are based on a random sample from a *single* distribution. In the context of IRT, however, such a situation will not happen unless all items are equivalent, which can be stated on the graded response level as: (1) all the n items have the same values of m_g , and, moreover, (2) the sets of $(m_g + 1)$ operating characteristics for the n separate items are all identical. In most research based on IRT, we need a variety of different sets of operating characteristics, and thus the assumption of equivalence of the n items is not acceptable.

To make the information functions useful in the context of IRT, therefore, the theorems based on a random sample will have to be expanded to apply to cases in which separate observations come from separate distributions, combined with the principle of local independence, which states that the conditional distributions of item scores, given θ , are independent of one another.

With some research data, the assumption of local or conditional independence can also go beyond the level of tolerance. There are ways of ameliorating the situation in pilot studies, however, by modifying or even replacing one or more items, without affecting the contents of the latent trait. Items are human-made, and they are only tools for measuring the individual's latent trait, so such modifications are perfectly justifiable.

In addition, in the statistics literature very little attention is paid to the information provided by individual responses. In IRT, however, the item response information function, $I_{x_g}(\theta)$, is very important because the item responses are the elements of a specific response pattern $V = v$, on which the individual parameter θ is estimated. Credit should be given, however, to the few exceptions to this (such as Lindgen's 1976 study), in which such information is presented and discussed in the context of a random sample from a single distribution.

Unique Maximum Condition for the Likelihood Function

The beauty of IRT lies in that, unlike classical test theory, θ can be estimated straightforwardly from the response pattern, without the intervention of the test score. Let $A_{x_g}(\theta)$ be:

$$\begin{aligned} A_{x_g}(\theta) &\equiv \frac{\partial}{\partial \theta} \log P_{x_g}(\theta) \\ &= \sum_{u \leq x_g} \frac{\partial}{\partial \theta} \log M_u(\theta) + \frac{\partial}{\partial \theta} \log [1 - M_{(x_g+1)}(\theta)]. \end{aligned} \quad (28)$$

Because, from Eqs. (21) and (28), the likelihood equation can be written:

$$\begin{aligned}\frac{\partial}{\partial \theta} \log L(x | \theta) &= \frac{\partial}{\partial \theta} \log P_v(\theta) \\ &= \sum_{x_g \in v} \frac{\partial}{\partial \theta} \log P_{x_g}(\theta) \\ &= \sum_{x_g \in v} A_{x_g}(\theta) \equiv 0\end{aligned}\quad (29)$$

a straightforward computer program can be written for any model in such a way that $A_{x_g}(\theta)$ is selected and computed for each $x_g \in v$ for $g = 1, 2, \dots, n$ and added, and the values of θ that makes the sum total of these n functions equal to zero are located as the MLE of θ for the individual whose performance is represented by v . Samejima called $A_{x_g}(\theta)$ the basic function, because this function provides the basis for computer programming for estimating θ from the response pattern v .

From Eqs. (28) and (29), it is obvious that a sufficient condition for the likelihood function to have a unique modal point for *any* response pattern is that the basic function $A_{x_g}(\theta)$ be strictly decreasing in θ , with a nonnegative upper asymptote and a nonpositive lower asymptote. It can be seen from Eqs. (22) and (28) that this unique maximum condition will be satisfied if the item response information function $I_{x_g}(\theta)$ is positive for all θ , except at a finite or enumerably infinite number of points.

The normal ogive model, the logistic model, the logistic positive exponent model, the acceleration model, and models derived from Bock's nominal response model all satisfy the unique maximum condition. Notably, however, the three-parameter logistic model for dichotomous responses, which has been widely used for multiple-choice test data, does not satisfy the unique maximum condition, and multiple MLEs of θ may exist for some response patterns.

Discussion

A strength of the graded response model in IRT is that it can be used in many different types of research, and there is still room for innovation. In doing so, model selection for specific research data should be made substantively, considering the nature of the data and the characteristics of the models.

Graph Theory

Stephen C. Locke

Florida Atlantic University, Boca Raton, Florida, USA

Glossary

algorithm A procedure for solving a problem.

bipartite graph A graph that has two classes of vertices; for example, vertices may represent men and women, with the additional property that no edge joins two members of the same class.

connected A graph is connected if for each pair of vertices, there is a path from one to the other.

cycle A route, using at least one edge, that returns to its starting point, but does not repeat any vertex except for the first and the last.

directed graph A generalization of a graph, in which some edges may have directions; similar to one-way streets in a city.

edge A connection between a pair of vertices, denoting that the two vertices are related in some way.

heuristic A procedure for obtaining an approximate solution to a problem.

matching A pairing of some vertices, so that the vertices in each pair are joined by an edge.

NP-complete A set of problems currently assumed to be computationally difficult; a subset of nondeterministic polynomial (NP)-time.

path A route that can be followed from one vertex to another by means of edges between successive vertices of the path.

simple Without loops or multiple edges.

tree A connected graph with no cycles.

vertex A basic element of the graph, possibly representing physical objects or places.

A graph can be thought of as a representation of a relationship on a given set. For example, the set might be the set of people in some town, and the relationship between two people might be that they share a grandparent. Graph theory is the study of properties of graphs. In particular, if a graph is known to have one property, what other properties must it possess? Can certain features of the graph be found in a reasonable

amount of time? In this article, a few of the more common properties of graphs and some theorems relating these properties are mentioned, with reference to some methods for finding structures within a graph.

History

The river Pregel flows through the city of Königsberg (Kaliningrad). In the middle of the river is an island, the Kneiphof, after which the river branches. There are seven bridges over various parts of the river. The citizens of the town enjoy strolling through the city and are curious whether there is a route that crosses each bridge exactly once. This problem, a popular mathematical game known as the “Königsberg Bridge Problem,” was solved by Leonhard Euler in 1736, and, in doing so, Euler stated the first theorem in the field of graph theory.

Another popular amusement is the “Knight’s Tour Problem”: can a knight travel around a standard chessboard, landing on each square exactly once, and returning to its initial square? This problem was treated by Alexandre-Theophile Vandermonde in 1771. A similar problem using the vertices and edges of a dodecahedron was marketed as the “Icosian Game” by Sir William Rowan Hamilton in 1857. The game was a flop, but over 1600 research papers on Hamilton cycles (cycles through all of the vertices) have since been published, and thousands more papers have explored related topics.

The word “graph” is derived from “graphical notation,” introduced by Alexander Crum Brown in a paper on isomers in 1864. Crum Brown was a contemporary of Arthur Cayley and James Joseph Sylvester, who used related graphs to study chemical properties. One of the most notorious problems in graph theory originated in 1852, when Frederick Guthrie asked his professor, Augustus De Morgan, whether four colors were always sufficient to

color the regions of a map drawn on a sphere. A mere 124 years later, Wolfgang Haken and Kenneth Appel finished the proof with extensive assistance from a computer program. There is, of course, an ongoing debate among mathematicians whether a computer-assisted proof should be accepted if the resulting proof is so lengthy that most mathematicians would not have time to read the entire proof. In other areas of mathematics, there are theorems with long, human-constructed proofs. Andrew Wiles wrote a 200-page proof of a 400-year-old number theoretic conjecture by Fermat. The record length for a proof done entirely by humans is 15,000 pages (for the classification of simple groups). It is expected that this proof can be condensed to 3000 pages.

In 1890, Percy John Heawood extended the idea of map-coloring problems to consider colorings on surfaces other than the sphere. For example, seven colors suffice for coloring regions on a torus (a doughnut). It is perhaps counterintuitive that the torus is easier to handle than the sphere. Heawood provided the upper bound for all of the orientable (two-sided, like a sphere or torus) surfaces and a few years later Heinrich Tietze provided the upper bound for the nonorientable (one-sided, like a Möbius strip) surfaces.

Notation

Figure 1 is a labeled graph depicting the relationships between various pairs of people. In the figure, vertices representing people have been drawn as small open circles, and an edge (connection) between two vertices indicates that the two people have spoken to each other. Thus, for example, Brad has spoken with Janet, and both have spoken with Frank. It would be easy to modify the picture to record that the interchanges had been in one direction. An arrow on the edge from Brad to Janet, pointing in the direction of the communication, would show that Brad has spoken to Janet, but Janet did not respond. To show that Brad spoke to himself, an edge (loop) could be drawn from Brad back to Brad. Five edges (a multiple edge) could also be drawn from Brad to Janet if they have spoken on five occasions. In the following discussions, unless otherwise specified, only simple graphs—those that are undirected, loopless, and lacking multiple edges—are considered.

Graph theory notation is not completely standardized and the reader should be aware that vertices may sometimes be called “nodes” or “points,” and edges may be called “lines” or “links.” Graphs can be used to model social relationships, transportation networks, hierarchies, chemical or physical structures, or flow of control in an algorithm. Perhaps one of the largest examples of a (directed) graph that many people use every day is

Figure 1 A graph depicting the relationships between pairs of people. Vertices representing people have been drawn as small open circles; an edge (connection) between two vertices indicates that two people have spoken to each other.

the World Wide Web. The files are the vertices. A link from one file to another is a directed edge (or arc).

Several properties of graphs can be studied. In Fig. 1, Frank and Janet would be called neighbors of Brad. If Brad wished to get a message to Moose, he could tell Janet, who would pass the message along to Rocky, and then Rocky would give the message to Moose. This describes a path from Brad to Moose. In this figure, there is a path connecting any two of the vertices and the graph is connected, or the graph has one component. The number of edges in the path is its length. The length of a shortest path between any two vertices is the distance between those vertices. The diameter of a graph is the maximum number that occurs as a distance. Figure 1 has diameter 3, because there is no path from Brad to Moose using fewer than three edges, but for every pair of vertices the path length is at most three. There are Internet web sites that will compute the driving distance between any two points in the United States. A famous metaconjecture (and movie title, “Six Degrees of Separation”) proposes building a graph similar to the example in Fig. 1, but with each person in the United States as a vertex, and edges between two people if they normally communicate with each other; that graph should have diameter 6 at most. This is a metaconjecture because it would take a great deal of trouble to prove it—the graph would be constantly changing and it would never be quite correct.

In Fig. 1, if Rocky were to move away from the social circle, Brad, Janet, and Frank could still communicate with each other, but Moose and Adrian would have no route for their communications, nor could they talk to the other group. Rocky would thus be defined as a cut vertex, i.e., a vertex that increases the number of components when deleted (in this case, disconnecting the graph). If both Frank and Janet were to leave, instead of Rocky, there would again be no way for Brad to communicate with Moose. Thus {Janet, Frank} is a cut set of vertices. Now, consider removing edges instead of vertices. Suppose that Rocky and Adrian have an argument and are unwilling to speak to each other. Then, there would be no way for, say,

Janet and Adrian to interact. The edge from Rocky to Adrian is a cut edge, i.e., an edge that increases the number of components when deleted. The two edges from Rocky to Janet and Frank constitute a cut set of edges.

Next consider Fig. 1 as representing members of a committee, with an edge between those pairs who are willing to work together. Perhaps some of the members of the committee need to pair off for some important tasks. For example, Brad (B) and Janet (J) could work together and Rocky (R) and Adrian (A) could work together. The juxtaposition of two letters will refer to the edge between the two vertices labeled by the letters of the committee members' names. The set {BJ, RA} is a matching or independent set of edges. A perfect matching, or 1-factor, is a matching that includes all of the vertices. Figure 1 does not have a perfect matching, but if an edge between Adrian and Moose is included, a perfect matching could then be found.

A complete graph is a graph in which every vertex is a neighbor of every other vertex. A subgraph of a graph consists of a subset of the edge set and a subset of the vertex set, with the proviso that both ends of every edge must be included. In Fig. 1, one of the subgraphs would be obtained by taking the edges {BJ, JF, BF} and the vertex set {B, J, F}. This subgraph is complete. Because it is not contained in any larger complete subgraph, it is sometimes called a "clique." The reader is encouraged to identify the four cliques in Fig. 1.

A set of vertices, no two of which are joined by an edge, is called an independent set of vertices or a stable set of vertices. There are 17 nonempty stable sets in Fig. 1; 6 of these have one vertex each, 8 have two vertices, and 3 have three vertices. The complement of a simple graph is the graph with same set of vertices, but with an edge between two vertices if and only if there was no edge in the original graph. The complement of the graph of Fig. 1 would have eight edges: AM, AJ, MJ, AB, MB, AF, MF, and BR. Maximal stable sets in any graph correspond to cliques in its complement.

A graph is bipartite if its vertex set can be partitioned into two sets X and Y , such that no edge has both ends in X or both ends in Y . The pair (X, Y) is called a bipartition of G . Suppose the vertices in X represent people and those in Y represent jobs and that an edge from person P to job J means that person P is capable of completing job J . We might wish to assign people to jobs so that nobody gets more than one job, and no two people get the same job. That is, we ask for a matching in this bipartite graph. If the edges are assigned weights representing the value to the company of that person doing that job, we might ask for a maximum weight matching. For a set S , we write $|S|$ for the cardinality (number of elements of) of S .

A k -edge-coloring of a graph G is an assignment of a color (number) from $\{1, 2, \dots, k\}$ to the edges of G so that each edge receives exactly one color. It is not

necessary to use all k colors. A proper k -edge coloring is one for which no two edges of the same color meet at any vertex; G is k -edge colorable if G has a proper k -edge coloring. A k -coloring of a graph G is an assignment of a color (number) from $\{1, 2, \dots, k\}$ to the vertices of G so that each vertex receives exactly one color. Again, it is not necessary to use all k colors. A proper k -coloring is one for which no two vertices of the same color are adjacent; G is k -colorable if G has a proper k -coloring. If G is a bipartite graph with bipartition (X, Y) , and if the vertices of X are colored red and those in Y are colored blue, the graph would have been properly 2-colored, because no edge would have both ends of the same color.

Suppose the vertices in the graph G represent courses at a university, with an edge joining two courses if some student is enrolled in both courses. At exam time, it is necessary to schedule the exams in k time slots, so that no student has two exams at the same time. If it is possible to schedule the exams with no conflicts, the assignment of time slots from $\{1, 2, \dots, k\}$ to the courses is a proper k -coloring of G . The vertices of a bipartite graph could also be used to represent the instructors at a high school and the classes they have to teach. The colors of a proper edge-coloring could designate the time slots in the school day.

Colorings have also been used to speed up testing for short-circuits on circuit boards. Two points within a certain specified distance might short, but two at greater distance are unlikely to short. In the graph representing the circuit board, an edge between two vertices that could short would be drawn. If the points are properly colored, with points that are adjacent designated by different colors, it is possible to test if there is any current flow between all the points of one color and all of the points of another. (Imagine a device designed to touch all of the red vertices simultaneously, and another designed to touch all of the blue.) Current flow between the set of red vertices and set of blue vertices would indicate that there is a short on the board. No flow for any pair of colors could reasonably ascertain that there is no short-circuit. Among the other uses for colorings are optimization of assignment of variables to registers by computer language compilers.

Consider an ant starting at a vertex of a graph G and crawling along the edges of G from one vertex to another. A cycle of G is the route traversed by the ant if that route uses at least one edge, repeats no edges or internal vertices (vertices of the cycle, which are neither the first nor the last vertex of the cycle), and returns to where it started. An alternative definition of a cycle is that it is a graph with an equal number of vertices and edges, and the vertices can be placed around a circle so that two vertices are adjacent if and only if they appear consecutively along the circle. A tree is a connected graph with no cycles. A forest is a graph with no cycles (a collection of trees). A Hamilton cycle of a graph is a cycle that passes through

every vertex. A graph that has a Hamilton cycle is called hamiltonian. The “Traveling Salesman Problem” seeks to find the minimum-weight Hamilton cycle in a graph that has edges with weights. Although this may seem a bit artificial, there is an application: in some manufacturing processes, it is necessary for a robotic arm to visit 100,000 sites on each article manufactured, and it is essential to have the trip take as little time as possible.

Algorithms

Having a list of problems that can be addressed with the language of graph theory is a useful end in itself. Even better, once a problem has been identified, problems of a similar nature can be sought. Often, these problems have been solved, and there will be an algorithm available. An algorithm is a finite, terminating set of instructions to solve a given problem. An algorithm is of order $T(n)$, or $O(T(n))$, if there is a constant c , such that for any input of size n , the algorithm takes no more than $cT(n)$ steps to complete its task, as long as n is large enough. If $T(n)$ is a polynomial in n , the algorithm is polynomial-time, or good. There is a special, very well-studied class of yes/no problems for which there are no known good algorithms, but the existence of a good algorithm for any one problem in the class would give a good algorithm for all problems in the class. This is the class of NP-complete problems (the technical definition of which is complicated and beyond the scope here). If a mathematician is having difficulty solving a problem from this class, the excuse that nobody else knows how to do it efficiently either is a good excuse!

Consider now some of the standard problems from graph theory, starting with some NP-complete problems. Assume in each case there is a graph G , and in some cases, there is an integer k :

1. Does G have a Hamilton cycle?
2. Does G have an independent set of k vertices?
3. Does G have a complete subgraph on k vertices?
4. Can the vertices of G be properly colored with k -colors, where $k \geq 3$?

These questions (problems) all have yes/no answers. If, for example, we wanted to see a Hamilton cycle, an independent set or complete graph of the specified size, or a proper k -coloring, this is at least as difficult. Such problems are called NP-hard. For these problems, we must settle for approximation algorithms, heuristics, or brute force.

Some Elegant Theorems

There are polynomial-time algorithms to address the problems discussed next. For simplicity, the algorithms

are not displayed, and the fastest algorithm to solve each problem is not necessarily presented.

1. Given a maze (labyrinth), consider the intersections as vertices and the passages between intersections as edges. If the entire maze is visible, a way out of the maze can be found, or it can be shown that no way out exists, by using Dijkstra’s algorithm. Dijkstra’s algorithm states that, given a graph G and a vertex v in G , the distances from v to all other vertices in G in $O(n^2)$ time can be found. A bipartite graph can be characterized as one that has no cycles with an odd number of edges. A minor variant of Dijkstra’s algorithm can be used to either find an odd cycle in a given graph or to find a bipartition of that graph.

2. Ford–Fulkerson algorithm. Given a graph G , the distances between every pair of vertices in G in $O(n^3)$ time can be found.

3. The southeastern coast of Florida has more than occasional heavy rain. Covered walkways between buildings are very useful. If the cost of connecting each pair of buildings by a walkway is known, the cheapest way to connect the buildings using walkways between pairs of buildings can be calculated so that it is always possible to walk from one building to another by some sequence of walkways. To minimize the cost, there would be no cycles. Thus, a minimum weight spanning (reaches all buildings) tree is sought. If it is allowed to choose some extra locations and build walkways to those locations as well as using direct connections, the problem becomes much harder. This Steiner tree problem is NP-hard.

Kruskal’s algorithm. Given a graph G , with weighted edges, a minimum weight spanning tree in G in $O(n^2)$ time can be found.

4. A set S isolates a vertex w if all of the neighbors of w are members of S . A set of vertices C is a cover if every edge has at least one end in C .

Consider operating a dating service; it has already been determined which pairs of people are suitable as a couple. Presuming interest only in the pairings of males with females, the data could be represented as a bipartite graph. Assume also that no person will be matched with more than one other person. This case is a matching in a bipartite graph. Hall’s theorem and König’s theorem give conditions on a maximum matching. These theorems yield algorithms that quickly find maximum matchings. The reader will notice that conditions have been introduced that may not exist in the original problem (male–female matching, no multiple partners). Adapting a known algorithm to fit the particular problem may be necessary. If weights are placed on the edges, perhaps to show a compatibility index between the people using the dating service, maximum weight matching could be attained, with the hope that the solution provided provides the best satisfaction level overall. Again, presuming the

graph is bipartite, this is the same problem as given in the problem of assigning jobs, mentioned previously.

Hall's matching theorem. If \mathbf{G} is a bipartite graph, with bipartition (\mathbf{X}, \mathbf{Y}) , then \mathbf{G} has a matching that meets every vertex of \mathbf{X} if and only if no subset \mathbf{S} of \mathbf{Y} isolates more than $|\mathbf{S}|$ vertices of \mathbf{X} . An easy consequence of Hall's theorem is that if a bipartite graph has maximum degree Δ , then it is Δ -edge-colorable. Obviously, any color class of a proper \mathbf{k} -edge-coloring of a graph \mathbf{G} is a matching. This edge-coloring can be thought of as having the following meaning: In time slot one, the edges of the first color give us a matching; in time slot two, the edges of the second color give us a matching; etc. This could be useful for scheduling examinations or for designing an experiment.

König–Egervary matching theorem. If \mathbf{G} is a bipartite graph, then the cardinality of a maximum matching equals the cardinality of a minimum cover. There is a polynomial-time algorithm to find a maximum matching \mathbf{M} in a bipartite graph and a corresponding cover \mathbf{C} . This is exceptionally elegant and useful;—it not only provides a method of finding the primary object (\mathbf{M}), but also receives a certificate (\mathbf{C}) to prove that \mathbf{M} is optimum. If \mathbf{M} and \mathbf{C} are passed to another person, that person does not have to understand how the algorithm works. The only requirement is to check that \mathbf{M} is a matching, \mathbf{C} is a cover, and that $|\mathbf{M}| = |\mathbf{C}|$. The Kuhn–Menkres algorithm produces similar solutions for weighted bipartite graphs in $\mathbf{O}(n^4)$ time. These results and other minimax theorems using network flows can be considered as special cases of the fundamental theorem of linear programming.

5. Consider the job of setting up a round-robin chess tournament. People can be paired in round one, possibly with some people not playing that round. Then, pairing is done a different way for round two, etc. In effect, this is asking for a coloring of the edges of a complete graph. In a more general case, a way to color the edges of an arbitrary simple graph might be sought. It is obvious that at least as many colors as the edges meeting any vertex are needed. Surprisingly, many more are not needed.

Vizing's theorem. If a simple graph has maximum degree Δ , then it is $(\Delta + 1)$ -edge-colorable. Suppose that a zoo is being built and putting certain animals together, if one is likely to eat the other, must be avoided. The animals could be represented as vertices in a graph and two animals would be connected if they are not compatible. The number of habitats needed is the number of colors needed to color the vertices of the graph.

6. Brooks' theorem. If a simple graph \mathbf{G} has maximum degree Δ , then it is Δ -colorable, unless \mathbf{G} is an odd cycle or a complete graph. In this latter case, $\Delta + 1$ colors are necessary and sufficient.

7. Having mentioned matchings in bipartite graphs, consider nonbipartite graphs, for which Tutte's theorem applies. To actually find a maximum matching, Edmonds algorithm can be used. Tutte's matching theorem states

that if \mathbf{G} is a graph, then \mathbf{G} has a matching that meets every vertex of \mathbf{G} if and only if for every subset \mathbf{S} of $\mathbf{V}(\mathbf{G})$ the number of odd components of $\mathbf{G} - \mathbf{S}$ is at most $|\mathbf{S}|$.

8. Ramsey's theorem. Any sufficiently large graph has a complete subgraph on \mathbf{k} vertices, or an independent set of \mathbf{k} vertices.

9. Dirac's theorem. If every vertex of the simple graph \mathbf{G} has degree at least \mathbf{k} , and if \mathbf{G} has at most $2\mathbf{k}$ vertices, then \mathbf{G} is a hamiltonian.

Unsolved Problems

In many areas of mathematics, it takes years of study to reach the point where it is possible to understand the interesting unsolved problems. In graph theory, a few hours of study already leads one to unsolved problems. The four-color problem, mentioned previously was unsolved for 140 years, yet it takes little to understand the statement of the problem. Bondy and Murty made up a list of 50 unsolved problems in 1976, and most of those problems are still open today. The two following problems interest many researchers.

1. The "cycle double cover problem": If a graph has no edge whose deletion disconnects the graph, is there a collection of cycles that together contain every edge exactly twice? If a graph can be drawn in the plane, and if that graph has no edge whose deletion disconnects the graph, then the faces of the graph are cycles that together contain every edge exactly twice.

2. The "reconstruction problem": Given the deck of a graph on at least three vertices, can we determine uniquely what the original graph was? Given a graph \mathbf{G} , with vertices $\mathbf{v}_1, \dots, \mathbf{v}_n$, let \mathbf{G}_k denote the subgraph of \mathbf{G} obtained by deleting the vertex \mathbf{v}_k . Now, draw these vertex-deleted subgraphs, $\mathbf{G}_1, \dots, \mathbf{G}_k$, as unlabeled graphs, each on a separate index card. This is called the deck of \mathbf{G} .

Further Reading

The books by Chartrand (1985) and Trudeau (1976) are accessible to high school students. For an undergraduate or beginning graduate presentation, Bondy and Murty (1976) or West (2001) would be useful. For further information on algorithms, see Even (1979). At the graduate level, there are texts on algebraic graph theory, algorithmic graph theory, cycles in graphs, graphical enumeration, matroid theory, random graphs, topological graph theory, as well as texts on specific unsolved problems.

Graunt, John

Philip Kreager

Somerville College, Oxford University, Oxford, England, United Kingdom

Glossary

life expectation The average number of additional years a person would live, when the rate of mortality indicated by a given life table holds.

life table A detailed descriptive model of the mortality of a population, giving the probability of dying at each age; 17th- and 18th-century tables were based on the assumption that populations are stationary, i.e., their total number and age distribution are constant.

natural history The scientific study of animals and plants based on observation rather than on experiment.

scholasticism Teaching based on the medieval university framework of the trivium (grammar, logic, and rhetoric) and quadrivium (mathematical arts of arithmetic, geometry, astronomy, and music); although developed originally in the context of theology and philosophy, Scholastic models continued to shape school curricula into the 17th century.

John Graunt's *Natural and Political Observations upon the London Bills of Mortality*, published in 1662, marks the inception of scientific social measurement. Immediate acclaim at the time of publication of the work led the Royal Society to make Graunt a charter member, and a long line of analysts from Farr and Pearson to Glass and Kendall have not hesitated to declare him the founder of statistics and demography. Graunt's book defined the direction of early modern numerical description and analysis of society, in which the state was seen as a population possessed of inherent quantitative regularities, natural in kind, but susceptible to political, medical, and economic management. Many of the quantitative measures Graunt invented, and his critical scrutiny of available numerical sources, make his population arithmetic appear modern. His work quickly became central to developments in the nascent calculus of probability. In the process, one of his

inventions (a hypothetical table of mortality by age) was elaborated to become demography's fundamental population model (the life table). Yet the concepts of method Graunt employed and the idea of population he developed differ profoundly from demography and statistics as they emerged much later, in the 19th and 20th centuries. The enduring importance of his work rests not only on its seeming anticipation of many aspects of later methodology, but on the originality and distinctiveness of his conception and what it can tell us about the nature of quantitative social inquiry.

The Historical Context of the *Observations*

John Graunt (1620–1674) wrote at a time when scientific uses of mathematics, confined largely to chemistry, astronomy, and physics, were commonly bound up with religious questions, alchemy, and astrology. The idea of a science of social and economic life was unformulated, and specialized disciplines such as demography and statistics were inconceivable. That man should develop mathematics in order to intervene into patterns of life and death was morally and theologically dubious to the great majority of Graunt's contemporaries. Graunt was, in any case, expressly not proficient in the new natural sciences, nor in higher mathematics. Yet he was able to compose a method of measuring populations that excited Huygens, Leibnitz, Halley, and other distinguished mathematicians and natural scientists of the time. The sensation Graunt's work created was not confined to the elite. Despite its unprecedented and questionable subject matter, and a text composed largely of computations and sustained quantitative reasoning, the *Observations* immediately attracted a wide readership, going through three

reprintings by 1665, and subsequent editions, translations, excerpts, and summaries over the course of the next century. Graunt's own life and the stated purposes of his work direct us to the contemporary issues that gave population arithmetic its immediate importance.

Biographical Note

The fragmentary but coherent record of Graunt's life owes largely to the careful research of David Glass. The story is at once brilliant and tragic. Graunt's formal education was limited to common schooling, based at the time on the Scholastic curriculum of logic and rhetoric. His mathematics was confined to bookkeeping arithmetic, learned presumably when apprenticed at age 16 to his father's London haberdashery business. From these modest beginnings, Graunt rose to be a respected London figure, holding a number of senior offices in the city council and the merchant community, and gaining a reputation as a shrewd and fair arbitrator of trade disputes. Graunt's success coincided with the period of the English Commonwealth, the period of religious and civil conflict that divided the country following the execution of Charles I. Graunt was a junior officer in Cromwell's forces, and knowledgeable in the dissenting faith of Socinianism, which denied claims to divine authority made by monarchists and the church, in favor of more egalitarian ideals. Contemporaries record Graunt as an assiduous scholar, competent in Latin and French, and articulate and witty across a range of philosophical, artistic, and economic topics. His independent learning and reputation in the city brought Graunt into contact with Royal Society members (who likewise had combined interests in science and trade), notably William Petty, for whom Graunt was able to use influence to secure a professorship in the 1650s.

English society by the early 1660s, however, had arrived at an important point of transition. The restoration of the monarchy in 1660 put an end to the Commonwealth. Religious and political differences, over which many lives had been lost, remained critical in science as well as in government, but there could be much tolerance for privately held views. The method of the *Observations*, as will be discussed later, reflects the ambivalence of Graunt's position at this time. It is noteworthy that his membership in the Royal Society, almost unique for merchants at the time, was favored expressly by Charles II. The new king's support would have certainly helped to alleviate any questions concerning Graunt's past. Yet, in the early 1670s, Graunt's life took an abrupt turn. Converting publicly to Catholicism, he rejected religious moderation and science, and alienated himself from most friends and contemporaries. Suffering financial ruin, Graunt died shortly thereafter in poverty.

Avowed Aims of Graunt's Text

The reasons underlying the reversal of Graunt's fortunes will probably never be known for certain. The tensions experienced by an acute and original mind, however, in an era in which the need to accommodate science, politics, and religion was an overriding concern, are evident in his text. The *Observations* is prefaced by two dedicatory letters that, despite their adroit use of literary conventions, do not quite conceal the conflicting orientations of the work. The first, addressed to a Minister of the Crown, concerns the usefulness of Graunt's many specific findings for government, particularly as they relate to defense, trade, disease, and the person of the King. Graunt here adopted the customary terminology of the body politic, which recurs in his text. By this long-established convention, the King is likened to the head and soul of the state; the strength of the body politic depends on the relative size and balanced proportion of its members, or population. Graunt's conventions were well chosen. The idea that a well-balanced polity implies a justly governed one had wide currency at the time, cutting across all political persuasions from critics of monarchy to believers in the divine right of kings. Good government, by general agreement, was government in conformity with natural law and God's will.

What was new was that Graunt's arithmetic opened up for the first time the possibility of taking these traditional images seriously, and showing precisely what proportions actually exist. The text of the *Observations* demonstrates repeatedly and in considerable detail the presence of enduring natural balances (for example, in sex ratios, reproductive levels, and causes of death). Where his ratios might be interpreted to imply imbalance (e.g., in certain causes of death, or the excessive growth of London relative to the kingdom as a whole), Graunt carefully stressed the regularity of numerical series over the long term. Evidence of natural order and national strength thus appeared to give consistent support to existing sovereign rule. The sensitivity of the subject is nonetheless acknowledged in the concluding sentence of the *Observations*, in which Graunt leaves the King and his ministers to decide whether such evidence should be confined to themselves.

Graunt addressed his second dedication to the President of the Royal Society. Here he acknowledges the methodological inspiration of his work in Baconian natural history. Francis Bacon, whose work directly inspired the Society, emphasized the importance of direct observation, of numerical representation, and of open methods of exposition that allow any experienced observer to test other researchers' evidence. Like Bacon, Graunt did not always succeed in adhering to these precepts, but his step-by-step presentation of numerical evidence and analysis follows Bacon's respected methodology closely. Bacon wrote a natural history concerned

with the vital forces that enable some people to live longer than others do, and Graunt's text, in proposing a natural arithmetic of life and death, followed logically from this. Graunt, moreover, encouraged readers to use his numerical evidence and methods to develop observations of their own. Knowledge of the population of a state is at base a scientific matter that his method opens to anyone prepared to follow it. This line of reasoning led Graunt to conclusions more consistent with his Socinianism than with his first dedication. The second dedication ends with a comparison of observation to political representation. Graunt likens the Royal Society to a "Parliament of Nature," saying that even though an observer like himself may be a mere commoner, he and his observations are entitled to be represented by the Society. The role of such a "parliament," by implication, is to serve as a forum in which proportional balances in the body politic may be discussed openly, so that scientific knowledge of natural forces can be brought to bear on whether governments actually pursue just policies that conform with nature.

The Method of the *Observations*

For more than a century before Graunt, the humanist writings that initiated the modern theory of the state had sought to define a legitimate basis for human government, a problem that well after Graunt continued to be concerned chiefly with defining proper relations between rulers and subjects. By Graunt's time, the need to control population distribution, size, and growth for political and economic purposes was generally recognized as a central difficulty in such relations, but the problem of means to reliable knowledge of population had not been broached. Graunt, writing in a context in which issues of legitimacy were unquestionably alive, broke new ground in European thought by restating the issue primarily in quantitative and scientific terms. More than this, Graunt's contribution was to see the specific problems that population raised as a question of method: such problems could be resolved at least in part by regular, replicable procedures applied from the level of the state down to particular subpopulations sharing specific vital, economic, or other characteristics.

Almost two centuries passed before national censuses and registration systems enabled Graunt's conception of a state, defined and evaluated by quantitative parameters, to become common practice, and before "statistics" became synonymous with quantitative data and its analysis. It is easy to forget that in the world in which Graunt wrote he needed to improvise terms if his new way of thinking was to be intelligible. In the absence of general terms of quantitative reference (e.g., wherein nouns such as "data," "population," and "statistics" would now be used), Graunt adopted customary bookkeeping phraseology

("accompts"), or stuck to popular usage ("inhabitants," "people," "city," "the whole pile"). Conventional formulas such as "the body politic" had to suffice for discussion of structural relationships in society. Standards of argument drawn from established rhetorical procedures enabled Graunt to develop his "observations," based on methods of natural history, as persuasive "positions," and to demonstrate, for example, why the sex ratio is the "true *ratio formalis* of the evil of adulteries and fornications." Unacquainted with the advanced mathematics that contemporary probabilists such as Pascal were developing, Graunt dealt with differing chances of death using the arithmetic that merchants employed to assess the "hazard," "odds," or "even lay" of risky business ventures.

Histories of statistics and demography have ignored, until recently, the imaginative process Graunt needed to create and present the first method of quantitative social inquiry. The focus instead has been on picking out those features that anticipate modern practice, and then assessing their limitations in light of current techniques. Three enduring accomplishments have been noted. Glass called attention to the "characteristically statistical" critical apparatus Graunt developed to evaluate and adjust 17th-century enumerations. For Sutherland, the *Observations* constituted "a methodology of descriptive statistical analysis" that included many later demographic measures and concepts. And Pearson, noting that Graunt's analysis "depends on the stability of statistical ratios," saw his method as grounded implicitly in mathematical statistics. Graunt's ability to reason along statistical lines almost two centuries before the emergence of demography and mathematical statistics testifies to the power of his vision. Yet the question of how he devised his method, and what it was, cannot be answered by projecting later developments back onto his work. How he arrived at his insights becomes understandable once they are considered in light of the three ideas of method, current in the 17th century, which shaped his text.

Baconian Natural History and Graunt's Critical Apparatus

The Bills of Mortality kept by London parish clerks provided Graunt with a substantial record of burials and baptisms from 1603 to 1660, distributed by locality and including causes of death from 1629. He supplemented this record with registers from a rural parish in Hampshire and added other sources in later editions. The difficult problems of how to present such bulky materials and to assess their reliability he solved by following Bacon's two-fold account of natural observation. First, it must be confirmed that evidence is based on direct sense impression, that those doing the observing are reliable, and that the record of observation allows independent confirmation.

The first issues addressed in the *Observations*, therefore, are to assess the acuity of the “searchers” who reported vital events to the clerks, and to provide the reader with a comprehensive summary of the Bills using a tabular form such as Bacon had recommended. Second, observation presupposes classification, the grouping together of related phenomena. The observer’s objective should be to isolate the simplest elements of which nature is composed, and this requires that he build up a body of experience so that regular patterns can be expressed as general rules or standards that convey concisely the implications of nature for society. Observation, in other words, entails judgment. Graunt’s second concern was to assess the overlapping classifications and numerical irregularities in the Bills, and reduce them to a reliable order, regrouping them as necessary into a set of primary topics. Conscious of Bacon’s insistence on open methods of exposition, Graunt informs the reader at each step of adjustments he has made to the figures and draws attention to their implications as balances in the body politic.

It is not difficult to see why this method so impressed Graunt’s contemporaries. His first set of observations includes proportions contrasting the combined impact of several causes of infant and child death to the mortality of plagues. The marked difference was plain to see: over a 20-year period, infant and child mortality accounted for one-third of all deaths, several times greater than the most feared of epidemics. Turning to Bacon’s interest in patterns of longevity, Graunt provided an elaborate but concise answer, showing the need to separate “acute” (i.e., epidemic) causes from “chronical” (i.e., endemic), and giving examples of how to calculate the odds of dying of particular diseases. The “absolute standard” of longevity is given by the proportion over age 70 to the total number of deaths in a given locality. Graunt provides the reader with direct and practical means of calculating which localities are most healthy and which causes of death are most dangerous in them.

The modernity that Sutherland and many others have noted in Graunt’s descriptive methodology arises not only from the critical and empirical attitude he took to his numerical sources, but from the topics that Bacon’s method led him to observe. These topics remained central when texts in medical statistics and demography began to appear in the 19th century. Following his discussion of endemic and epidemic causes of death, their relations, and causes relating to particular age groups, Graunt treats in turn the seasonality of births and deaths; natural increase (including rural and urban differentials); sex ratios; ratios showing the growth of London over time, and the differing contributions of localities within it; estimates of the population size of London and England; and the use of age structures to determine numbers of women of reproductive age and manpower.

Graunt’s Concept of a Population

Graunt’s application of arithmetic to natural history was not confined entirely to Bacon’s precepts, because the latter gave no quantitative guidance beyond stating the need for careful enumeration and classification. Graunt’s second dedication remarks the second methodological practice on which he relied, which he calls “the mathematics of my shop-arithmetic.” The Bills, like a merchant’s account books, provided a continuous record of additions and subtractions in a constantly changing numerical whole. Graunt, in effect, treated the idea that nature has an inherent quantitative order as analogous to the balance of debt and credit in merchant bookkeeping. His seeming prescience in assuming the “stability of statistical ratios” arises from this analogy. Graunt referred to each cause of death in the Bills as a separate “account”; the series of deaths from 1603 onward showed the changing debt or credit in this account as a proportion of one of the wider populations of burials or christenings he was analyzing. Abrupt changes in a given series led Graunt, as natural bookkeeper, to question his accounts, just as a merchant would, for instance, check whether a striking disproportion might be due to misclassification (e.g., confusion with entries in some other account), to some error of calculation, or to unusual events. In each case, the disproportion might be corrected by applying a proportion as a multiplier to the series; the irregularity was, in effect, smoothed. Merchants also applied multipliers where they lacked information, for example, to compare potential profits and losses in ongoing accounts; Graunt used this technique to estimate national population totals and to distribute the population into age groups. The *Observations* employs many of the standard devices of double-entry bookkeeping in use in the mid-17th century.

Graunt’s accounts are not populations as demographers now understand them, and it is of note that Graunt nowhere uses the term. Vital rates in demographic analysis are computed with reference to a single base population, but Graunt, following contemporary accounting practice, used different denominators and applied proportions derived from one account as multipliers in the analysis of unrelated accounts when relevant information was lacking. Observation for Graunt, as for Bacon, cannot be separated from experience and judgment. The actual number of inhabitants, like a merchant’s total worth, involved many debts and credits that were changing all the time; experience showed that such figures were mere abstractions, and much less important than assessing the state of profit or loss in a particular account. Graunt’s assumption of the inhering proportional regularity in human accounts for the first time enabled merchants, king’s ministers, and natural historians to estimate relative orders of magnitude, providing an informed basis for opinion.

Contemporary Rhetorical Method and the Calculus of Probability

The *Observations* addressed a recognized need for reliable knowledge of life and death, whether for the individual, in managing his own affairs, or the state, in which the distribution and size of population were considered a material factor in the success of policies of war and trade. As Graunt made clear, no matter how candid or experienced an observer might be, the observer's results depended on judgments and were subject to the judgments of others. Graunt's guarded attitude to whether the natural balances he calculated really demonstrate the legitimacy of kingly rule is a reminder of just how loaded apparently simple arithmetical measures can be. Not surprisingly, Graunt's work was taken up immediately by other thinkers who saw in quantitative methods a means of systematizing judgment. Probability, or the calculus of chance, emerged at this time in the attempt to construct a mathematics of degrees of belief. Huygens, DeWitt, Hudde, Leibnitz, and Bernoulli found in Graunt's observations the only materials other than hypothetical gaming problems in which this mathematics could be explored. Within a decade of the publication of the *Observations*, Graunt's proportional account of age structure was redeveloped by the first three of these analysts to make the first calculation of life expectation, which they applied to data on the mortality of Dutch annuitants.

The additions that Graunt made to later printings of his work show no awareness of these developments, and there is no indication in the records of the Royal Society that he contributed to advanced mathematical discussion. As noted, Graunt was able to conceive his "statistical" ideas on the basis of established bookkeeping practice, employing an arithmetic of risk familiar in the merchant community. His handling of longevity was confined to the questions Bacon had raised, and he never applied his account of age structure to calculating life chances. Mathematical probability was, in any case, known only to a tiny elite of specialist mathematicians. Graunt adopted instead the approach to matters of opinion that prevailed in his time, and in which he proved to be very skilled.

Schooling based on logic and rhetoric taught that matters of opinion are decided largely by systematic and artful presentation. Although Bacon argued that rhetorical methods had no place in natural history, neither he nor Graunt were able to keep them out. The *Observations* shows Graunt to be a master of rhetorical technique, using it to structure his numerical evidence, to organize the sequence of primary topics, and to argue impressively from them to the lessons of population arithmetic for managing the body politic. There is some irony, of course, that the first scientific social measurement should begin in the methodology of the Scholastic curriculum. This dependence was, however, characteristic of many important

17th-century scientific developments, and belongs to a wider Humanist rethinking of the role of rhetoric in science and government. Graunt's awareness of these developments is, moreover, no secondary matter in the lasting importance of his work. First, it enabled contemporaries, who were reared in the same intellectual traditions, to appreciate his work readily, despite its questionable subject matter and unprecedented numerical approach. Second, it enabled Graunt to present his method as visibly supportive of the existing political order, despite its pronounced republican undercurrent. Third, the positive and general reception of Graunt's work established a place for population arithmetic, even though the need for basic vital data as a basis of informed government was not accepted by most European states for another two centuries. That Graunt succeeded in persuading his audience of the potential of his method is shown by the diversity of his readership over that intervening period, which extended far beyond scientific circles to include the full range of religious persuasions (Catholic, Anglican, Dissenting, Atheist), royalists, and republicans, and a diverse professional audience of physicians, public officials, surveyors, estate managers, economists, and schoolteachers, as well as his fellow merchants.

Graunt's Influence

The sensitivity of population arithmetic as a matter of state remained a dominant factor into the later 18th century. Before the revolutions in France and America, only powerful monarchies such as those in Prussia, Sweden, and France dared to establish systems of data collection, but were careful to restrict public access to information. The *Observations*, however, opened the door to quantitative inquiries by individuals, and the intellectual and technical development of population arithmetic owes to their initiative. Four main developments followed from Graunt's work. Each entailed a significant narrowing of his vision, but together they laid the foundation for the generalization of population arithmetic in the statistical reforms of the 19th century.

First, Huygens' reinterpretation of Graunt's account of age structure initiated the first formal population model, the life table, subsequently developed by a distinguished line of mathematicians including Halley, De Moivre, Euler, and Price. By the early 19th century, this tradition had given rise to the first large-scale corporate structures based on mathematical models (life insurance), and was able to exercise a major influence on data requirements of the new national census and registration systems then being erected in Europe. Many simple proportional measures pioneered by Graunt were reintroduced at this time as key parameters of medical and social evaluation.

The numerical regularity of mortality, together with the consistency of sex ratios that Graunt also first demonstrated, became important in a second, “physico-theological” interpretation of population arithmetic, which attained wide influence in European thought through the writings of Süssmilch. Here the political conservatism of Graunt’s first dedication prevailed entirely. The potential of population arithmetic to demonstrate deficiencies of government was ignored, and its use was confined to demonstrating the apparently seamless unity of divine, natural, and monarchical order—an approach that certainly helped to make social measurement acceptable in the *ancien régime*.

The ambiguities and deficiencies of population arithmetic became apparent with the rise of a third successor to Graunt’s method, known as “political arithmetic.” This phrase was introduced by Petty in the 1670s to refer jointly to Graunt’s work and his own. Graunt’s discredit at that time appears to have encouraged a few later authors, especially Petty’s heirs, to attribute the *Observations* to Petty, but later scholarship has found no substance in these claims. The choice of “political arithmetic” as a rubric in itself indicates the major divide that separates Petty’s thinking from Graunt’s. With Petty, the practice of natural history, with its critical emphasis on the quality and open presentation of numerical evidence, ceased to be a primary concern. Nor was the careful use of arts of persuasion continued in order to secure support for quantitative approaches. Dispensing with the overall methodological framework Graunt had provided, Petty extended and popularized the use of multipliers in arguments that supported particular landed, royal, and merchant interests. The relative simplicity of multipliers, the frankness of party interests, and the lax attitude to numerical sources all made political arithmetic topical, as well as much easier to practice. A wide range of medical, religious, and economic writers responded, drawing on an *ad hoc* selection of Graunt’s ratios and applying them to parish, hospital, and other records. Stimulating but inconclusive debates followed, and by the mid-18th century, a more critical attitude began to be reasserted, particularly in France. Much greater care was again taken by some writers to ensure the accuracy of figures. Declining population was linked to the condition of the poor and attributed to defects of monarchical rule.

Finally, the need for reliable numerical records was a theme often repeated by Graunt’s successors, but the scrutiny and openness he advocated was pursued by few. Probabilists developing life tables for use in welfare and insurance, such as Price, and public officials who sought to show their governments that accurate censuses were

realizable, such as Vauban and Michodiere, are cases in point. Graunt’s most direct legacy in this respect was to Gregory King, whose scrutiny and analysis of population and tax records in the 1690s initiated the study of national income. The sensitivity of King’s subject, however, delayed its publication until the 19th century.

In conclusion, the sources, method, and subsequent development of Graunt’s observations show that social measurement owes its beginning to a specific conjunction of historical, cultural, and scientific circumstances. Population arithmetic was premised in an idea of inhering quantitative order that raised difficult questions about the legitimacy of differing forms of government and religious belief. Graunt’s method was an attempt to clarify, and potentially to resolve, such difficulties via an original synthesis of three methodological traditions: observation, as practiced in natural history; the accounting model of merchant bookkeeping; and Scholastic and Humanist methods of rhetorical presentation.

Guttman Scaling

George Engelhard, Jr.

Emory University, Atlanta, Georgia, USA

Glossary

coefficient of reproducibility Indicator of fit between data and requirements of a Guttman scale; defined as 1 minus the ratio of the number of errors predicted by a Guttman scale divided by the total number of responses; this coefficient ranges from zero to 1.

item characteristic curve Representation of the probabilistic relationship between a response to an item and person locations on a latent variable.

items Any set of stimuli intended to provide a structural framework for observing person responses; synonymous with tasks, exercises, questions.

latent variable The construct that is being measured or represented by the scale; also called an attribute.

perfect scale Another name for a Guttman scale.

persons The object of measurement; synonymous with subjects, participants, examinees, respondents, and individuals; groups or institutions can also be objects of measurement.

population of objects Target group of persons that a scale is designed to measure.

scalogram analysis Another name for Guttman scaling.

universe of attributes Target set of items that a scale is designed to represent; universe of content.

Guttman scaling (also called scalogram analysis) is a technique for examining whether or not a set of items administered to a group of persons is unidimensional. A data matrix (persons by items or persons by categories within items) meets the requirements of Guttman scaling when person scores reproduce the exact item responses in the data matrix. A set of items that meets this condition is defined as a Guttman scale.

Introduction

In the 1940s, Louis Guttman laid the groundwork for a new technique designed to explore the unidimensionality

of a set of test items. Guttman considered the quest for unidimensionality to be one of the fundamental problems in scaling. Guttman scaling stresses the idea that the items or questions included in a scale should have the same meaning for all persons responding to the items. If the meaning of the items is invariant across persons, then persons can be ranked on the same dimension. Items that do not provide the same stimulus to different persons cannot be used as a basis for developing a unidimensional Guttman scale. Guttman proposed a set of requirements that can be used to test the hypothesis of unidimensionality. Guttman scaling, or scalogram analysis, is the specific technique that he recommended for determining whether or not a set of items and group of persons met the requirements of a Guttman scale.

Guttman scales are also called perfect scales. Guttman determined the requirements of these perfect scales based on an ideal model of a scale. Methodologically, this is related to the concept of ideal types proposed by the German sociologist Max Weber. This methodological approach involves comparisons between theory-based ideal types and observed cases in order to test specific hypotheses about events and to identify deviant cases. Guttman used this style of comparative analysis by first identifying the requirements of an ideal or perfect scale and contrasting these perfect scale patterns derived from theory with observed response patterns. Guttman focused not only on the item patterns that met the requirements of a perfect scale, but also stressed the importance of case studies of persons with deviant response patterns. Guttman suggested that imperfect item-response patterns may yield important new understandings of both items and persons. The study of deviants and apparently anomalous results can play an important role in scientific progress.

Defining a Guttman Scale

Guttman scales can be defined in several ways. These definitions apply to data matrices composed of

either dichotomous or polytomous responses, but the presentation here will be limited to the dichotomous case (two response categories: right/wrong, correct/incorrect, agree/disagree, etc.). A data matrix (persons by items) meets the requirements of Guttman scaling when person scores reproduce the exact item responses in the data matrix. Guttman sought a method of scaling that would yield numerical values for each item and person that could be used to reproduce the observations or responses of each person on each item. Guttman's ideal scale meets these requirements and he proposed a variety of graphical and numerical methods for determining whether or not a scale deviates from the ideal scale patterns.

One popular graphical method is called a scalogram. When persons and items are ordered and displayed in a table, then the data matrix forms a distinctive triangular pattern for an ideal or a perfect scale. This pattern is shown in the left-hand panel of Table I. The person scores are listed in descending order (4 to 0) and the items are ordered from easy to hard (A is easy, D is hard). It should be noted that person scores assigned to each response pattern exactly identify the specific items that the person answered correctly or incorrectly. No information is lost by replacing item-response patterns with person scores. For example, a person with a score of 3 and a perfect response pattern is expected to respond correctly to the three easiest items (A, B, and C) and incorrectly to the hardest item (D). A four-item test composed of dichotomous items has 16 possible response patterns ($2^4 = 16$). There are 5 perfect response patterns and 11 imperfect patterns. The 11 imperfect patterns are shown in the right-hand panel of Table I.

Another way to illustrate a Guttman scale is to use item-response theory. A scale can be represented as a line with items ordered from easy to hard and persons ordered from low to high. This line reflects the attribute or latent variable that defines the construct being measured. Item characteristic curves can be used to show the relationship between the latent variable or attribute being measured and the probability of correctly answering an item. A Guttman scale is considered a deterministic model because Guttman items yield the distinctive pattern that is shown in Fig. 1. The x axis in Fig. 1 represents the attribute or latent variable with Items A to D ordered from easy to hard. The items are rank-ordered and there is no requirement that the x axis have equal intervals. The y axis represents the probability of responding with a correct

Figure 1 Illustrative item characteristic curves for Guttman items (deterministic model).

Table I Possible Response Patterns for Four Dichotomous Items

Items (Perfect patterns)					Items (Imperfect patterns)				
Person scores	A	B	C	D	Person scores	A	B	C	D
4	1	1	1	1	4	None	None	None	None
3	1	1	1	0	3	1	1	0	1
2	1	1	0	0	3	1	0	1	1
1	1	0	0	0	3	0	1	1	1
0	0	0	0	0	2	1	0	1	0
					2	0	1	1	0
					2	1	0	0	1
					2	0	1	0	1
					2	0	0	1	1
					1	0	1	0	0
					1	0	0	1	0
					1	0	0	0	1
					0	None	None	None	None

Note: Four dichotomous items yield $16 (2^4 = 2 \times 2 \times 2 \times 2)$ response patterns. Items are ordered from easy (Item A) to hard (Item D). There are 5 perfect Guttman patterns and 11 imperfect Guttman patterns.

answer to each item. For example, a person located on the x axis between Items B and C is expected to answer Items A and B correctly (probability is 1.00) and Items C and D incorrectly (probability is 0.00); this yields a score of 2 and a perfect response pattern [1100]. These distinctive step functions also serve to define a Guttman scale. It will be shown later that the Rasch measurement model is a probabilistic form of a Guttman scale.

Algebraically, Guttman scales yield perfect conjoint transitivity based on the requirement that a person who endorses a more extreme statement or item should endorse all of the less extreme statements. This property is represented by the ordering of the items (typically by an estimate of item difficulty) that reflects the following relationships:

$$\begin{array}{l} \text{If Item A} < \text{Item B} \quad \text{and} \quad \text{Item B} < \text{Item C,} \\ \text{then} \quad \text{Item A} < \text{Item C.} \end{array}$$

In a perfect Guttman scale, the property of transitive inequality is invariant over persons. If this requirement of perfect conjoint transitivity is met and the items define a common content, then this data matrix can be summarized as a Guttman scale.

Guttman recognized that obtaining perfect conjoint transitivity was necessary, but not sufficient for creating a useful scale. Two other concepts play a key role in Guttman's theoretical perspective on scaling. These concepts are the universe of attributes and population of objects. Guttman defined the universe of attributes as all of the possible items from a common content area that could be used to define the construct. The universe of attributes has also been called the universe of content. Guttman makes clear that items must have common content if they are to be used to define a unidimensional scale and that these items should be viewed as being sampled in some sense from a larger universe of potential items that could be used to define the construct or latent variable. Based on person responses to a sample of items, researchers can draw inferences about the universe of content. If the requirements of a Guttman scale are achieved, then invariant scaling of persons is possible regardless of the particular sample of items used to rank-order the persons.

The population of objects defines the objects of measurement. Guttman stressed the importance of defining and describing the population of persons that define the target group for the scale. In some ways, the concept of a population of objects corresponds to the standard statistical problems of sampling persons from a population with the object of measurement and person population defined differently depending on the purpose of the scale. In other ways, Guttman put his own unique twist on the issue by considering that the scalability of a set of items may not be invariant over different groups of persons. This becomes a very important issue because if the items are

not invariant over groups, then it is not possible to compare them. This concern with item invariance across groups appears within modern measurement in the form of differential item functioning.

Evaluating a Guttman Scale

There is a variety of methods that have been proposed for determining whether or not the requirements of a Guttman scale have been achieved. The methods that are briefly described here are Guttman's reproducibility coefficient, Loevinger's coefficient of homogeneity, and Rasch's simple logistic model. These indices were chosen because of their didactic value and strong connections to current work in measurement theory.

The methods proposed for evaluating Guttman scales involve a comparison between observed and expected or perfect response patterns. The differences between methods depend on how errors are defined and summarized. Guttman recognized that perfect scales are not to be expected in practice and suggested that deviations from a perfect scale be measured by a coefficient of reproducibility. Guttman's coefficient of reproducibility was defined by summing the number of errors predicted by perfect response patterns, dividing by total number of responses, and subtracting this fraction from 1. Although Guttman proposed different acceptable values for his coefficient of reproducibility, 90% reproducibility or higher is generally considered necessary for an acceptable Guttman scale. This coefficient of reproducibility is defined as

$$\begin{aligned} Rep_{GG} &= \frac{1 - \text{total number of errors}}{\text{total number of responses}} \\ &= 1 - \left[\frac{E_{GG}}{nk} \right], \end{aligned}$$

where E represents an error count, n is the number of persons, and k is the number of items. This definition of reproducibility follows a similar definition by Goodenough and is called the Guttman-Goodenough coefficient of reproducibility.

Another coefficient of reproducibility was described by Suchman. Suchman derived a method that attempts to minimize the number of errors obtained when observed item-response patterns are assigned to score groups based on perfect Guttman patterns. This coefficient is called the Guttman-Suchman coefficient of reproducibility by Mokken. This coefficient of reproducibility is defined as

$$\begin{aligned} Rep_{GS} &= \frac{1 - \text{total number of errors}}{\text{total number of responses}} \\ &= 1 - \left[\frac{E_{GS}}{nk} \right], \end{aligned}$$

where E_{GS} is defined based on Suchman's definition of errors.

Another way to count errors in Guttman scales is to create a cross-tabulation of ordered item pairs. If items form a perfect scale, then there is a distinctive pattern in these tables. This distinctive pattern is based on the fact that with a perfect scale, no one who succeeds on a harder item fails on an easier item. This yields a zero cell that must always occur with the cross-tabulation of two dichotomous items that meet the requirements of a Guttman scale. Any persons in this cell constitute errors. Loevinger developed her coefficient of homogeneity independently of Guttman's work, but it has been used frequently to evaluate Guttman scales. Mokken has shown how Loevinger's coefficient of homogeneity (H coefficient) can be estimated using item pairs and counts of error cells. For a scale composed of k items, there are $k(k-1)/2$ unique cross-tabulations of item pairs. Loevinger's coefficient of homogeneity can be defined as

$$H_{\text{tot}} = 1 - \left(\frac{\sum F}{\sum E} \right),$$

where F is the count of the persons in the observed error cell (easier item wrong, harder item right) in the 2×2 cross-tabulation of item pairs, E is the expected number of persons in the error cell assuming statistical independence, and the summation is understood to be over the $k(k-1)/2$ ordered item pairs. As will be shown later in the empirical example, these values can also be summed for an individual item to create a scalability coefficient for each item. Loevinger's coefficient of homogeneity is of particular importance because it was incorporated and extended by Mokken and others into nonparametric item-response theory.

The Rasch model can also be used to compare observed and expected response patterns with error counts. Andrich has made a compelling case for viewing the Rasch model as a probabilistic realization of a Guttman scale. Rasch's simple logistic model (SLM) can be used to model the probability of dichotomous item responses as a logistic function of item difficulty and person location on the latent variable. The SLM can be written as

$$\Pr(x_{ni} = 1 | \theta_n, \delta_i) = \frac{\exp(\theta_n - \delta_i)}{[1 + \exp(\theta_n - \delta_i)]}$$

and

$$\Pr(x_{ni} = 0 | \theta_n, \delta_i) = \frac{1}{[1 + \exp(\theta_n - \delta_i)]},$$

where x_{ni} is the observed response from person n on item i (0 = wrong, 1 = right), θ_n is the location of person n on the latent variable, and δ_i is the difficulty of item i on the same scale. Once estimates of θ_n and δ_i are available, then the probability of each item response and item-response pattern can be calculated based on the

SLM. Model-data fit can then be based on the comparison between the observed and expected response patterns that is conceptually equivalent to other methods of evaluating a Guttman scale. If the Guttman's model is written within this framework, then Guttman items can be represented as follows:

$$\Pr(x_{ni} = 1 | \theta_n, \delta_i) = 1, \quad \text{if } \theta_n \geq \delta_i$$

and

$$\Pr(x_{ni} = 0 | \theta_n, \delta_i) = 0, \quad \text{if } \theta_n < \delta_i.$$

This reflects the deterministic nature of Guttman items that was illustrated in Fig. 1.

One of the challenges in evaluating a Guttman scale is that there are different ways to define errors. Mokken has pointed out that there may even be errors in the perfect response patterns. Probabilistic models provide a more flexible framework for comparing observed to expected item-response patterns and a less rigid perspective on errors. Guttman's requirement of perfect transitivity appears within the Rasch measurement model as perfect transitivity in the probabilities of ordered item responses.

Empirical Example

Table II presents data from Stouffer and Toby that are used to illustrate the indices for evaluating a Guttman scale presented in the previous section. Table I provides the response patterns for 261 persons responding to four items (A, B, C, and D) designed to measure whether or not persons tend toward universalistic values or particularistic values when confronted by four different situations of role conflict. Persons with higher scores provide more particularistic responses (reactions to role conflicts are based on friendship). It should be noted that earlier re-analyses coded positive (+) and negative (−) responses differently. Table I reflects the original Stouffer-Toby scoring with positive responses (+) coded 1 and negative responses (−) coded 0; the items are reordered from easy to hard to endorse (e.g., Stouffer-Toby Item 4 is Item A here) for Form A (Ego faces dilemma).

The four items in the Stouffer-Toby data have the following difficulties (Item A to Item D): 0.21, 0.49, 0.50, and 0.69. Item A is the hardest to endorse, whereas Item D is the easiest to endorse for these persons. Based on this difficulty in ordering, the expected patterns for a perfect scale are shown in column 2 of Table II. Column 3 presents the observed patterns and their assignment to a particular expected item pattern based on the sum of the items. For example, the observed pattern [1110] sums to person score 3 and it is assigned to the expected item pattern of [1110]; there were 38 persons with this observed pattern and there are no errors. In contrast, the

Table II Response Patterns for Empirical Example

Person scores	Expected item pattern	Guttman-Goodenough				Guttman-Suchman			
		Item pattern (ABCD)	Frequency	Errors	Error frequency	Item pattern (ABCD)	Frequency	Errors	Error frequency
4	1111	1111	20	0	0	1111	20	0	0
						1101	9	1	9
						1011	6	1	6
						0111	2	1	2
						0101	2	2	4
						0011	1	2	2
3	1110	1110	38	0	0	1110	38	0	0
		1101	9	2	18	0110	7	1	7
		1011	6	2	12				
		0111	2	2	4				
2	1100	1100	24	0	0	1100	24	0	0
		1010	25	2	50	0100	6	1	6
		0110	7	2	14				
		1001	4	2	8				
		0101	2	2	4				
		0011	1	4	4				
1	1000	1000	23	0	0	1000	23	0	0
		0100	6	2	12	1010	25	1	25
		0010	6	2	12	1001	4	1	4
		0001	1	2	2				
0	0000	0000	42	0	0	0000	42	0	0
						0010	6	1	6
						0001	1	1	1
		$k = 4$	$n = 216$	24	140	$k = 4$	$n = 216$	13	72

Note: Higher person scores indicate a more particularistic response, whereas lower person scores indicate a more universalistic response. Items are ordered from easy (Item A) to hard (Item D). Guttman-Goodenough reproducibility coefficient: $1 - [140/(216 \times 4)] = 0.84$. Guttman-Suchman reproducibility coefficient: $1 - [72/(216 \times 4)] = 0.92$.

observed pattern [1101] also sums to person score 3, but when the expected and observed response patterns are compared, there are two errors. The Guttman-Goodenough reproducibility coefficient for these data is 0.84: $1 - [140/(216 \times 4)]$. This value is lower than the value of 0.90 recommended by Guttman for an acceptable scale. The last four columns of Table II illustrate another approach for classifying observed item-response patterns to expected item patterns. Using the Guttman-Suchman approach for classifying observed to expected patterns, there are significantly fewer errors. The Guttman-Goodenough reproducibility coefficient is 0.92: $1 - [72/(216 \times 4)]$. Under the Guttman-Suchman error counting system, the number of errors has dropped from 140 to 72. This approach was used by Stouffer and Toby. This higher value indicates an acceptable Guttman scale. Unfortunately, the Guttman-Suchman approach seems to be somewhat arbitrary and destroys the simple relationship between the expected and observed item-response

patterns based on ordered items and person scores. The Guttman-Suchman approach changes the goal of scaling from the comparison of observed and theory-based definitions of expected item patterns to the minimization of errors that is highly dependent on the vagaries of the particular sample of persons that responded to the scale.

Table III provides the cross-tabulation of Items A and B that form the basis for calculating Loevinger's homogeneity coefficient based on Mokken. Item A is easier than Item B and, thus, based on the requirements of Guttman scaling, there should not be any persons in the error cell. For the Stouffer-Toby data, there are 17 persons who failed Item A (easier item) and succeeded on Item B (harder item). Based on the assumption of statistical independence, the expected number of errors is 33.5: $(108 \times 67)/216$. Table IV summarizes the results of the Loevinger's analyses based on Mokken scaling. The estimated H_{tot} for this set of items is 0.41 with individual item results ranging from 0.35 to 0.51. Mokken

Table III Cross-Tabulation of Items A and B (Observed and Expected counts), Stouffer-Toby Data

Item A (<i>easier</i>)	Item B (<i>harder</i>)		Total
	0	1	
0	(Error cell)		
Observed	50	17	67
Expected	33.5	33.5	67.0
1			
Observed	58	91	149
Expected	74.5	74.5	149.0
Total			
Observed	111	108	216
Expected	111.0	108.0	216.0

Note: Error cell includes persons who fail (0) the easier item (item A) and succeed on the harder item (item B).

Table IV Loevinger's Coefficient of Homogeneity for Stouffer-Toby Data

Item cross-tabulations	Observed error cell	Expected error cell	H coefficient
A \times B	17	33.5	
A \times C	16	32.6	
A \times D	6	14	
B \times C	38	52.5	
B \times D	12	22.5	
C \times D	16	23.1	
Total	105	178.2	0.41
Items			
A	39	80.1	0.51
B	67	108.5	0.38
C	70	108.2	0.35
D	34	59.6	0.43

Note: H coefficient for the total scale is $1 - [105/178.2] = 0.41$. H coefficients for items are based on the sum over pairwise tables that include the target item. For example, the H coefficient for Item A is $1 - [39/80.1] = 0.51$.

recommends the following interpretive scheme for the H coefficient:

$$\begin{aligned}
 0.50 \leq H & : \text{strong scale;} \\
 0.40 \leq H < 0.50 & : \text{medium scale;} \\
 0.30 \leq H < 0.40 & : \text{weak scale.}
 \end{aligned}$$

Based on these guidelines, the Stouffer-Toby data would be considered a medium scale.

Table V presents the results of using Rasch's SLM to analyze the Stouffer-Toby data. The estimated Rasch item difficulties are -1.89 , -0.20 , -0.10 , and 2.20 logits for

Items A to D, respectively, and the estimated person locations on the latent variable are 1.52 , -0.06 , and -1.54 logits. Estimates of person locations under the Rasch model are not provided for perfect scores of 0 and 4, although estimates can be obtained for these scores if additional assumptions are made about the data. The item characteristic curves for these four items are shown in Fig. 2. It is important to note how close Items B and C are in terms of difficulty. Column 4 gives the probability of observing a perfect item-response pattern for each person score. For example, a person with a score of 3 ($\theta = 1.51$) has an expected response pattern in the probability metric of 0.97, 0.85, 0.84, and 0.34 for Items A to D, respectively. It is clear that persons with scores of 3 are expected to have more than a 50/50 chance of succeeding on Items A, B, and C, whereas they have less than a 50/50 chance of succeeding on Item D. This ordering reflects a probabilistic transitivity for these items that mirrors the deterministic transitivity of the perfect item pattern [1110] for a person with a score of 3. Column 5 gives the conditional probability within each person score group of obtaining the various item-response patterns. These values were obtained by estimating the likelihood of each pattern conditional on θ and standardizing these values so that the likelihoods sum to 1 within each score group. As pointed out by Andrich, the conditional probability of observing a Guttman pattern within a score group is more likely than the other patterns. For example, the probability of a person with a θ of 1.52 (score of 3) having an observed response pattern of [1110] is 0.830, whereas the probability of this person having an observed response pattern of [0111] is only 0.013. In order to follow the theme of error counting, Rasch measurement theory provides an index of person fit that quantifies the difference between the observed and expected response probabilities. The person fit statistics (standardized residuals) are reported in the last column of Table V. It is clear that the most unusual patterns have the highest standardized residuals, with values greater than 2.00 reported for patterns [0111], [0101], [0011], and [0001].

Conceptual Contributions to Measurement

Guttman made quite a few significant conceptual contributions regarding scaling and measurement theory. One index of his influence is reflected in the strong and opposing views generated by his work. Cliff viewed Guttman scales as one of the good ideas in all of measurement, whereas Nunnally cautioned that the intuitive attractiveness of Guttman scaling does not overcome its fundamental impracticality.

Table V Probabilities of Item-Response Patterns Based on the Rasch Model

Person scores	Item patterns ABCD	Frequency	Expected response pattern	Conditional probability of response pattern	Person fit (standardized residual)
4	1111	20		1.000	0.00
3 ($\theta_3 = 1.52$)	1110	38	0.97, 0.85, 0.84, 0.34	0.830	-0.78
	1101	9		0.082	0.44
	1011	6		0.075	0.50
	0111	2		0.013	2.03
2 ($\theta_2 = -0.06$)	1100	24	0.86, 0.54, 0.51, 0.09	0.461	-0.63
	1010	25		0.408	-0.55
	0110	7		0.078	0.93
	1001	4		0.039	1.51
	0101	2		0.007	2.22
	0011	1		0.007	2.24
	1000	23		0.734	-0.58
1 ($\theta_1 = -1.54$)	0100	6	0.59, 0.21, 0.19, 0.02	0.136	0.20
	0010	6		0.120	0.25
	0001	1		0.010	2.20
	0000	42		1.000	0.00
0					
	$k = 4$	$n = 216$			

Note: Rasch item difficulties are -1.89 , -0.20 , -0.10 , and 2.20 logits for Items A to D respectively. Higher person scores indicate a more particularistic response, whereas lower person scores indicate a more universalistic response.

**Figure 2** Item characteristic curves for Rasch model (probabilistic model) using Stouffer-Toby data.

Guttman scaling is important because it lays out in a very obvious way many of the issues and requirements that are necessary for the development of a scale. Guttman preferred to limit his approach to scaling to ranks and ordinal-level person measures that reflect a deterministic and nonparametric approach to scaling. Even though his requirements for a perfect scale are imbedded within a deterministic framework, Andrich has shown how a probabilistic model based on Rasch

measurement theory can achieve these theory-based requirements. Andrich has pointed out the close connections between Guttman's deterministic model and Rasch's probabilistic model. Andrich stresses that these connections are not a coincidence and that both Guttman scaling and Rasch scaling embody the same essential requirements of invariance of item and person locations on the latent variable. In addition to the strong relationship between Guttman scaling and Rasch measurement theory,

the origins of nonparametric item-response theory can be found in Guttman's early work. Mokken scaling has its origins in Guttman scaling.

In many introductory textbooks, a Guttman scale is simply defined for the dichotomous case and the other conceptual contributions of Guttman scaling are not discussed. The concepts of a perfect scale, universe of attributes, and population of objects have been very influential in areas as diverse as generalizability theory, item-response theory, and nonparametric item-response theory. In summary, Guttman made several fundamental contributions to measurement and scaling theory that are well worth revisiting. Even though much of the work on Guttman scaling was performed more than 50 years ago, a careful reading of Guttman's original texts still forms a sound introduction to most of the major scaling issues that researchers continue to face.

Glossary

categorical mapping A mapping having one set for its domain (population) and a Cartesian set for its range (items are the facets of the range).

facet One way of classifying variables according to some rule; a set that plays the role of a component set of a Cartesian set.

Guttman scale A perfect scale; a unidimensional scale.

mapping A rule by which elements from one set are assigned to elements from another set.

monotone regression A relationship in which the replies on variable $-x$ increase in a particular direction as the replies on variable $-y$ increase without assuming that the increase is exactly according to a straight line. The trend is always in one direction (upward or downward) with the possibility that variable y can occasionally stand still.

perfect scale A set of profiles in which there is a one-to-one correspondence between the profiles and the scale ranks; a Guttman scale.

stem facet A content facet that directly modifies the name of the range of a structured mapping sentence, but does not modify any other facet.

structured mapping sentence A mapping having two major varieties of facets for its domain (population and content) and one facet (or few) for the range.

structuple A profile.

Louis Guttman (1916–1987) contributed to the social sciences in a large variety of areas. His first developments on scaling theory were made while he was a student at the University of Minnesota. He later continued this work in two stages: as an expert consultant to the U.S. Secretary of War during World War II and, after his immigration to Israel in 1947, when he established the Israel Institute of Applied Social Research. His pioneering work on scaling

theory is cited in 1971 in *Science*, one of 62 “major advances” in the social sciences from 1900 to 1965. In the 1960s, Guttman started another wave of new developments in intrinsic data analysis and facet theory. These topics constituted his major teaching and research activities at the Hebrew University in Jerusalem and at the Israel Institute of Applied Social Research. In particular, he developed new substantive theories concerning structural lawfulness for social attitudes, intelligence tests, and other aspects of human behavior.

Biographical Highlights

Louis Guttman was born in Brooklyn, New York, on February 10, 1916, to Russian immigrant parents. When he was 3 years old the family moved to Minneapolis where he completed his formal education. His father was a self-taught amateur mathematician who published several papers in the *American Mathematical Monthly*.

Although skilled in mathematics he decided to major in sociology. His studies also included courses in psychology equivalent to a major in the field. Upon realizing the importance of statistics to social research, he returned to his study of mathematics, of which he had a solid knowledge. This led him to formalize—while still a graduate student—techniques for data analysis, some of which were published in 1941 and constitute the foundations of his later work on scale theory, factor analysis, and other topics (his first publication was in 1938 in *Regression Analysis*). Guttman attained his B.A. (1936), M.A. (1939), and Ph.D. (1942) degrees in sociology from the University of Minnesota. Guttman’s doctoral dissertation constituted original formulations to the algebra of matrices in general and to the algebra of factor analysis in particular.

For 1 year he studied at the University of Chicago (a predoctoral fellowship), which was at that time the only place in the United States where factor analysis was taught. Histies with Samuel Stouffer began at that time. His theorems concerning communalities that he developed while a graduate student are still part and parcel of the basics of factor analysis theory. The issues associated with factor analysis and reliability theory were addressed by Guttman in a series of articles that appeared between 1941 and 1961. Some 15 years later, in the mid-1970s, the factor indeterminacy problem led to controversial publications that Guttman called “the Watergate of Factor Analysis.” His two then-unpublished papers concerning this issue can be found in Levy’s 1994 compilation of his work.

In the 1970s, he also summarized his insights regarding statistics in a paper entitled “What Is Not What in Statistics” (1977). In this paper, he unmasks maltreatments of statistics and conceptualization in the social sciences by use of aphoristic and challenging headings such as “Partial Correlation Does Not Partial Anything,” “Proportion (or Percentage) of Variance Is Never ‘Explained,’” and “Nominal, Interval and Ratio Scales Are Not Scales.” With these, he not only exposed the naive lack of understanding of researchers, but indicated that most data analysis techniques, in particular statistical inference, do not provide answers to substantive problems and are irrelevant to replication, which is the “heart of cumulative science.”

Of special importance are the monotonicity coefficients developed by Guttman. Of these, the weak monotonicity coefficient, denoted by μ_2 can be compared directly to Pearson’s product-moment correlation coefficient. μ_2 expresses the extent to which replies on one variable increase in a particular direction as the replies to the other variable increase, without assuming that the increase is exactly according to a straight line (as in Fig. 1 below). It varies between -1 and $+1$. $\mu_2 = +1$ implies a perfect monotone trend in a positive direction; $\mu_2 = -1$ implies a perfect monotone trend in a negative or descending direction. By *weak* monotonicity is meant that ties in one variable may be untied in the order without penalty. Unlike Pearson’s product-moment coefficient, μ_2 can equal $+1$ or -1 , even though the marginal distributions of the two variables differ from one another. Therefore, it is especially appropriate in conditions, as in the social sciences, in which marginal distributions differ from item to item.

The formula for weak μ_2 is as follows:

$$\mu_2 = \frac{\sum_{h=1}^n \sum_{i=1}^n (x_h - x_i)(y_h - y_i)}{\sum_{h=1}^n \sum_{i=1}^n |x_h - x_i| |y_h - y_i|}$$

When Pearson’s coefficient equals $+1.00$, 0 , or -1.00 , the weak monotonicity coefficient μ_2 for the same data will have the same values. In all other cases, the absolute value of μ_2 will be higher than that of Pearson’s coefficient,

including the phi coefficient for dichotomies—in which case μ_2 equals Yule’s Q . Most similarity coefficients are special cases of Guttman’s coefficient of monotonicity.

As for the problem of the misuse of statistical inference, Guttman developed a new kind of efficacy coefficient for comparing arithmetical means, based on the monotone concept. The coefficient is called a discrimination coefficient (DISCO). It is distribution-free, avoiding both unrealistic assumptions about the normality of population distributions and equality of variances within the populations. DISCO equals 1 if there is no overlap between the distributions, no matter how large the within variance. It equals 0 if there are no differences among the means.

He regarded none of the methods that he developed as sociology or psychology. It may come as a surprise to the uninitiated that theory, not method, was Guttman’s primary interest. In fact, he saw the two as inseparable, arguing in 1982 that “A theory that is not stated in terms of the data analysis to be used cannot be tested. . . . the form of data analysis is part of the hypothesis.” Hence, his main interest lay in developing structural theories, which led to empirical lawfulness as evidenced in his definition of theory.

Guttman did not believe in mathematical psychology or mathematical sociology, and he rejected formalized axiomatic theories. The mathematics he used was not for the substantive theory but rather for technical features of data analysis. He stated that

Those who firmly believe that rigorous science must consist largely of mathematics and statistics have something to unlearn. Such a belief implies emasculating science of its basic substantive nature. Mathematics is contentless, and hence—by itself—not empirical science. . . . rather rigorous treatment of content or subject matter is needed before some mathematics can be thought of as a possibly useful (but limited) partner for empirical science.

(Guttman 1991, p. 42)

During Guttman’s service as expert consultant to the Secretary of War with the Research Branch of the Education Division of the U.S. Army in World War II, he developed scale analysis (1944) and techniques that were used for attitude research in many aspects of army life. These developments were documented and published in 1950 in the volume edited by Stouffer and colleagues, *Measurement and Prediction* (Vol. 4 of the *American Soldier: Studies in Social Psychology*).

Guttman’s academic base during that period (beginning in 1941) was Cornell University, where he was associate professor of Sociology. There he met Ruth Halpern, a student at the upper campus, whom he married in 1943. In 1947 he received a postdoctoral fellowship from the Social Science Research Council (SSRC) of the United States, and they left for Palestine. They lived in Jerusalem, where their three children were born. Years later, his

connections with Cornell University were renewed, and he served as a professor-at-large from 1972 to 1978.

The social science know-how accumulated during World War II at the Research Branch was useful in setting up a similar unit for the Hagana (the Jewish underground army in Palestine) while the British Mandate was expiring (1948). His collaboration with Uriel Foa began in this framework. The underground research group of volunteers developed into the Psychological Research Unit of the Israel Defence Forces, headed by Guttman. This unit provided the basis for the Behavioral Science Unit of the Israel Defence Forces. The Public Opinion Section of the army's Psychological Research Unit developed into the Israel Institute of Applied Social Research in 1955, of which Guttman was the scientific director. The history of the Institute, its unique continuing survey, and its scientific activities can be found in Gratch (1973). In 1955, he became professor of Social and Psychological Assessment at the Hebrew University of Jerusalem. Louis Guttman passed away on October 25, 1987.

Guttman's work on factor analysis and other multivariate problems led him to nonmetric structural ideas such as the simplex, circumplex, and radex and to the idea of facets for definitional frameworks and structural theories. Guttman introduced the term circumplex in 1954 to indicate a particular kind of correlational pattern, having a circular arrangement. Since then, the circumplex model has been applied by many researchers to personal traits and interpersonal behaviors as an alternative to explanatory factor analysis.

The breakthrough for facet theory occurred in the mid-1960s when structural lawfulness in the area of intelligence tests was established, both with the advent of the electronic computer and with his collaboration with Lingo, who was the first to program Guttman's nonmetric techniques. Only then did Guttman finally feel that he was "doing" sociology and psychology," as a flourishing facet theory helped to establish substantive structural laws of human behavior in a variety of areas such as well-being, adjustive behavior, values, intelligence tests, and involvement. Thus, he pioneered the road to a cumulative social science.

Even a brief inspection of his proposed tentative outline for his planned book on facet theory reflects the great variety of issues with which he was involved. A selection of a wide variety of Guttman's works, including the first two chapters from his unfinished book on facet theory, together with a full comprehensive and detailed bibliography (approximately 250 publications), is to be found in Levy's 1994 compilation.

Scientific Societies

Guttman participated in a diversity of professional organizations. He was a member of the Israel Academy of

Sciences and was appointed chairman of the Israel Psychological Association, the Israel Association for Research and Labor Relations, the Israel Sociological Association, and the Israel Statistical Association. He was the first nonresident president of the Psychometric Society (of the United States), and was elected a foreign member of the American Academy of Arts and Sciences.

Awards

Awards and honors bestowed on Guttman during his career include fellow at the Center for Advanced Study in the Behavioral Sciences (1955–1956), the Rothschild Prize for Social Science (1963), Outstanding Achievement Award from the University of Minnesota (1974), the Israel Prize in the Social Sciences (1978), the Educational Testing Service Award for Distinguished Service to Measurement (1984), and the Helen Dinermann Award from the World Association of Public Opinion Research (1988, posthumously).

Scale Theory

Introduction

The overall concept that underlies Guttman's work is structural theory, with the universe of content to be studied as the starting point. Very early, he realized that focusing on concepts and classifying content must precede data analysis; that is, content alone defines the universe and not data analysis. It is the empirical structure of the universe of content that is at issue.

For qualitative data, the first complete example of structural theory was that of a perfect scale of a class of attitudes (or attributes), developed in the U.S. Army during World War II.

The Definition of a Scale

Guttman defined a scale in 1944:

For a given population of objects, the multivariable frequency distribution of a universe of attributes (attitudes) will be called a "scale," if it is possible to derive from the distribution a quantitative variable with which to characterize the objects such that each attribute is a simple function of that quantitative variable. Such a quantitative variable is called a scale variable.

A variable y with m distinct ordered values is said to be a simple function of a variable x , with n distinct ordered values, if for each value of x there is one and only one value of y . The converse need not hold; for the same value of y , there may be two or more values of x . This relationship is illustrated in the regression curve in

Figure 1 A simple function of variable y on variable x : the monotone trend.

Figure 2 A graphical presentation of a perfect scale.

Fig. 1. Obviously, if y is to be a single-valued function of x , then its distinct values cannot be higher than the distinct values of x ($m \leq n$). The regression in **Fig. 1** is of a monotone trend. Indeed, monotonicity is the underlying feature in all of Guttman's intrinsic multidimensional methods—similarity structure analysis, SSA; multidimensional structuple analysis, MSA; and partial-order structuple (scalogram) analysis with base coordinates, POSAC—that serve as partners to the definitional framework (by facets) of the universe of content.

The simple function of y on x can also be presented graphically as a perfect scale by plotting the x values on a straight line and cutting it into numerical intervals (scale scores), according to which the objects are ordered (**Fig. 2**). **Figure 2** is a perfect scale because it has the property of perfect interval consistency, the intervals along the straight line being the one-dimensional regions of the scale. Because there is a one-to-one correspondence between the profiles over the observed two-item categories and the scale ranks, predictability from the ranks is exactly the same as from the profile.

Thus, the basic concepts that underlie Guttman's later developments in intrinsic data analysis and facet theory—universe or content, monotonicity, and regionality—can be traced to his early scale theory.

Departure from a Perfect Scale: Image Analysis

Perfect scales are very rare. According to Guttman "perfect scales are not to be expected in practice." The first measure he developed (in 1944) for deviation from perfection was the coefficient of reproducibility. Later (in 1953), he developed a general theory of deviations, namely, image theory. Image theory provides general techniques for discovering the common structure in

the observed data by first defining and eliminating the deviations. This is done by predicting, in turn, each item in the given observed set from all the rest of the items. The predicted values are called images. Because image techniques allow us to deal systematically with deviations, the concept of reproducibility is no longer of central importance in measuring deviations from a perfect scale. Image analysis for the departure from unidimensionality is used, *inter alia*, for job evaluation, defined by Guttman in terms of the level of restriction in performing a job. This issue has been found repeatedly to be essentially unidimensional. In later years, the perfect scale constituted a special case of MSA and POSA.

Principal Components of Scalable Attitudes

In 1954, scale theory expanded in the direction of developing substantive psychological and sociological theories for principal components of scalable attitudes. The first principal component is a monotone function of the scale ranks. The second, third, and fourth components are expected to have certain polytone regressions on the ranking of the population on the attitude: The second (intensity) is a U-shaped function, the third component (closure) is an N-shaped function with two bending points, and the fourth component (involvement) is an M- or W-shaped function with three bending points. Guttman hypothesized that certain types of personal norms for involvement may often serve as direction finders for predicting when to expect a W- or an M-shaped function.

The principal components have proven indispensable for properly interpreting survey results and for making predictions, especially by marking the proper zero point of the scale. They also illuminate the problem of attitude change.

Facet Theory: Structural Lawfulness—Spaces of Variables

Introduction

The problem that pertains to scale analysis (as well as to any structural analysis) is that of defining the universe of content. The facet theory approach was developed by Guttman to answer this problem. Scale theory, its insights already achieved in the 1940s, constitutes the basis of facet theory, which was introduced and elaborated by Guttman later on. As Guttman put it in 1960, "Facet Theory is proving to be a vast topic in which scale analysis occupies but one small—though important—corner."

Definition of Theory

The point of departure of facet theory is Guttman's definition of the concept of theory itself: "A theory is an

hypothesis of a correspondence between a definitional system for a universe of observations and an aspect of the empirical structure of those observations, together with a rationale for such an hypothesis." This definition implies that we as researchers have to worry about two distinct things: (1) the design of the observations and (2) the empirical structure of those observations. The theoretical leap requires thinking about these two things in partnership. The mapping sentence device is intended to promote this partnership. The concept of rationale is added because it enables us to proceed cumulatively on the basis of already established hypotheses.

Guttman proposed four theoretical constructs for theory development: (1) definition, (2) specification, (3) rationale, and (4) hypothesis. These constructs constitute a basic facet in his 1972 "Mapping Sentence for Strategies of Theory Development."

The Concept of a Mapping Sentence

The mapping sentence generalizes R. A. Fisher's design of experiments to the design of any observations. It coordinates formal concepts (facets) and informal verbal connectives. Each facet is one way of classifying variables according to some rule, and the elements of the facet conform to the rule. Guttman's more formal (1972) definition of facet is "a set playing the role of a component set of a Cartesian set." A properly defined set of m facets, namely the mapping sentence, "provides an m -way simultaneous classification of variables."

A mapping sentence includes three varieties of facets. The first, usually symbolized by X , designates the population of respondents being researched. The second variety of facets classifies the content of the variables. These two varieties of facets together define the domain of the mapping sentence. The third kind of facet is the range, namely the set of response categories specified for the universe of items under study.

The mapping can be expressed abstractly in the following nonverbal form:

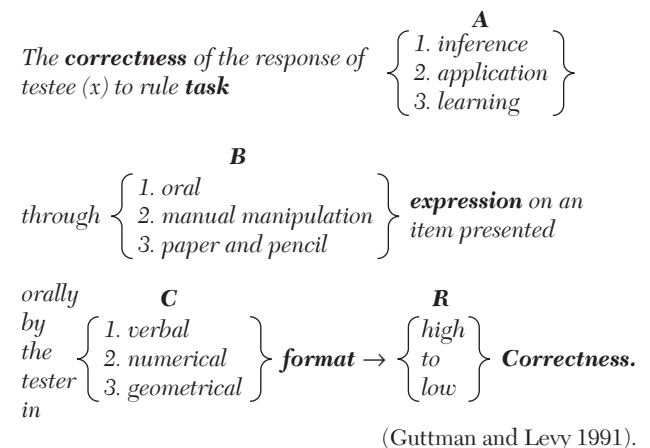

The left member, or domain of the mapping is the Cartesian set $XABC \dots N$, giving all possible combinations of the form $xab \dots n$, that is, of each member of the population x with each of the content facets of the Cartesian set $ABC \dots N$. The arrow indicates the mapping of the domain onto the set R of possible responses; namely, facet R (the range facet) is the image of the domain. An actual observation is made by choosing one and only one element from the range facet for each sentence

generated by the domain facets. Hence, each respondent (x) has one and only one response in R for each question (or test, or any other stimulus) classified by the elements of the content facets $ABC \dots N$. This classification of elements is known as structuple, the components of which make up a structuple that is known as struct.

The Structured Mapping Sentence: A Definitional Framework for Variables

In order to give an abstract mapping empirical meaning, Guttman proposed to add verbal connectives and further literary additions to make the mapping readable in ordinary language. Such a substantive elaboration of the mapping is called a mapping sentence. For example, here is a mapping sentence for the Revised Wechsler Intelligence Tests for Children (WISC-R):

This mapping sentence defines the varied substance of the WISC-R in terms of three distinct content facets. The sentence is very clear with respect to the rule of each facet, with the elements of each facet being mutually exclusive. Each facet appears in the mapping sentence as a set of elements listed in bracketed columnar form. The name (rule) of each facet appears (in boldface) right before or after its list of elements, depending on the verbal structure of the sentence. Verbal connectives are added to make the mapping sentence readable in ordinary language. The common range for intelligence-test items is expressed in the mapping sentence by the level of correctness of the responses (facet R) after the arrow. Note that the meaning of the range is also indicated in the domain—the left member of the mapping. (The content facets are detailed and discussed later, in the context of regional hypotheses.) Such a mapping sentence is termed a structured mapping sentence. A structured mapping sentence should make sense in ordinary speech, regardless of the number of the facets involved. Otherwise there may be conceptual flaws in the proposed facets. ("Making sense"

is no guarantee of theoretical or practical fruitfulness; it is only a necessary condition, not a sufficient one.)

It should be noted that even the facets of a given design are generally only a sample from a much larger set of possible facets. Hence, “developing a fruitful facet design for content is an evolutionary process—in a sense never-ending as is all science.”

Sampling of Items

The number of ordinary sentences derivable from the mapping sentence presented in the previous section is $27 (3 \times 3 \times 3 = 27)$. These serve as guides for actual item construction, specifying both the similarities and differences among the designed items. Each test is defined by the mapping sentence in a manner independent of its specific formulation. Consider, for example, the faceted definition $a_2b_1c_1$: The task imposed on the testee is application (a_2) of a rule expressed orally (b_1) in a verbal format (c_1). A possible test item constructed according to this structuple is: “Who is the president of the United States?” Similarly, a possible test item constructed according to the structuple $a_3b_1c_2$ can read as follows: “I will now cite loudly some numbers. Listen carefully, and immediately after I finish, repeat the numbers.” Namely, the task imposed on the testee is learning (a_3) expressed orally (b_1) in a numerical (c_2) format. Many other items can be constructed for each of these two structuples. The same holds for all the structuples derivable from the faceted definition. The Wechsler Manual specifies only 12 subtests, and yet these allow for structural lawfulness because each element of each facet is represented in at least one of the subtests.

The number of derivable sentences from a structioned mapping may be very large, depending on the number of facets and the number of elements within each facet. Although generally “there is no probability distribution for a facet design of content,” in each case a small sample of items that will nevertheless suffice to yield the essential information about the facets can be systematically constructed. The actual item construction has to conform to the research topic, which may result in placing different emphases on certain facets and, within facets, on certain elements. A structioned mapping sentence can also be used as a culling rule for a universe of content that already exists, telling us how to choose items from among existing ones.

Are Scientific Definitions “Correct”?

Scientific definitions can never be “correct” (or “incorrect”); rather, they can be reliable or clear (or unreliable). Hypotheses are classified as correct or incorrect. Scientific definitions are not fruitful by themselves, but only in partnership with other concepts. The issue is

whether they fit into some partnership that leads to some form of empirical lawfulness. The definitional framework provided by the structioned mapping sentence helps ensure clarity and reliability, and it also facilitates the formulation of empirical lawfulness. Furthermore, it helps ensure continuities in research: “through knowing what facets are common to different studies, one can begin to learn about lawfulness in several studies.”

Strategies of Modification

Formal definitions are necessary for scientific progress. Though striving for formality by its formal facets, the structioned mapping sentence enables the use of fruitful strategies for systematic theory development because it lends itself easily to correction, deletion, submission, extension (adding elements to a facet), and intension (adding content facets), based on cumulative research.

The Common Range: Laws of Positive Monotonicity (First Laws)

A central feature of the design of observations is the range facet. In the previous mapping sentence, all the Wechsler intelligence subtests are assigned a common range of extent of “correctness,” namely a right-to-wrong range with respect to an objective rule.

There are two conditions for a universe of items to have a common range: (1) The range of each item in the universe must be ordered, and (2) the ranges must have a uniform meaning of their orders, regardless of their actual phrasing. The problem of meaning is semantic (substantive) and is related to the general framework of the research, whereas phrasing is a technical problem.

The observation that the right-to-wrong range is most common to almost all traditional mental testing (the Wechsler tests among them) led Guttman to propose in 1973 the following faceted definition of the universe of intelligence items, specifying both range and domain for the items:

“An item belongs to the universe of intelligence items if and only if its

domain asks about a $\left\{ \begin{array}{l} \text{logical} \\ \text{scientific (factual)} \\ \text{semantic} \end{array} \right\}$ *objective rule, and its range*

is ordered from $\left\{ \begin{array}{l} \text{very right} \\ \text{to} \\ \text{very wrong} \end{array} \right\}$ *with respect to that rule.”*

(Guttman in Gratch 1973;
Guttman and Levy 1991).

This definition encompasses all approaches to intelligence, known in this field. It was published simultaneously

with the First Law of intelligence testing. (A short time before his death, Guttman suggested the term “The Law of Positive Monotonicity” to replace the term “First Law.”) The law reads, “If any two items are selected from the universe of intelligence test items, and if the population observed is not selected artificially, then the population regressions between these two items will be monotone and with positive or zero sign.”

The regression curve is obtained by plotting the range of one variable against the range of the other. Thus, the definitional communality of range provides part of the rationale for the positiveness of regression slope. The law has been known implicitly since mental testing began some 100 years ago. For ordinary populations (child or adult), only positive correlations have been observed between mental test items. Now, there is a rationale for the phenomenon of positive correlations, namely the common range. However, this phenomenon cannot be termed a law without the formal definition just cited. This law, like any scientific law, states the conditions under which positive or zero correlations (based on monotone regressions) are to be expected. In the case of intelligence items, two conditions are stated: (1) The items must be intelligence items according to the definition and (2) the population is not specially selected with respect to the test items.

Many replications supporting the Positive Monotonicity Law of Intelligence Tests can be found in the literature. Similarly, Guttman’s mapping definition of attitude facilitated the formation of the Positive Monotonicity Law of Attitude. These were published together with the First Law of Intelligence in 1973. According to Guttman (in 1982):

I would not have thought that the First Law of Attitude was a law had I not been aware of the phenomenon of intelligence, well established in research Actually, I thought about the two laws simultaneously. It is doubtful that I would have had the courage to state either law separately The sheer idea of seeing similarity in two different areas of human behavior of this sort lent support to the idea that laws are possible, and the similar rationale of the laws gave further support – and courage.

Guttman’s mapping definition of the universe of attitude items followed by the First Law of Attitude (Positive Monotonicity Law) is as follows:

“An item belongs to the universe of attitude items if and only if its

domain asks about behavior in a $\left\{ \begin{array}{l} \text{cognitive} \\ \text{affective} \\ \text{instrumental} \end{array} \right\}$ *modality toward an*

object, and its range is ordered from $\left\{ \begin{array}{l} \text{very positive} \\ \text{to} \\ \text{very negative} \end{array} \right\}$ *towards that object”*

(Guttman, in Gratch 1973, 1982; Levy 1985).

The Positive Monotonicity Law of Attitude stating the conditions under which positive or zero correlations are to be expected among attitudinal items reads as follows: “If any two items are selected from the universe of attitude items towards a given object, and if the population observed is not selected artificially, then the population regressions between these two items will be monotone and with positive or zero sign.”

Like intelligence and attitude, most of the concepts of social science are multivariate, and the technique of a mapping definition is helpful in defining them. Indeed, further concepts were defined through mapping sentences, some of them being special cases of attitudes. Examples are:

Attitudinal: well-being, worry, coping (stress reaction), value, protest.

Nonattitudinal: modernization, involvement, social problem indicators.

The First Law of Attitude has been reconfirmed cross-culturally in a large array of research areas. A First Law, like the other laws to be discussed, refers to the overall trend within the population as a whole, but not to individuals. Any correlation that is not precisely equal to +1 implies that there are individuals who are “contradictory” in their behavior.

Positive monotonicity laws are concerned with the shape (monotone) and fixed sign of the regression and are derived from a consideration of the range (or ranges) of the mapping definition. These laws make redundant most of the work merely aimed at establishing the existence of positive correlations among various classes of behavior. Progress has been made in developing hypotheses about lawfulness concerning the sizes (i.e., relative sizes) of the correlations, using further facets to define the items under study (such as the mapping sentence for defining the WISC-R).

Roles of Facets in Establishing Structural Lawfulness

The General Hypothesis of Facet Theory

The general hypothesis of facet theory is that the specification of formal roles for the facets in a mapping sentence provides a rationale for structural theories concerning a correspondence between the definitional framework (the mapping sentence) and an aspect of the empirical data, thereby facilitating the formation of scientific lawfulness in a cumulative fashion.

Theories in social science concern qualitative observations for the most part. In the quest for lawful relations between the content design and the observed data, Guttman’s problem was how to present the data “in some numerical form without losing the qualitative features of the data.” This led Guttman to develop his

intrinsic data analysis methods, especially similarity structure analysis (SSA; previously called smallest space analysis). In this technique, as well as in the other techniques developed by Guttman, the data are treated intrinsically in terms of inequalities, needing no explicit prespecified model.

Similarity Structure Analysis

SSA is a technique for viewing a similarity (correlation) coefficient matrix. It is an intrinsic data analysis technique with an emphasis on looking at regions in the space of variables rather than on coordinate systems.

The Symmetric Case The symmetric case (SSA-I) is the first of the Guttman-Lingoes series designed for analyzing symmetric matrices. SSA treats each variable as a point in a Euclidean space in such a way that the higher the correlation between two variables, the closer they are in the space. The space used is of the smallest dimensionality that allows such an inverse relationship between all the pairs of observed correlations and the geometric distances. Reference axes are *not* in the general definition of SSA. (The empirical data to be analyzed are not limited to coefficients of similarity. They can also be dissimilarity coefficients, such as geographical distances. In such a case the monotonicity condition becomes as follows: the smaller the dissimilarity coefficients between two variables, the closer their points are in the space.) Only the relative sizes of coefficients and the relative distances are of concern. The goodness of fit between the observed coefficients and the geometrical distances is assessed by the coefficient of alienation, which varies between 0 and 1, where 0 designates a perfect fit. The goodness of fit is also expressed graphically by plotting the input coefficients versus the computed distances. This scattergram is called shepard diagram, and it actually portrays the metric nature of the implied monotone function. The less the spread around the negative monotone regression, the better the fit. To put it in another way, the shepard diagram is a graphical representation of the coefficient of alienation. Any such coefficient is blind to content considerations and, hence, alone is inadequate for cumulative science. There is always a need for a partnership with some content theory in determining the shape of the space. Lawfulness regarding sizes of correlations has been established largely in terms of regions of content of the SSA space.

The Asymmetric Case The Guttman-Lingoes SSA series also treats asymmetric matrices (SSA-II). In this program, each item is presented as a point in a Euclidean space, in such a manner that, for any three variables, the two most dissimilar will be farthest apart. Namely, distances are produced within rows or within columns, but not between rows and columns.

Asymmetric Matrix as a Submatrix of a Symmetric Matrix: Weighted Similarity Structure Analysis Producing distances only within rows or within columns, as is done in SSA-II, raises both theoretical and algorithmic questions. To solve these questions Guttman introduced in the mid-1980s the WSSA technique for symmetric matrices, with the inclusion of missing submatrices. WSSA, like SSA-I, requires symmetric matrices, but, unlike SSA-I, it enables us to treat missing data by assigning them zero weight. By doing this, the asymmetric matrix can be regarded as a submatrix of a larger symmetric matrix. Thus it is possible to treat the original asymmetric matrix via the WSSA technique, having the distances produced simultaneously for rows and columns in the same space.

Among other uses, this has facilitated the development of a new theoretical approach to sociometric issues involving square-asymmetric matrices. The same holds for rectangular matrices. Guttman considered this to be the only SSA program with no mathematical problems.

The Concept of Regionality

The regional laws with which the SSA acts as a partner support the general hypothesis of facet theory. Regional hypotheses relate to the roles that the content facets of the variables play in partitioning the SSA space. Three major roles emanate from considerations of order among elements in the facets: the polar, modular, and axial:

Polar Role: *Unordered facet (or alternatively, a facet whose elements have a circular order). Each element of the facet corresponds to a different direction in the SSA space, emanating from a common origin.*

Modular Role: *Simply (or partly) ordered facet, with an "absolute" origin, this origin being common to that of a polar facet.*

Axial Role: *Simply ordered facet, where the notion of order is unrelated to that of other facets.*

(Guttman 1977, in Levy 1994, Ch. 10)

Each content facet corresponds to a certain partitioning of the SSA space into as many regions as there are elements to the facet. Having several content facets, each with its own role, leads to intersecting partitions that generate various geometrical structures such as radex, cylindrex, duplex, and multiplex.

The regionality concept is coordinate-free; regions are to be defined by content considerations. Regions are indicated by—and usually share—boundary points; they are usually not clusters that are discernible by empty space around them. Regional hypotheses are for a space that in principle has points everywhere. This means that some variables in one region may correlate less with other variables of the same region than they do with variables from other regions. Such variables are substantively

dissimilar, yet statistically closer to one another than to similar variables (from the same region). This is a relatively new principle initiated by facet theory, and it enables the detection of lawfulness in data that has hitherto been unobserved or misinterpreted. Attaining more and more refined regions leads to more and more refined restrictions on sizes of correlations.

Stem versus Modifying Content Facets

A rationale for partitioning correspondences can come not only from considerations of order among elements in the facets, but also from the roles that the content facets play within the framework of the mapping sentence.

A differentiation is made between two varieties of content facets: stem and modifying facets. (The term “stem” was suggested by Guttman a short time before his death; earlier this facet was known by different names.) A stem facet directly modifies the name of the range, but does not modify the other facets. An inspection of the mapping sentence for defining the WISC-R, presented previously, suggests that the task imposed on the testee (facet A) is a stem facet. The range of the mapping sentence refers back directly to facet A because what is being assessed from “correct” to “incorrect” is the task (“inference,” “application,” or “learning” a rule) imposed on the testee.

According to Guttman, “stem facets should partition the space orthogonally to each other. A modifying facet sub-partitions into stem facets.” Guttman’s hypothesis was actually confirmed in the 1970s for the area of well-being and was reconfirmed and extended in 1990.

The conceptual independence between the stem and the modifying facets may provide a rationale for their orthogonality. Furthermore, because a stem facet modifies only the range of the mapping sentence, it is by definition an ordered facet; this is because the range (or ranges) of a structured mapping is ordered (according to a common meaning) and hence may play an axial or modular role in partitioning the space.

Number of Facets and Dimensionality of Similarity Structure Analysis

The hypothesized dimensionality of the SSA space is not necessarily connected to the number of content facets in the structured mapping sentence. In general, the dimensionality of SSA can be equal to, greater than, or less than the number of content facets.

Regional Lawfulness in Practice: The Cylindrical Structure for Intelligence Tests

The following is an illustration of the regional theory for the WISC-R, which are defined by the mapping sentence presented previously. This mapping sentence includes three distinct content facets. Facet A distinguishes among the tasks imposed on the testee according

Figure 3 Schematic representation of the cylindrical structure of the Revised Wechsler Intelligence Tests for Children. Reprinted from *Intelligence*, Vol. 15, L. Guttman and S. Levy, “Two Structural Laws of Intelligence Tests,” pp. 79–103, Copyright 1991, with permission from Elsevier Science.

to three elements: rule inferring, rule applying, and rule learning. The elements of facet B are the modalities of expression of the testee, and facet C lists three formats of communication: verbal, numerical, and geometrical. The data come from a 1991 study by Guttman and Levy of two populations; U.S. and Israeli children ages 6–16.

The correlation coefficients for each of the observed matrices yield a three-dimensional structure that can be described schematically by a cylinder (Fig. 3). The placement of points of the subtests of the WISC-R are presented schematically in the cylinder of Fig. 3, which also shows the three intersecting partitions of the space corresponding to facets A, B, and C. The circle (radex) and the axis orthogonal to it provide the cylindrical framework.

The Circular Base (Radex) of the Cylinder The elements of the format facet (C) have the rationale for a polarizing facet because there is no notion of order among the formats of communication (verbal, numerical, and geometrical). Emanating from a common origin, each of the formats corresponds to a different direction in the SSA space, resulting in a partitioning of the space into three wedgelike regions.

A further partitioning of the circular base is by the distance of the subtests from the origin, conforming to the order of the elements of facet A, the task imposed on the testee. Thus, the task facet plays a modulating role corresponding to the notion of order that results both from being a stem facet and from substantive considerations of the meaning of the order among the elements. Tests in the inner circle around the origin have the element of rule inference, whereas those in the outer bands have the elements of rule application and rule learning. Thus, the task facet modulates the order from the origin from inference to application and to learning (instant memory) an objective rule.

The radex lawfulness of the cylinder base means that subtests requiring rule inference tend to be highly correlated among themselves, even though they may be presented in different formats that correspond to different directions of the space. In contrast, correlations among rule-application tests may even approach zero, depending on differences in their format. This radex lawfulness has repeatedly been verified for paper-and-pencil intelligence tests; their regionality prowess was first published by Guttman in 1965.

The Axis of the Cylinder Because the WISC-R are not limited to expression by paper and pencil, an additional dimension is needed to allow the portrayal of the axial role of the additional mode-of-expression facet (facet B). The elements of this axial facet are ordered from oral to written expression, with manual manipulation in between.

Cross-Cultural Replication The same cylindrical lawfulness has been replicated separately for each age group in the United States and in Israel, even though the apparent averages are different.

The Road to Cumulative Social Science

Our example demonstrates the efficacy of the mapping sentence in establishing scientific lawfulness. The mapping sentence provides both the definitional framework for the observations and the rationale for regional hypotheses by assigning formal roles to the content facets that correspond to regional partitioning of the empirical space of the observations.

When a few facets are used, they generally partition the space into relatively large regions. The finer the partitioning into regions, the sharper the delimitation of the sizes of the correlation. The road to finer partitioning is through increasing the number of content facets (intension of the mapping sentence). Most research until now has been limited to a relatively few facets, but these have sufficed to establish basic lawfulness.

The effectiveness of the facet approach in establishing lawfulness for the structure of similarity (correlation)

coefficients matrices in the social sciences in fields such as intelligence, attitudes, social indicators, well-being, values, ethnic identities, involvement, multitrait multimethod matrices, and so forth has been documented by a collection of cross-cultural and long-term replications. They continue to be replicated and extended. The facet approach has also been successfully applied in other scientific disciplines such as engineering, medicine, architecture, and zoology. The many published examples that use the facet approach and arrive at structural lawfulness provide growing evidence that supports the general hypothesis of facet theory. As in all science, attention should be paid to “deviants” from an anticipated structural lawfulness because these may be springboards to further growth.

Facet Theory: Typologies and Spaces of Subjects

Introduction

The formation of scientific structural laws hitherto discussed has concerned typologies and spaces of variables. Here we discuss the branch of theory construction that typologizes subjects (of any population), namely the scalogram, defined as any tabular way of printing out a listing of structuples (profiles). The roots of scalogram analysis are in the unidimensional scale developed by Guttman in the early 1940s. The rarity of the perfect scale raised the need for higher-dimensionality methods to enable a systematic representation of complex multivariate distributions. Multidimensional structuple analysis (MSA) addresses the problem of defining dimensionality for structuples of subjects, with no restrictions whatsoever on the nature of the variables categories. MSA provides a geometrical portrayal of the multivariate distribution in as few dimensions as possible using a principle called contiguity. Partial-order structuple analysis (POSA) deals with the dimensionality of structuples of subjects with ordered categories.

Partly Ordered Typologies

Classification of Subjects: The Categorical Mapping Sentence

A frequent variety of typology is one that results when a given population is classified simultaneously by several criteria (variables), the categories of each criterion being ordered in a sense common to all criteria. Each member of the population has an observed structuple (profile) composed of n structs (categories), one from each criterion, the categories of each criterion being empirically exclusive and exhaustive. In other words, the population is

mapped onto a Cartesian set of a common range. This mapping is termed a categorical mapping sentence and can be expressed abstractly in the following form:

$$x \longrightarrow V_1 V_2 V_3 V_4 \dots V_n$$

Thus, in the categorical mapping, there is one set for the domain, namely population, and a Cartesian set for the range, the items or criteria. Hence, the items are the facets of the range, and their categories are the elements of the range facets.

The Concept of Partial-Order

Although the subjects are simply ordered on each item separately, they are only partly ordered by their structuples from all the items simultaneously because there may be several structuples for each rank. Hence, the overall partial order is an automatic consequence of the simple orders on each item separately. The empirical problem is to ascertain the dimensionality and the substantive meaning of the partly ordered system.

Consider the following set (scalogram) of seven structuples (profiles) observed from a certain population. The four items (facets) *A*, *B*, *C*, and *D* all have a commonly ordered range, where within each item $1 < 2$. The structuples are listed in Table I according to their structuple “sum” or rank. Clearly, this set is not a perfect scale because there is not a one-to-one correspondence between the structuples and the ranks. But it can be easily portrayed as a two-dimensional POSA (Fig. 4). Four symbols for comparability are used: $>$, $<$, $=$, and

$\#$. By definition, a structuple is “higher” than another structuple ($IV > II$) if and only if it is higher on at least one item and not lower on any other item; therefore for structuples II (2111) and IV (2121); IV is higher than II. A similar definition holds for a “lower” relationship: I (1111) $<$ II (2111). Two structuples are “equal” if they are equal in all items. Two structuples are comparable whenever one of these three relationships (“higher,” “lower,” or “equal”) holds. In Fig. 4, comparable structuples are connected by a line. Two structuples are noncomparable ($\#$) if and only if one structuple is higher on at least one item while the other structuple is higher on at least one other item; for example, structuples II (2111) $\#$ III (1112). In Fig. 4, all structuples in the same row are noncomparable, indicating similarity in rank but difference in content. In other words, two structuples with the same score are noncomparable. A scalogram containing noncomparable structuples requires two or more dimensions for its portrayal. A Guttman scale presented earlier, is the case in which all structuples are comparable. The one-to-one correspondence between the structuples and the ranks of a Guttman scale, implies that all the monotonicity coefficients between the scale items equal 1. This means that, in SSA terms, a perfect scale constitutes only one point (zero-dimensional space). However, in the case in which the scale items are only a subset of the items included in an SSA space, the scale items may be presented by more than one point because their monotonicity coefficients with the remaining items may differ and the monotonicity condition of SSA breaks ties.

The stratification of subjects among themselves is automatically a part of the stratification of the entire population that they are a part of. Because the partial order of a subset does not depend on the partial order of the total set, the internal ordering holds regardless of the subjects not in the sample.

Table I List of Structuples

	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>
I	1	1	1	1
II	2	1	1	1
III	1	1	1	2
IV	2	1	2	1
V	2	1	1	2
VI	1	2	1	2
VII	2	2	2	2

Figure 4 A two-dimensional partial-order.

The Partial-Order Structuple (Scalogram) Analysis with Base Coordinates (POSAC) Technique for Portraying a Partial Order

The systematic, yet detailed, study of the similarities and differences among the structuples is facilitated by viewing them in the space of the smallest dimensionality that can preserve the partial order. To determine the (smallest) dimensionality of the partial order, the POSAC technique was introduced by Guttman.

POSAC calculates a mathematically optimal pair of base axes (x and y) for the empirical partial order. Each structuple appears as a point in the two-dimensional space. Any two comparable structuples will have their two points on a line with a positive slope, namely the joint

direction ($x + y$). Hence, in the case of a perfect (unidimensional) scale, all the structuples have their points on a line with positive slope. In contrast, two noncomparable profiles have their points on a line with a negative slope, that is in the lateral direction ($x - y$). "All four kinds of directions in the 2-space (x , y , *joint* and *lateral*) have a role in interpreting the results." These directions are presented schematically in Fig. 5.

The program provides a coefficient for the goodness of fit for the representation of the partial order, named CORREP. It specifies the proportion of structuple pairs correctly represented by POSAC. Three CORREP coefficients are specified, for the entire partial order for the comparable structuples and for the noncomparable structuples.

As already stated, such coefficients alone are not sufficient for determining the shape of the space. A detailed analysis of the systematic differences among the items is made in terms of n POSAC diagrams, one for each item. These are called item diagrams.

The concept of regionality plays a basic role also in the spaces of structuples. The role of the items (which are the facets of the categorical mapping) is to partition the space of the subjects into exclusive and exhaustive regions ordered according to their categories in one or more of the directions of the POSAC space (Fig. 6). The cell (or point)

of a structuple as a whole, is the intersection of all the regions of its structs. Although there need not always be items that correspond to one or more of the POSAC main directions, we may assume that in any universe of items that partly orders a population there will be at least one item corresponding to a main direction, while the others will correspond to directions that are a combination of the main directions.

In case there are variables that correspond to the base coordinates, the partly ordered space is essentially spanned by these two variables. For example, in a 1985 study Levy and Guttman present a partly ordered typology of thyroid cancer patients, according to eight prognostic variables. Two of the prognostic variables were found to correspond to the respective base axes (x and y), meaning that the partly ordered space is essentially spanned by these two prognostic variables. The base axes were then assigned a substantive meaning and the items were termed basic items. Thus, the POSAC revealed systematic differences according to the *kind* of prognostic variables and not just according to the *level* of severity of symptoms. These differences may have implications for treatment procedures as well as for progress toward a richer theory.

Partial-Order Structuple (Scalogram) Analysis with Base Coordinates and Discriminant Analysis for External Criteria

POSAC has an optional routine for predicting an external criteria. The external criteria to be predicted are transcribed onto the partial order. Such a superimposition helps reveal the relationship (if any) between the partial order and the criteria to be predicted. In the 1985 thyroid cancer study, almost a perfect discriminant function was provided by the joint direction for prognosis of survival. This example demonstrates the power of POSAC in bringing out the substantive lawfulness in terms of internal discrimination of symptoms and in establishing the optimal discriminant function for prognostic purposes. "POSAC, with its space diagrams and item diagrams, milks the multivariable distribution to the maximum, and hence provides the best possible

Figure 5 Schematic presentation of the directions of the POSAC space (base coordinates, joint direction, and lateral direction).

Figure 6 Schematic presentation of item diagrams partitioning the POSAC space into regions by item categories, corresponding to the directions of the POSAC.

basis for discriminant analysis, without preconceived assumptions.”

Toward a Richer Theory: Transforming from a categorical to a structured Mapping

The structuples of partial order result from a categorical mapping. This raises the question of constructing a richer theory.

In a structured mapping sentence, there is a Cartesian set for the domain (population and content facets) and one facet (or a few) for the range; however, in a categorical mapping there is a Cartesian set for the range (the items are facets) and one set for the domain (population). Unlike the categorical mapping, the structured mapping sentence leads to theory construction because it enables a simultaneous definition of the universe of observations to be analyzed in accordance with the definitional system. Hence, the main issue for theory construction is the transition from categorical mapping to structured mapping. The first step in doing this is, of course, to consider the uniform substantive meaning of the common range facet. Next we may consider the substantive meaning of the items in the space of the subjects' structuples, such as meaningful base items, as representing elements of content facet(s).

I conclude with the words of Clyde Coombs regarding facet theory. When discussing the complex problem of defining domain boundaries in the social sciences in 1982, he stated that he believed that Guttman's facet theory is “the only substantial attempt to provide a general theory for characterizing domains; in this sense it is a metatheory. As behavioral science advances, so will the need for such theory.”

Half-Life Method

Arthur M. Schneiderman

Independent Consultant, Boxford, Massachusetts, USA

Glossary

balanced scorecard (BSC) A deployment approach for linking strategy to action.

experience curve A normative model of cost reduction based on the learning curve.

half-life method A normative model for predicting rates of incremental improvement for processes of different complexity.

incremental improvement Continuous process improvement achieved by breaking a big problem into many easily solvable little pieces.

organizational complexity The degree to which activities or decisions within a process confront conflicting demands or considerations caused by the way that the participants are organized.

outsourcing Moving an internal process or process step to an independent external source.

PDCA (Plan-Do-Check-Act) cycle The Shewhart/Deming cycle used in improvement activities.

quality circle A supervisor and his or her direct reports who meet regularly to improve the process that they execute.

redesign To fundamentally change the technology employed by or the reporting relationships of the participants in a process.

systematic problem-solving method A documented step-by-step improvement process based on scientific methodology, for example the 7-step method.

SDCA (Standard-Do-Check-Act) cycle The cycle that a worker follows in doing his or her daily job.

technical complexity The degree to which employed technology is understood and mastered by its users.

total quality management (TQM) An evolving set of tools and methods used as part of a companywide focus on continuous improvement.

The half-life method is a normative model for predicting the rate of incremental improvement of nonfinancial performance measures. It can be used both as a diagnostic tool and to set goals. Because it identifies the fastest rate at which a measure can be improved using current incremental improvement tools and methods, it is particularly valuable in testing the achievability of strategically significant balanced-scorecard (BSC) goals without major process redesign (reengineering) or outsourcing.

Introduction

Consider the following situation. You have identified the vital few things that you need to do in order to achieve your strategic objectives, developed actionable metrics, and determined appropriate time-based goals for each of them. Now the question is: Can you achieve those goals in a timely way and thereby feel confident that you have done everything that you possibly can in order to assure your strategic success?

Today many organizations have implemented some form of a balanced scorecard (BSC) that promises to help them translate their strategy into action. But from my experience, only a very small fraction of them have thoughtfully addressed the question of meaningful goals for each of their scorecard measures—goals whose achievement will really make a strategic difference. An even smaller percentage of them have addressed the issue of which methodology or approach they will use in order to achieve these goals. That exercise is generally left to those who will be held responsible for their achievement. There do not appear to be any rigorous impartial studies that provide evidence in conflict with my observations.

Don't burden me with more ideas about how to farm better. . . . I'm not doing what I know how now.

Anonymous Iowa Farmer

What is clear is that simply extrapolating historical performance improvement trends on each of the selected scorecard measures will not get them to their strategic objectives. Or as the saying goes, “Doing what you did, will (at best) get you what you got,” and in most cases that is just not good enough.

It is now widely recognized that improvement of performance measures requires a process focus—the identification and improvement of those underlying processes within an organization that are the leveraged drivers for closing those strategically identified stakeholder-requirement gaps that must be rapidly eliminated if the strategy is to succeed. Once these have been identified, there appear to be three options open to the organization for closing these gaps:

1. Incrementally improve the process.
2. Redesign (reengineer) the process.
3. Outsource the process.

Deciding which is the best choice requires a thorough understanding, for each of them, of the amount of improvement that can be achieved, how long it will take, and how much it will cost. The outsourcing option is further restricted to noncore processes; those that simply support core competencies that differentiate the organization from its competition. These usually are not the processes that can really make a strategic difference. In other words, organizations cannot outsource those crown-jewel processes that give them their distinct competitive advantage.

The cost of achieving the goal, must be addressed on a case-by-case basis. But as a general rule of thumb, outsourcing is the least costly in terms of required cash outlay and redesigning is the most costly. Fortunately, the other two criteria—the greatest possible improvement and the time it will take to achieve it—can be viewed from a normative perspective. That is the principal subject of this entry.

The Half-Life Method

Let us start by considering Fig. 1, which frames the issue by looking at a typical performance measure as a function of future time. The figure shows the measure’s current state. Assume that the measure is defined so that its decrease represents improvement. For incremental improvement, experience shows that improvement follows a typical path. At first, it is as rapid as the “low-hanging fruit” is plucked; but it gradually slows as root-cause and solution identification become more elusive. This is sometimes called the law of diminishing returns. Eventually improvement stalls as fundamental limits on the process’s inherent capability are encountered; the results

Figure 1 Typical improvement curve. Time history of improvement.

just cannot get any better because of basic technological or human limitations.

There are many causes of technological limitations, including fundamental machine variability, finite cycle times, and cues caused by clumps in demand. In the manufacture of semiconductors, the density of airborne dust particles above a certain size in the clean room determines the maximum possible yield that a given facility can achieve. Humans are subject to inevitable and predictable errors, particularly when carrying out highly repetitive tasks such as inspection. So every process has fundamental limits that can only be overcome with new technology (including automation) or by structural reorganization. This almost always involves significant financial cost. Once we acknowledge that zero-defects are economically impossible for any real-world situation and that physics dictates what any process can ultimately achieve, we must recognize that, without significant capital investment, there exists a fundamental limiting performance level for any given process.

It is worth noting here that process reengineering, which is often referred to as discontinuous or stepwise improvement, is not often so in reality. The fundamental effect of process reengineering is a significant improvement in the process’s inherent capability—its theoretical performance limit. Usually this involves replacing people or older machines with automated systems that produce the desired output better, faster, and cheaper. As a rule of thumb, this improvement must be approximately 10-fold to justify it economically in the first place.

And when the new process is activated, at first performance often gets worse, not better! It takes time to iron out the initial wrinkles in the reengineered process and to establish new standard operating procedures to be followed by both operators and the machines themselves (called software). Once startup is complete, the new process, like the old one, must then be incrementally improved in order to approach, over time, its new

and improved limits. In fact, actual performance-improvement histories after process reengineering have a strikingly similar appearance to Fig. 1, but hopefully with a lower asymptote.

To make the economically rational decision whether to improve, reengineer, or outsource, we need some way to predict the expected performance improvement over time.

Serendipity

In 1984, on a flight returning from a study mission to Japan, I made a remarkable discovery. Like many such discoveries, this one was also serendipitous. I was reviewing materials from a presentation given by Kenzo Sasaoka, then president of Yokagowa Hewlett-Packard (YHP). YHP had recently won the coveted Deming Prize. One display (see Fig. 2) showed the multiyear efforts of a quality circle working on the reduction of soldering defects in the manufacture of printed circuit boards.

Starting at a defect level of 0.4%, which corresponded on average to two defects on each board produced, the team systematically reduced the defect level to near zero—or so it appeared. Each of the pointing fingers in the figure represented the implementation of a major corrective action resulting from one cycle of their improvement process. Recognizing that their near perfection was a graphical illusion, the team generated the second graph, which measured the defect level in the

smaller units of parts per million (ppm; 1 ppm = 0.0001% and is equivalent to 6.3σ). With this magnified view, the incremental improvement trend was seen to continue. Over a period of 5 years, the team reduced the defect level by a factor of more than 10,000. Now, instead of having to rework every board on average, only one in 600 required this costly and non-value-adding step.

This is interesting data, but how did it help reduce the boredom of a 15-hour flight? Well, I am an engineer; so faced with those two graphs, I recognized that they could be combined into a single graph if a logarithmic scale was used for the defect level. But I am also a manager and no longer travel with semilog graph paper in my briefcase—and, remember, that was before the now-ubiquitous laptop computer. Therein lay my first challenge. The next few hours were spent creating semilog paper using my calculator and a ruler and regraphing the YHP data. Figure 3 is the result.

Looking at that result, I recognized that radioactive decay has the same general behavior. It is characterized by the constant amount of time it takes for the radiation level to drop by 50%, which is called the half-life. Using that analogy, I calculated the “half-life” for the printed-circuit-board defect rate; it was 3.6 months! In other words, starting at a defect level of 0.4%, after 3.6 months it was down to 0.2%, in another 3.6 months down to 0.1%, in another 3.6 months down to 0.05%, and on and on. In fact, the team went through more than seven halvings of the defect level before something happened and the rate of improvement slowed dramatically to a new and again constant half-life of approximately 8 months. I return to why that happened later.

Figure 2 Process quality improvement. Reduction of soldering defects in a dip soldering process.

Figure 3 Yokogawa Hewlett-Packard dip soldering defects graph.

By the way, John Young, at that time CEO of HP, in describing these same accomplishments commented that:

It's worth noting that the machinery used by YHP was considered obsolete by another HP division in 1973. The insertion defect rate, at 100 ppm, is more than 50 times better than we've achieved at Cupertino.

On my last visit to YHP, that same team was measuring their defect levels in parts per billion (ppb). So the incrementally improvement versus reengineering decision is not always as obvious as it may seem.

Half-Life Math

A mathematically inclined reader will immediately recognize that the path of improvement shown in Figs. 1–3 follows an exponential curve described by the formula:

$$m - m_{\min} = (m_0 - m_{\min})e^{-a(t-t_0)/t_{1/2}}$$

where:

m = current value of the scorecard metric

m_{\min} = minimum possible value of m

m_0 = initial value of m at t_0

t = current time

t_0 = initial time

$t_{1/2}$ = half-life constant

$a = \ln 2 \approx 0.7$

The half-life is measured in units of time, typically months, and represents the amount of time it takes to achieve a 50% improvement in the metric. One of the remarkable features of exponential improvement is that the half-life does not depend on the initial point; in other words, it is a constant over the large range of improvement. Let us say, for example, that our scorecard metric is on-time delivery. If the current performance is 75% and the best possible performance given the processes fundamental limitations is 95%, then there is a performance gap of 20%. If we assume a 6-month half-life, then we should achieve 85% performance after 6 months, leaving a 10% gap remaining. In the 6 months after this, we should be able to reduce the gap by 50% (which is 5%), so our resulting performance after a total of 1 year should be 90%. This pattern continues with each successive 6-month period chewing up half of the remaining gap.

In calculating the half-life from historic data, it is only necessary to get an approximate value. If the data are provided using a linear axis, start by drawing a smooth curve through the data shaped roughly like the curve in Fig. 1. Then simply choose a convenient initial point on that your curve and estimate the time it took for half that value to be reached. Repeat this at several points on the curve and simply average the results. If the data are plotted using a semilog scale, then fit a straight line through the data and repeat the described procedure. It is straightforward to determine the half-life more rigorously using software packages such as Excel or Lotus 123. Using them provides the additional benefit of providing a measure of statistical significance of how well the model fits the data.

What Determines the Improvement Half-Life?

The obvious question that arises is “What determines the improvement half-life?” I discovered the answer to this question nearly 15 years ago and published my findings in two articles that appeared in *Quality Progress*, a publication of the then American Society for Quality Control, now called the American Society for Quality. The answer is that the improvement methodology employed, as well as the complexity of the process that the metric represents, determines the half-life.

Over the millennia, various means have been employed to change the current state to a more desirable one. Figure 4 is my attempt to capture many of these approaches. The ones of interest here are on the branch containing the various systematic methodologies that rely on real-world data and are based on the scientific methodology embodied in the Shewhart-Deming or PDCA (Plan-Do-Check-Act) cycle.

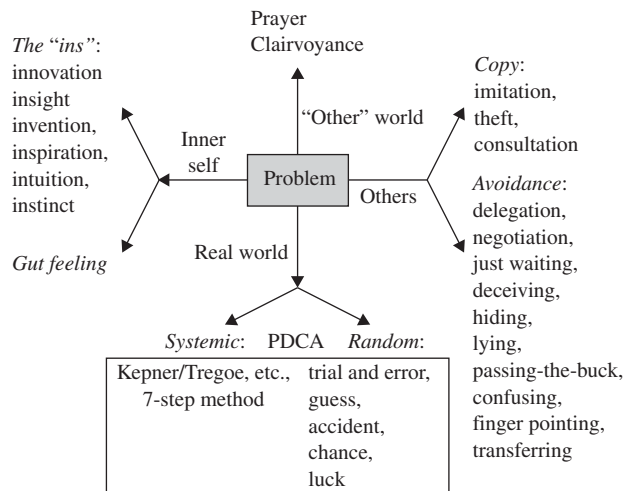

Figure 4 Options for problem solving.

Science versus Chance

Although scientific methodology has been around for thousands of years, its application has been restricted to a very small set of individuals who have been trained in its use. By using a scientific approach, the rate of improvement is increased 10-fold over trial and error, evolution's apparent approach to improvement. The Industrial Revolution prompted a desire to broaden its user base. In the early part of the twentieth century, leaders such as Frederick W. Taylor and Walter Shewhart were teaching simplified versions of the scientific method of discovery to nontechnically trained individuals out on the shop floor. In the late 1930s, Kepner and Tregoe even made a franchised consulting business of it. By the 1950s, at the prompting of Ed Deming, the Japanese Union of Scientists and Engineers (JUSE) institutionalized it in their Quality Circle movement. Figure 5 is an example of its current state of refinement, known as the 7-step method.

The 7-step method shown in Fig. 5 distinguishes itself from trial and error in a number of critical ways. It uses root-cause analysis to mitigate the waste inherent in the trial-and-error approach (steps 2 and 3). It validates candidate solutions to assure that they have the desired effect (step 5). It retains improvements in the process's memory by incorporating them in written standards (step 6). And, perhaps most important, it embodies double-loop learning by encouraging its users to consider ways to improve their problem-solving methods and skills and to prepare for their next cycle of improvement (step 7). Compare this 7-step method to its more commonly used cousin that consists only of steps 1 and 4.

Motivated by what I discovered at YHP, I studied nearly 100 separate exemplary process-improvement

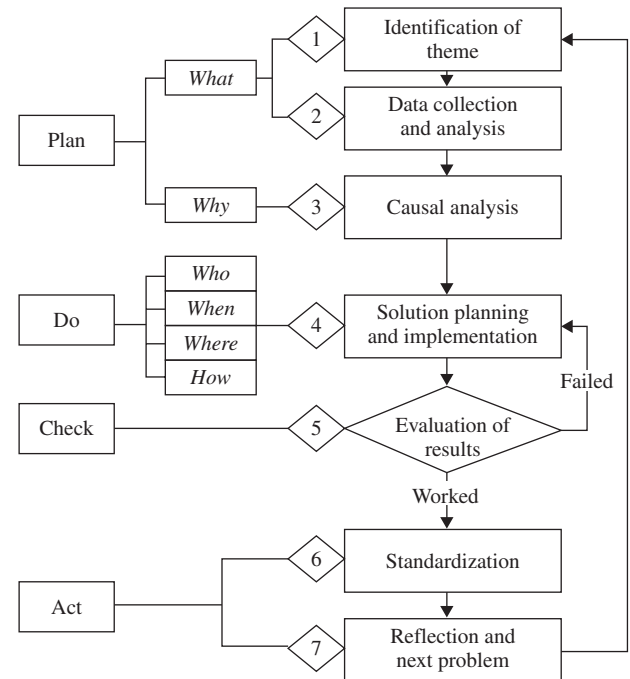

Figure 5 Incremental improvement, the PDCA cycle and the 7-step method.

efforts, each of which employed what was essentially this 7-step method. On average, these projects achieved a sevenfold improvement in their metric over a 3-year period by maintaining an 11-month half-life. I discovered in all cases that the rate of improvement, captured by the half-life metric, was essentially constant (average $r^2 = 0.77$) within each effort, but varied from project to project ranging from less than 1 month to more than 4 years.

The Role of Process Complexity

The stratification of the resulting observed half-lives demonstrated that this variation was the result of differences in the organizational and technical complexity of the process being improved. The half-life matrix shown in Fig. 6 summarizes my findings.

Organizational complexity spans the range from uni-functional to cross-functional to cross-business processes. Technical complexity captures the maturity of the embodied technology from simple and well established to new and not yet fully developed. For processes of average organizational and technical complexity, the use of a systematic improvement methodology such as the 7-step method will usually yield a half-life of 9 months; that is, the gap between current and potential performance will close at the rate of 50% every 9 months.

For the most complex processes, the half-life increases to nearly 2 years, whereas for the least complex ones a half-life of 1 month is more typical. An inspection of

		Target half-lives, months		
Organizational complexity	High	14	18	22
	Med	7	9	11
	Low	1	3	5
		Low	Med	High
		Technical complexity		

Figure 6 Half-life matrix.

Fig. 6 shows that increasing organizational complexity has about three times the slowing effect of increased technological complexity. This clearly supports the current notion that organizations should be structured around processes rather than functions in order to increase their potential rates of improvement.

Returning to the YHP example, what caused the observed half-life to suddenly change from 3.6 to 8 months? At a subsequent visit to YHP, I shared Fig. 3 with Mr. Sasaoka and his vice president of manufacturing. After much discussion, we discovered that around the time that the improvement rate slowed, the team discovered that most of the root causes of the remaining defects lay not with manufacturing but with the design of the boards themselves. The team needed to be expanded to include the design function, not just manufacturing, thus increasing the organizational complexity of the process.

Why the Half-Life Method Works

The half-life method is an empirically based normative model for process improvement. Yet there is a simple explanation of why it works. First, consider the notion of the dual function of work depicted in Fig. 7. In this contemporary view of the purpose of work, all members of an organization have two distinct responsibilities. The first is to do their daily job of contributing to the organization's ongoing value-creating activities. They do this by executing their current process using its associated standard operating procedure. But, unlike Charlie Chaplin's character in the classic movie *Modern Times*, they are also empowered to spend a portion of their time improving the way that they do that job. These two activities are referred to as the SDCA (Standard-Do-Check-Act) and PDCA (Plan-Do-Check-Act) cycles.

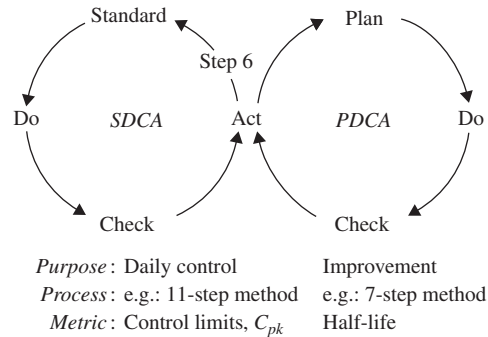

Figure 7 The dual function of work, SDCA and PDCA cycles.

The portion of time spent and the tool set employed in PDCA activities vary by organizational level. Typically, production workers spend 5–10% of their time in improvement activities, whereas people in top management spend approximately one-half of their time improving or managing the improvement of the organization's critical processes. Because, in general, process complexity increases as the organizational level of its executors increases, the tools change from simple statistical analysis to more complex language-based and modeling methods.

Like any normative model, it is difficult to mathematically prove why the half-life method works. But by studying how continuous process improvement is done in practice, we can understand its underlying “physics.” First, we need to look at the typical findings of steps 2 and 3 in the 7-step method. A common format for presenting these findings is the Pareto diagram, a rank-ordered bar chart showing the identified causes of the performance gap. It should come as no surprise that all possible causes are not created equal; some are more important than others. So in nearly all cases, the 80-20 rule applies, with 20% of the likely causes being responsible for 80% of the gap. In fact, Pareto charts almost always show an exponential decline in the significance of each successive rank-ordered cause. Typically, the most significant one, called the root cause, is responsible for 30–50% of the total gap. Once this root cause has been mitigated, the Pareto chart for the remaining gap looks very similar in shape to the original one. The new root cause (usually the second bar on the earlier chart) now represents 30–50% of the new and smaller gap.

The nature of the continuous improvement process is such that the team that is executing it continuously cycles through the 7-step method, gnawing away at the remaining ever-decreasing gap. How long does it take for each cycle? The answer depends on the complexity of the process that is being improved, but in general it ranges from 3 to 6 months. Both worker and manager impatience and the need to see short-term results conspire so that the total gap be broken down into small enough pieces to assure visible progress can be made in that time frame.

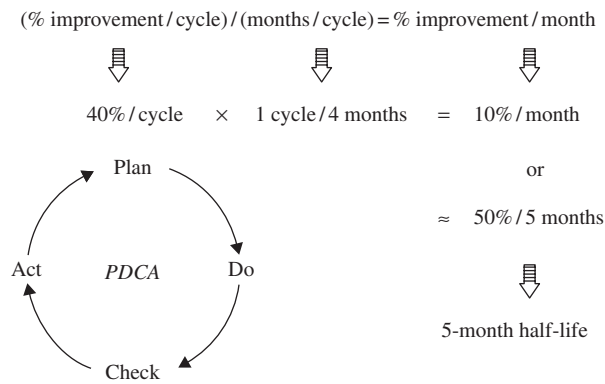

Figure 8 Why the half-life method works.

Knowing the percentage improvement per cycle and the number of months it takes per cycle allows us to determine the improvement per month (by simple division). Figure 8 depicts this calculation, showing how a 40% improvement every 4 months corresponds to a 5-month half-life.

Process complexity affects both the improvement per cycle and the months per cycle. Complex processes have more potential causes, and each cause tends to have a smaller individual effect; in other words they have flatter Pareto diagrams. Also, it takes longer to complete each cycle because cross-functional issues and technological complexities inevitably slow progress. So the half-life method works because the causes of the remaining gap nearly always obey the 80-20 rule and because the time required to execute each PDCA cycle remains roughly constant for a given level of organizational and technological complexity.

Half-Life Method versus Experience Curve

I am often asked how the half-life method differs from the experience curve popularized in the 1960s by Bruce Henderson, founder of the Boston Consulting Group. Henderson promoted, under a new name, the learning curve that was discovered by T. P. Wright and published by him in 1936. The learning curve, developed in the aircraft industry, was based on the observation that unit direct-labor use, expressed in total worker-months, declined with increasing experience. Henderson noted that the same was also true for unit cost. Based on this observation, he went on to develop a strategy model that had the experience curve at its cornerstone.

The experience curve, like the half-life, is also an empirical observation. It states that for each doubling of cumulative experience (total units produced from the very beginning, not just this year), real unit cost drops

by a constant percentage, for example 20%. If your first million units have an average cost of \$10 each, then your next million units should average \$8 each, your next 2 million units, \$6.40, your next 4 million units, \$5.12, and so on. Given that cost is driven by cumulative units produced (1 million + 1 million + 2 million + 4 million in our example), the rate of decline of the cost tends to drop over time unless unit volume grows at a sufficiently high offsetting rate.

The half-life method, on the other hand, predicts that the rate of decline of the defect level is constant over time. Why the difference? We cannot say for sure because the experience curve is purely an empirical observation and is not based on any underlying theory. We can list the things that probably affect the slope of the experience curve, but we cannot write an equation in which they are the independent variables. On the other hand, as already described, there is a theoretical basis for the half-life method.

Also, keep in mind that the half-life deals with defects, not cost or labor hours. Of course, defects, defined as any gap between current and potential performance, are often a principal driver of unit costs, so the two are clearly related. Twenty years ago, the unexplainable leapfrogging done by Japanese industry baffled experience-curve practitioners. How could they possibly achieve experience-curve slopes two or more times steeper than their Western counterparts? The initial reaction was that they were using predatory pricing, selling below cost in order to buy market share. The furor even made its way to the U.S. Congress. But careful study of the situation, the object of my first visit to Japan, showed that their hyperfast cost reduction was real and the result of their new approach to process improvement: Total Quality Management (TQM).

The experience curve became the very basis of competitive strategy for several decades after its discovery, leading to a focus on the positive feedback loop between market share, cumulative experience, and unit cost. The half-life method can be used to form the basis of a similar competitive dynamic.

Using the Half-Life Method

There are two basic uses for the half-life method: improvement process diagnosis and goal setting. If we benchmark similarly complex processes and find that the best-practice half-life is significantly shorter than what we are experiencing, then we can infer that the best-practice organization's improvement process itself is capable of faster rates of improvement than the one that we are using. This should trigger careful study of what they are doing that we are not, thus providing a valuable source for organizational learning.

The second use, goal setting, is in a critical step (step 9) in the creation of a type 7 balanced scorecard, an approach for linking strategy and action. It is also used in step 5 of my seven steps of process management. Earlier in this entry, I described a key strategic decision that must be explicitly made if an organization is to have any chance of achieving its strategic objectives—whether to incrementally improve, redesign, or outsource. Those objectives have been translated into a few vital set of metrics and associated time-based goals that must be achieved for strategic success. The half-life method provides a tool for assessing the likelihood that the goal can be achieved through best-practice incremental improvement. By placing the driving process in the appropriate cell of Fig. 6, a target half-life can be determined. Using this half-life value and estimating the gap between current and potential performance, that performance can be projected to the date associated with the achievement of the scorecard goal. If the result is better than the goal, then in principle it can be realized using state-of-the-art incremental improvement. If it fails to meet the goal, then no amount of wishing or cajoling will produce success. You just cannot get there from here by merely improving the existing process.

In making this calculation, it is important to consider the underlying assumptions that form the basis for the half-life method:

1. The people who execute the process will do the improving.
2. They only spend a small portion of their time on it.
3. They will use a systematic problem-solving methodology equivalent to the 7-step method.

Modify any of these assumptions and you must reflect that change in the half-life value that you assume. For example, assigning expert resources such as a trained process engineer or statistician to assist the team will usually lead to faster improvement. The same holds if you increase the amount of time spent on improvement versus daily job activities.

If incremental improvement still cannot get you there, then process redesign or outsourcing are your only alternatives. If neither of those are feasible, then the only remaining recourse is to change your strategy or accept the fact that the strategy you are pursuing is just not achievable.

Talk (of Action) Is Cheap

Reading the current popular literature on new management practices is often very frustrating. Many of the “new” ideas promoted by today’s leaders are merely the repackaging of old ones with at best a slightly new twist. I believe that this phenomenon arises from the difficulty

organizations often have in truly institutionalizing new ideas. A case in point is the inculcation of TQM into an organization’s culture. Ask nearly any major organization if they do TQM and their answer will more than likely be, “Oh yes, why we did that 10 years ago.” But seek evidence that it has become a real part of their way of doing business, and you will begin to doubt their assertion.

In particular, look at the rates of improvement that they have achieved on their BSC metrics. You will most likely find them significantly slower than the half-life method would predict. In fact, they probably will differ little from the pre-TQM rates of approximately ~5% per year; and most of that will have come from technology, not process improvement. In other words, as that anonymous Iowa farmer said, “We’re not doing what we know how now.”

The half-life method gained much visibility in the business world as the result of a still-popular Harvard Business School case study by Kaplan, first published in 1989. The Board of Directors of one Fortune 100 aerospace company, a well-known TQM advocate, even adopted it as its official nonfinancial metric for judging business unit performance. However, after a few years of embarrassingly long half-life results, it was relegated to the back burner as a management tool. Why? Was the concept incorrect, or was this just another case of shooting the messenger?

I believe that the half-life method is a measure of process learning and that the reduction of a half-life over time is an indicator of organizational learning. As such, it is only useful to organizations that are committed to continuous applied learning. For others, it will probably be of questionable value as a performance metric.

Hazards Measurement

Susan L. Cutter

University of South Carolina, Columbia, South Carolina, USA

Glossary

disaster A singular hazard event that results in widespread human losses or has profound impacts on local environments.

discharge The quantity of water flowing past a point on a stream or river per some unit time.

exposure models Statistical or analytical models that delineate the probability of risk, its source, the type of risk, and the geographic extent of danger.

hazard The potential threat to humans (risk) as well as the impact of an event on society and the environment.

intensity The measure of event severity based on subjective human experience of it.

magnitude The strength or force of a hazard event.

recurrence intervals The time between events of a given magnitude or the magnitude range for a specific location.

risk The likelihood or probability of occurrence of a hazard event.

temporal spacing The sequencing and seasonality of hazard events.

vulnerability The potential for loss or the capacity to suffer harm from a hazard event.

Hazards measurement entails a suite of models, methods, and tools used to assess what makes people and places vulnerable to environmental threats, including the source and physical characteristics of environmental threats, and an evaluation of their impacts on society over time and across space.

The Origin of Environmental Hazards

Environmental hazards are threats to people and the things we value. They have many different origins, yet

we normally think of hazards as occurring as a consequence of the interaction between natural systems, technological systems, and human systems. As such, we often classify hazards according to their causal agents—natural events that are infrequent (earthquakes and hurricanes) and relatively common (blizzards and coastal erosion), technological events (extreme and common events such as nuclear power plant accidents or chemical spills), social disruptions (terrorism, riots, and warfare), biological agents or biohazards (epidemics, infestations, and bioterrorism), and chronic and global significant hazards (climate change, pollution, and environmental degradation) ([Table 1](#)).

Hazard Identification

The identification of hazards poses real challenges because we discover new sources of threats on a daily basis. For example, the rediscovery of anthrax as a biological hazard came to light only after the terrorist attacks of September 11, 2001, despite its longevity as a known hazard to the agricultural community. Likewise, a recent federal survey of streams found trace amounts of antibiotics, steroidal compounds, nonprescription drugs, and disinfectants, all of which are found in consumer products. This prompted the Food and Drug Administration (which approves these products for human and animal use) to begin thinking about the adverse environmental impact of these substances after they have been excreted from the body (human and animal), thus identifying yet another hazard in the environment.

Two methods are primarily used to identify risks and hazards: quantitative risk assessment, a procedure used to identify human health risks from involuntary exposures to hazardous substances; and environmental indicators, which monitor ecosystem diversity and

Table I Origins of Environmental Hazards

<i>Causal agent</i>	<i>Example</i>
Natural hazards	
Hydrologic	Drought, floods, flash floods
Atmospheric	Hurricanes (cyclones), tropical storms, tornadoes, severe storms, temperature extremes, lightning
Seismic	Earthquakes, volcanic eruptions, tsunamis
Geomorphic	Landslides, mass movements, avalanches, soil subsidence, rockfalls
Other	Wildfires
Biological agents	
Epidemics	Influenza, cholera, AIDS
Infestations	Locusts, termites, bees, grasshoppers
Other	Bioengineered substances, bioterrorism
Social disruptions	
Civil disorders	Ethnic violence, urban riots
Terrorism	Bombings, chemical/biological weapons, hijackings
Warfare	Conventional war, weapons of mass destruction
Technological	
Extreme Failures	Nuclear accidents, dam failures, industrial explosions
Common Occurrences	Hazardous materials spills, chemical accidents, oil spills
Chronic/globally catastrophic hazards	Pollution, environmental degradation, famine, nuclear war, global environmental change, natural resources depletion

health. Traditionally, human health risks have been identified through disease clusters (a large number of outbreaks of illnesses in one location that exceed the random probability of such events), such as the cancer clusters found in Love Canal, NY, or Woburn, MA; epidemiological surveys that involve detailed field surveys to determine the linkage between an environmental contaminant and human disease, such as John Snow's nineteenth-century classic study of cholera in London; and bioassay data, the foundation of toxicological research, in which chemical exposures in laboratory animals determine dose-response relationships that are then extrapolated to human populations.

For environmental hazards, the most often used methods for hazard identification are surveillance and monitoring. Documenting variability in spatial and temporal patterns of environmental indicators is a first step in identifying environmental hazards. The real-time detection of seismic events anywhere in the world is now possible through the global seismic network. The development of WSR-88D Doppler radar has improved our ability to forecast and track the path of tornadoes, for example, whereas light airborne detection and ranging (LIDAR) systems are able to predict the potential extent of flooding based on digital terrain models or establish the height of the debris pile from the collapse of New York

City's World Trade Center. Improvements in sensor technology and the satellites have resulted in better spatial resolution (1×1 meter) than in the past, thereby improving the remote monitoring of floods, wildfires, volcanic eruptions, snow cover, hurricanes and tropical storms, chemical releases, and nuclear accidents, among others. These systems have been instrumental in developing better forecasting information, resulting in fewer injuries and loss of life from environmental hazards.

Hazard Characteristics and Risk Characterization

Because the origins of environmental hazards are so diverse, it is difficult to compare them over time and space. However, we can use a common set of characteristics that enable us to measure the relative strength or impact of a particular hazard event and in this way compare them. Unfortunately, not all types of hazards have sufficient quantifiable measures of each of these characteristics. As a consequence, for some hazard events these characteristics are described in qualitative terminology such as large or small, strong or weak, fast or slow, whereas

others have quantifiable scales. The parameters used to characterize hazards and risks are described next.

Magnitude

The sheer strength or force of an event is one characteristic that can be used to compare hazards. For earthquakes, the Richter scale, developed in 1935, provides a measure of the seismic energy released (in ergs) from an earthquake, using a logarithmic scale. The magnitude of an earthquake increases 10-fold from one Richter number to the next, so that an earthquake measured as 7.2 on the Richter scale produces 10 times more ground motion than a magnitude 6.2 earthquake, but it releases nearly 32 times more energy. The energy release best indicates the destructive power of an earthquake. The Saffir-Simpson hurricane scale (ranging from category 1 to 5) is a measure of hurricane strength based on maximum sustained winds. In the case of floods, the magnitude is simply quantified as the maximum height of floodwaters above some base elevation (mean sea level, flood stage, or above ground). Snow avalanches also have a magnitude scale ranging from 1 to 5, based on avalanche size relative to the avalanche path size. Finally, the volcanic explosivity index (VEI) provides a relative measure of the explosiveness on a 0–8 scale based on the volume of materials (tephra) released, eruption cloud heights, explosive energy, and the distance traveled by the ejecta. For example, the 1980 eruption of Mt. St. Helens is rated 5 on the VEI, whereas the 1815 Tambora, Indonesia, eruption that killed more than 92,000 people is rated 7 on the VEI.

Intensity

In addition to magnitude based solely on physical characteristics, intensity offers a metric to gauge the severity of an event based on the subjective human experience of it. The modified Mercalli scale (class I to XII) is a measure of the effects at a particular location. On the modified Mercalli scale, the intensity of earthquakes is based on magnitude, distance from the epicenter, building construction, and local geology, all of which contribute to the damage of structures and human experiences (e.g., whether they are felt by people or not). The Saffir-Simpson hurricane scale also has an intensity element within it, offering qualitative descriptions of probable property damage and potential flood levels based on anticipated storm surges. The Fujita scale of tornado intensity is another index used to measure hazard severity. Based on postevent structural-damage assessments, tornadoes are classified (with approximate wind speeds) as F0 (minimal tornado) to F5 (catastrophic and totally devastating). In the case of drought, there are quite a few drought intensity indices. The most well known in

the United States is the Palmer drought severity index based on precipitation, temperature, and local availability of water in the soil (water balance) and is used to delineate abnormally wet or dry conditions. Last, the international nuclear event scale (developed in 1990 in the aftermath of the Chernobyl nuclear power plant accident) is used to distinguish accidents based on the type of release (off site vs. on site), the amount of radioactivity released, reactor damage, and potential human health and environmental impacts. The scale ranges from 0 (nonsignificant) to 7 (major accident with acute health effect and long term environmental consequences).

Frequency

This characteristic details how often an event of a given magnitude or intensity occurs. More often than not, the frequency of events is based on qualitative judgments of rare or frequent. More quantitative assessments are available in the form of recurrence intervals or frequency of occurrence (the number of events per number of years in the period of record) metrics. Flood frequency curves are generated based on the available history of discharge for a river or river stretch. For regulatory purposes involving floodplain management, a commonly used indicator for flood events is the 100-year flood. This does not mean an expectation of one large flood every 100 years (a common misperception) but rather signifies a 1% chance of a flood with this specific discharge occurring in any given year. Snow avalanche return intervals are common as well, but these are normally based on the age of trees on the avalanche path rather than some arbitrary time frame such as 100 years.

Duration

Another temporal dimension of environmental hazards describes how long the event lasts. Some hazard events have a very short duration measured in seconds to minutes (earthquakes), whereas others are prolonged events that can last years to decades (droughts). There are no specific scales or indices that depict duration.

Speed of Onset

The speed of onset provides a measure of the length of time between the first appearance of an event and its peak. Hazards are often described as rapid-onset hazards (earthquakes and tornadoes) when they offer little or no opportunity for warnings to get people out of harm's way once the impending signals are received or slow-onset hazards (soil erosion and drought), which take a year to decades to fully develop from their initial appearance. Of course, there is the occasional extreme drought year such as the 1976–1977 drought in California, the Great Plains,

and Upper Midwest, which caused more than \$10 billion in direct losses.

Temporal Spacing

Some hazards events are quite random in their timing, whereas others have a distinct seasonality (hurricanes and blizzards) to them. The designation of “hazard seasons” (June 1–November 30 for Atlantic basin hurricanes, April–November for tornadoes, winter for blizzards, and summer for heat) assists in the emergency preparedness, planning, and management of these hazards.

Areal Extent

This is a measure of how much of the geographic area was affected by the hazard event and is usually described as large or small. It should not be confused with hazard zones, which are clearly demarcated areas that are high risk such as floodplains or barrier islands. Disasters normally have large areal extents, whereas a small tornado or hazardous material spill has a more localized impact (one house or one segment of a road). There are no consistent scales that empirically define the areal extent of impacts from hazards.

Spatial Dispersion

Hazards are also described and compared based on their spatial distribution. For example, at a national scale we can see some cluster of tornado touchdowns in particular regions (such as the so-called “Tornado Alley”), yet when we examine the distributions within this region, they appear to be more random. Tornadoes at smaller spatial scales may relate more to the nuances of physiography, whereas at larger scales atmospheric circulation and air masses are more likely to dictate the spatial dispersion of tornadoes. Spatial concepts (dispersion, contiguity, density, and concentration) and geographic-scale differences are useful in examining hazard events because they provide additional information on the distribution of those types of events in a given area.

Nature of Exposure

The final characteristic of hazards is less indicative of the physical characteristics of the hazard, but more oriented toward how individuals and society respond to them. Primarily using the criterion voluntary or involuntary, this dimension differentiates hazards in which there is some degree of human intervention in the level of exposure, either through locational choices (residing in a known floodplain or on a coastal barrier island), voluntary participation in certain risky activities (sky diving, smoking, and scuba diving), or consumer preferences for products

(herbal supplements, organic produce, child restraints in cars, or bicycle helmets). Oftentimes, these hazards and risks are perceived as more acceptable and less frequent in their occurrence. On the other hand, risks and hazards that we are involuntarily exposed to, such as nuclear fallout, climate change, and radioactive waste disposal, produce greater societal concern to reduce their adverse impacts.

Assessment Tools and Techniques

Risk Estimation Models and Indices

The majority of risk estimation models are hazard specific, such as hurricane strike predictions or the pathway of a toxic plume. They are designed to assist in the issuance of hazard warnings to the public and in the development of protective actions to guard against potential harm. In some instances, they can be used to determine the population that is potentially exposed to the risk. As mentioned previously, the hazards field is so diverse that it is virtually impossible to identify, let alone describe, all the risk estimation models. The discussion here highlights some of the most important ones currently in use.

Dispersion Models for Hazardous Air Pollutants

Dispersion models are crude mathematical representations of the airborne transport of contaminants and the downwind concentrations. Many can accommodate multiple sources, multiple receptors, and varied timing and duration of releases. The most commonly used are the U.S. Environmental Protection Agency’s (USEPA’s) Industrial Source Complex (ISC) suite of models, such as the short-term version called ISCST3. For emergency managers, USEPA’s Areal Locations of Hazardous Atmospheres/Computer-Aided Management of Emergency Operations (ALOHA/CAMEO) model is the most widely used air dispersion model.

Coastal Storm Surge Inundation

Areas subject to flooding in hurricanes are measured by the Sea, Lake, and Overland Surges (SLOSH) model developed by the U.S. National Weather Service. This dynamic model was initially developed to forecast real-time hurricane surges, but has proven so successful that it is now widely used for preimpact hurricane planning, including the delineation of evacuation zones.

Hurricane Strike and Wind Field Intensity

The National Hurricane Center provides forecast information on storm track, intensity, and surface winds for both tropical storms and hurricanes. Using dynamic and statistical models such as Navy Operational Global

Atmospheric Prediction System (NOGAPS) and Geophysical Fluid Dynamics Laboratory (GFDL), improvements in storm path designations have been made. At the same time, enhancements of some of the cyclone intensity models have resulted in better estimations of the wind field strengths in advance of the storm.

Tornado Risk

Tornado risks were first identified visually by people who happened to see a funnel cloud and called the local weather station or by designated tornado spotters whose job was to go out and watch the sky. With the development of Doppler radar, detection improved with the ability to identify rotation and air velocity in parent storms (mesocyclone signatures) that spawn tornadoes as well as the distinct hook-shaped feature on the radar. These improvements have increased our warning times from less than 5 minutes 20 years ago to more than 10 minutes today.

Flood Events

Flood risk models require precipitation inputs and runoff estimates. Working in tandem, both the U.S. Geological Survey (USGS) and the U.S. Weather Service provide the relevant exposure data for flood events. There are a variety of runoff-rainfall models that are used for flood hazards such as the USGS's Distributed Routing Rainfall-Runoff model (DR3M). The most widely used flood damage model is the U.S. Army Corps of Engineers's Hydrologic Engineering Center's Flood Damage Assessment model (HEC-FDA). Finally, the National Weather Service has a couple of models that examine the potentially affected downstream areas from floods caused by dam failures (DAMBRK and BREACH).

Nonpoint Source Pollution

Developed by the U.S. Department of Agriculture, the Agricultural Nonpoint Source (AGNPS) pollution suite of models is a widely used tool to predict soil erosion and nutrient loadings from agricultural watersheds. This model captures runoff, sediment, and nutrient transport (especially nitrogen and phosphorus) inputs in trying to assess surface water quality.

Seismic Risk

Seismic risks are determined either through mapping of known surface and/or subsurface faults and by estimates of ground motion. Both approaches employ historical analogs. Probability approaches that include some indicator of the likelihood of an event or the exceedence of some ground-shaking threshold are the mostly commonly used. The Federal Emergency Management Agency (FEMA) uses effective peak acceleration and effective peak velocity measures to delineate seismic risks.

Extremes of Heat and Cold

The heat index (based on temperature and humidity) provides a measure of the "felt" temperature and sends warning information to residents to reduce physical activity so as to not induce heat stroke. Its corollary, the wind chill index, is used to monitor the effect of wind on "felt" temperatures to forecast conditions that are conducive to hypothermia.

Social Consequences and Loss Estimation

There is very little consistent data on what environmental hazards cost the United States on an annual basis. This is a direct function of measurement issues. For example, there is no consistent agreement on what is meant by loss, yet the prevailing wisdom is to equate losses with costs, expenditures, and lost benefits. These can be direct or indirect, tangible or intangible. Direct losses relate to actual building damage, injury, or loss of life as a consequence of a hazard event. Some of these losses are privately insured or are reimbursed to individuals and communities by the government. Indirect losses are more difficult to measure and monitor because they are often hidden and appear much later after the initiating event. An example of indirect costs are losses incurred relating to the lack of revenue from tourism on a barrier island beach in the aftermath of a hurricane. An additional complicating factor in measuring losses is how to quantify some of the intangible losses such as loss of life or debilitating injuries caused by an environmental hazard. There are no uniform standards or criteria for these, so loss estimations from environmental hazards events often are more an art than a science.

A number of models are currently in use to assess direct losses from natural hazards. These tools are specific to the type of loss (direct economic or environmental) and scale (individual structure, county, or region). Private-sector approaches examine direct losses through financial risk assessments based on probabilistic models of event frequency and magnitude and potential property exposure. Reinsurance companies use financial risk assessment models as well, but these are usually based on worst-case scenarios, which are then used to set the premiums charged to insurance companies.

Hazards US

FEMA has developed a tool, called Hazards US (HAZUS), that forecasts damage estimates and economic impacts from earthquakes at the local level. Using a scenario earthquake, HAZUS incorporates the physical characteristics of the event coupled with building inventory, infrastructure, and population data. This tool is quite effective in providing loss estimates at

a variety of geographic units for earthquake-induced damages throughout the country. Recently, a wind module and a flood module were added so that the top three natural hazards (earthquakes, floods, and hurricanes) are now part of the multi-hazard assessment tool.

Ecological Risk Assessments

Ecological risk assessments provide a quantitative estimate of ecosystems or species damage due to toxic chemical contamination. Similar to human health risk assessments, ecological risk assessments normally focus on a single contaminant at a time and on a single species. However, the use of multiple stressors (contaminants), end points (type of damage), and scales (species to ecosystem) is beginning to take hold.

Geographical Information Systems

Geographical information systems (GIS) is a computer-based tool that enables the integration of disparate data (topography, infrastructure, hazard zones, population, and surveillance data) in order to analyze, model, and map information. In this regard, GIS offers the capability to manage, store, and analyze large volumes of data within a specific geographic setting. These data can contribute to loss-estimation modeling, help determine the potential population at risk, or be used in preimpact planning and mitigation efforts. GIS is widely used throughout the U.S. federal agencies involved in hazards measurement and monitoring.

Data Caveats

There are many federal, state, and local agencies as well as the private-sector organizations that collect and disseminate data on hazard events and losses. The methods used vary widely, as do the definitions of losses. The temporal and geographic coverage is equally variable, rendering much of these data incompatible with one another. For example, FEMA compiles statistics on presidential disaster declarations, but does not archive hazard event or economic loss data that do not qualify for that designation. Similarly, flood event and loss data are compiled by three different federal agencies (USGS, National Weather Service, and the U.S. Army Corps of Engineers) for very different purposes, yet are rarely shared or reconciled. Natural hazards are cataloged differently than technological hazards. Private insurance companies compile insured loss data, but what about uninsured losses? Access to data is limited (especially in the private sector) and is increasingly becoming more so. Along with issues of accuracy, precision, incompatibility, and dissemination come concern about data maintenance and archiving. It is often not in the purview of a mission agency to warehouse historical data on hazard events. The result

is fragmented and incomplete data on hazard events, their characteristics, and the losses incurred from them. Thus, the measurement of hazards poses significant challenges for the future and until such time as there is a national clearinghouse for such data, the United States will continue to underestimate the true extent of the annual costs of hazards to this country.

Glossary

correlation A measure of the strength of the relationship between two measures.

divergent thinking tests Open-ended problem-solving tasks in which people are asked to generate multiple solutions.

domain An area of work or task performance involving a shared body of knowledge and skills.

heuristics Strategies for executing the processing of operations involved in complex problem solving.

ill-defined problems Situations in which the goals are unclear and multiple paths to problem solutions are available.

problem construction The cognitive process involved in structuring, or defining, the problem to be solved.

processes Major cognitive operations that must be executed during problem solving.

scenario A written description of a problem and its setting.

think aloud A procedure for analyzing problem solving based on verbalizations during task performance.

The strategies people use to solve complex problems are commonly referred to as heuristics. The particular heuristics people apply in problem-solving, and the effectiveness with which they execute these heuristics, represent critical influences on performance in a variety of settings. In the present article, the procedures used to identify the heuristics involved in performance and the procedures used to measure the effectiveness of heuristic application are examined.

Introduction

History

The term “heuristics” was first applied in the social sciences some 50 years ago. Initially, this term was used to refer to

the strategies people employed to reduce the cognitive demand associated with certain decision-making tasks. These strategies involved, for example, “satisficing,” which refers to peoples’ tendency to use readily available representations as a basis for framing decision tasks. “Means-end analysis” was the term coined to describe a strategy whereby people work backward from a given goal using trial and error to identify the operations needed for problem solving.

As interest grew in problem-solving, planning, and decision-making on the complex, ill-defined cognitive tasks encountered in the real-world (such as planning the Olympic games, creating a new aircraft, or selecting an investment portfolio), it became apparent that multiple solution paths exist that might lead to successful performance. Alternative solution paths, often paths in which simplification proves useful, allow for multiple alternative strategies that might contribute to performance. Accordingly, the concept of heuristics was expanded, and the term is now commonly used to describe both effective and ineffective strategies people apply in executing complex cognitive processing operations, although some scholars prefer to limit use of this term to strategies that simplify complex cognitive operations.

Illustrations and Applications

The shift in conceptualization of cognitive processing has led to a new wave of research intended to identify the various heuristics linked to good and poor performance on different kinds of complex cognitive tasks. In one study along these lines, there was an attempt to identify the heuristics related to performance when people are gathering information for use in creative problem-solving. It was found that better performance was observed on

creative problem-solving tasks when people searched for key facts and anomalies rather than for a wide array of information. In another study along these lines, the researchers sought to identify the heuristics contributing to performance on managerial planning tasks. They found that performance improved when plans were structured around a limited number of key causes—specifically, key causes under ready managerial control. These illustrations of recent research are noteworthy in part because they illustrate one reason why social scientists are interested in heuristics. By identifying the heuristics associated with good and poor performance, it becomes possible to identify the kind of interventions that might be used to improve performance. In fact, studies of heuristics have provided a basis for job redesign efforts, software development, reconfiguration of control systems, and the design of new educational curriculum. Moreover, studies of heuristics have provided a new way for looking at, and assessing, complex cognitive skills.

Although few would dispute the importance of these practical applications, studies of heuristics have proved even more important for theoretical work. Studies of heuristics have not only allowed validation of models of complex processing operations, they have allowed social scientists to specify how various processes are executed in certain performance domains. Indeed, many advances in theories of problem-solving, decision-making, and planning can be traced to identification of heuristics associated with more or less effective execution of certain key cognitive processes.

Objective

Despite the theoretical importance of heuristics, the practical implications of studies of heuristics beg a question: How is it possible to go about identifying relevant heuristics and measuring their application? The intent here is to examine the relative strengths and weaknesses of the various approaches that have been used to identify, and measure, the heuristics people apply to tasks calling for complex cognitive processing activities. More specifically, three general approaches that have been applied are examined: observational, experimental, and psychometric. In examining the methods applied in each of these three approaches, there is no attempt to provide a comprehensive review of all pertinent studies. Instead, the general approach is described and illustrated through select example studies.

Observational Methods

Naturalistic Observations

Although they are not commonly used to assess differential effectiveness, naturalistic observations are used to identify the heuristics people apply as they work on

real-world problems, primarily complex problems in which performance unfolds over a long period of time. Investigator observations represent one of the more frequently used observational techniques. In one example of how this technique has been applied in studies of heuristics, research meetings in six microbiology laboratories varying in productivity were recorded. The video and audio recordings, along with relevant documents and notes, were then analyzed for content indicative of select cognitive operations identified in prior research. This content analysis, focusing on problem-solving behaviors, led to the identification of a number of heuristics that appeared to contribute to scientific problem-solving, such as a focus on explanation of inconsistent results and the application of local, or near, analogies in formulating problem solutions.

Observations require ongoing access to people working on a problem. When ongoing access cannot be obtained, naturalistic investigators commonly turn to an alternative technique for identifying heuristics, the interview. In interviews intended to identify heuristics, questions are developed that focus on the actions taken in producing a piece of work. Interviewees' recall of their activities is used to draw inferences about the heuristics being applied. For example, in one study, the interest was in the heuristics used by artists as they developed, over a period of months, pieces of work for exhibition or commission. Sixteen artists were interviewed for 1 or 2 hours on three occasions: (1) as they began work on the project, (2) midway through the project, and (3) after the project was completed. A structured interview format was applied such that these artists were asked to describe the specific actions they took during each phase of work on the project. A content analysis of the resulting interview data indicated that, during idea development, artists were not concerned simply with expression. Instead, they structured ideas, expanded initial ideas, and restructured these ideas before they began work on the piece.

In contrast to direct observations, studies seeking to identify the heuristics applied to complex real-world tasks have, from time to time, used an indirect observational approach based on analysis of historic records. Use of record-based approaches has been most common in studies of scientists, engineers, musicians, and writers, who work in fields in which a substantial body of written material (e.g., articles, drafts, notes) is typically produced. Content analysis of this material, especially analysis of changes in peoples' strategies over time as they move toward completion of a project, is used to draw inferences about the heuristics involved in the work. One illustration of this approach involved an historic analysis of the heuristics used by Bell and Edison in their attempts to develop the first working telephone. Although the need for a sizable body of records tracking progress on a project has limited application of this technique to select

fields, the widespread use of computers may, in the future, permit application of historic techniques in a wider range of domains.

Structured Observations

All unstructured observational techniques suffer, to some extent, from the problem of selective information presentation in the presence, or assumed presence, of observers. However, a more critical problem lies in the fact that these techniques do not capture data about heuristics that remain unarticulated. To address this problem, many researchers have come to rely on “think-aloud” protocols. In this technique, people are asked to verbalize, or think aloud, as they work on a cognitive task. Transcripts, or recordings, of these verbalizations are obtained. Heuristics are identified through a content analysis focusing on verbalizations about strategy selection, justifications for the actions being taken, and the sequences of actions described. This approach has been used to identify the heuristics used by anesthesiologists planning medical operations and to identify the heuristics used by students working on creative problem-solving tasks.

The widespread use of think-aloud procedures in heuristic identification may be traced to three advantageous characteristics of this technique. First, protocols can be obtained for people who presumably are more or less skilled with respect to the application of relevant heuristics—experts versus novices, successful versus unsuccessful problem solvers, and gifted versus nongifted students. Comparison of these groups, of course, allows relatively unambiguous identification of the heuristics associated with good and poor performance. Moreover, vis-à-vis careful structuring of the conditions of task performance, situational factors moderating heuristic application can be identified. Second, because all groups are exposed to a common task, or set of tasks, controlled inferences about heuristic application are possible. Third, content coding schemes can be tailored to specific actions on a known set of problems, thereby enhancing the reliability and validity of assessments.

Although these observations recommend the application of think-aloud procedures in identifying heuristics, this technique does have limitations. Due to the nature of verbalization techniques, it is difficult to apply this approach to highly complex real-world tasks, especially tasks for which performance unfolds over substantial periods of time. Moreover, unless multiple, carefully selected, stimulus tasks are applied, the generality of the conclusions flowing from application of this technique are open to question. Along related lines, it is difficult to collect protocol information for a large number of people, a characteristic of the technique that limits power and population inferences. Finally, due to the complexity of the material obtained, it is difficult to

apply this technique in appraising differences among people in the effectiveness of heuristic application.

Scenario-based measures represent an alternative technique used to examine the effectiveness of heuristic application. Scenario assessments present people with written descriptions of a complex real-world cognitive task. Subsequently, people are asked to respond, in writing, to a series of questions about the kinds of actions they would take to address the problem broached in a scenario. The questions asked following a scenario are intended to elicit the exhibition of certain heuristics. Judges’ evaluations of either the nature, or effectiveness, of heuristic application provide a basis for assessment.

One illustration of the scenario technique may be found in a study in which 1818 army officers were presented with a set of military planning scenarios calling for creative problem-solving. Subsequently, these officers were asked to provide short answers, in writing, to a series of questions intended to elicit heuristic application. Questions asked, for example, what information should be gathered in planning an invasion, or what would be key problems once the invasion began. Judges’ evaluations of responses to these questions with respect to the effective application of the relevant heuristics produced interrater agreement coefficients near 0.70. More centrally, these measures of heuristic application were found to yield multiple correlations in the 0.40s when used to predict various measures of on-the-job performance.

Experimental Methods

Experimental techniques are used in both the identification of heuristics and the assessments of heuristic application. Experimental techniques base identification and assessment of heuristics on observable performances on a particular task or set of tasks. Four general kinds of tasks are commonly applied in studies of heuristics based on the experimental approach: optimization tasks, choice tasks, skill acquisition tasks, and simulation/gaming tasks.

Optimization Tasks

The basic principle underlying optimization tasks is that departures from an optimal standard can be used to appraise the heuristics associated with sub par performance. Some studies apply a variation on this approach whereby departures from a theoretical minimum are used to identify the heuristics that contribute to performance. Accordingly, application of this approach, an approach commonly applied in studies of decision-making heuristics, is contingent on the feasibility of determining theoretical minimums and maximums.

One illustration of this approach may be found in a study that used computational modeling to define best and worst possible performance on a medical diagnosis task. The maximum possible performance was specified using statistical decision theory. The worst possible performance was defined based on a randomization model. Six heuristics involved in medical diagnosis were examined. It was found that performance approached the statistical optimum when a schema, or principle-based search, was applied in information acquisition, and multiple hypotheses were generated concerning the cause of the illness.

Of course, when optimization techniques are applied, the kind of heuristics identified will depend on the standards, either minimum or maximum, being used as benchmarks. Heuristics associated with suboptimal performance, biases, or errors will be identified when maximum standards are applied. Heuristics contributing to enhanced performance will be identified when minimum standards are applied. Though the referencing of heuristics against *a priori* theoretical standards is an attractive feature of this approach, the conclusions drawn in optimization studies will depend on the validity of the minimums and/or maximums applied. As a result, when strong *a priori* theory cannot be used to define applicable standards, it will prove difficult to apply this approach.

Choice Tasks

Choice tasks, in contrast to optimization tasks, apply relative, rather than absolute, standards to measure heuristics. More specifically, choice tasks measure heuristics by examining preferences for applying one heuristic over another as people work on certain cognitive tasks. Assessment is based on the assumption that people will use preferred heuristics in performing both the task at hand and in performing other tasks lying in the same domain. As a result, use of this approach typically requires prior identification of relevant heuristics. It is applied when the concern at hand is identifying more or less useful heuristics. When these conditions are met, however, the ability to link heuristic preferences to performance on a variety of tasks makes this approach an attractive vehicle for assessing heuristic application.

This approach has been used to assess the heuristics involved in problem construction, a processing operation commonly held to play a key role in creative problem-solving. In one study, people were presented with a short written description of four scenarios in which the problem at hand could be defined in a number of different ways. People were to review 16 alternative problem definitions and were asked to select the best four definitions under conditions in which these alternatives were structured to reflect the tendency to define

problems in terms of (a) goals, (b) procedures, (c) restrictions, and (d) key information. It was found that most people tended to define problems in terms of key information. However, performance on two complex creative problem-solving tasks was related to a preference for defining problems in terms of procedures and restrictions. Thus, people apparently preferred to use a heuristic that was not one of those contributing to subsequent performance.

Skill Acquisition Tasks

When prior research has provided strong theory concerning the heuristics underlying performance, an alternative to choice tasks may be found in skill acquisition tasks. The assumption underlying the skill acquisition approach is that differences among people in heuristic application can be induced through training. Thus, this approach is applied when heuristics can be developed, typically through relatively short-term interventions. Subsequent comparison of trained and untrained groups with respect to performance on one or more transfer tasks provides the basis for identifying the heuristics contributing to performance.

This approach was used to examine three heuristics held to be involved in creative problem-solving: (1) a hierarchical heuristic whereby ideas are generated by looking for communalities among concepts, (2) a brainstorming heuristic whereby performance is held to depend on generation of many ideas, and (3) a changing perspectives heuristic whereby ideas are generated by considering the views of others. Undergraduates were trained in the application of one of these heuristics, and their ability to generate novel solutions to a roommate interaction problem was assessed. It was found that the hierarchical heuristic resulted in significantly better solutions on this creative problem-solving task as compared to the brainstorming and changing-perspectives heuristics.

Not only can skill acquisition tasks be used to identify the heuristics contributing to performance, variations of this approach can be used to assess the effectiveness of heuristic application. For example, in one study, people were trained in the application of various heuristics involved in the processing activities required for creative problem-solving. The rate of heuristic application and the knowledge about relevant heuristics were assessed. It was found that these measures evidenced adequate validity in performance prediction, suggesting that learning may at times provide a basis for assessing heuristic application.

Simulations/Gaming Tasks

The fourth, and final, experimental procedure used in the identification and assessment of heuristics is simulation or gaming. In simulation and gaming exercises, heuristics are

identified and measured through the choices people make as they work on the exercise. In one study, a record was kept of operating decisions and requests for information as managers worked on a simulation exercise intended to model the operations of a small manufacturing company. It was found that the level of profits, a criterion measured through quarterly profits, was associated with a smaller number of decisions and a tendency to focus decision-making on a limited number of key issues linked to efficiency considerations.

Though simulations and gaming exercises provide an appealing tool for identifying and measuring heuristics, three points should be borne in mind when applying this approach. First, simulation and gaming exercises will prove useful only if decision and action metrics are formulated in such a way that they capture relevant heuristics. Second, the validity of the resulting assessments will depend on these metrics as much as the apparent realism of the exercise. Third, when these exercises are applied, some attempt should be made to control for gaming heuristics, i.e., heuristics specific to the exercise that are not relevant to the general form of task performance.

Psychometric Methods

In the psychometric approach, heuristics are identified and assessed with respect to people, and the performance differences observed among people, rather than with respect to the particular actions observed for a given set of tasks. This point is of some importance because the psychometric approach tends to emphasize heuristics associated with performance differences, discounting heuristics that are applied in a similar fashion by all individuals. To elicit these individual differences, psychometric studies rely on one of two basic techniques: self-report and tests.

Self-Report

One version of the self-report approach assumes that people are aware of, and understand the implications of, the strategies they apply as they execute tasks lying in different domains. Of course, given this assumption, it is possible to identify heuristics simply by asking people about the heuristics they apply in different endeavors. In accordance with this proposition, in one study, undergraduates were asked to indicate whether they applied heuristics such as visualization, step-by-step analysis, and analogies when working on interpersonal, academic, or daily life tasks. It was found that people could describe where, and how frequently, they applied these general heuristics. This direct reporting approach, however, has proved less effective when specific heuristics, particularly heuristics applied nearly automatically, are under consideration.

When it is open to question whether people can say when, and how, they apply heuristics, an alternative strategy is often used. In an approach referred to as the critical-incidents technique, people are not asked to report on strategies applied. Instead, they are asked to indicate the behaviors they exhibited when performing certain tasks. Specifically, they are asked to describe the setting, the event prompting performance, the actions taken in response to the event, and the outcomes of these actions. Content analysis comparing good and poor performers, or good and poor performances, is used to identify more or less effective performance strategies and the behaviors associated with application of these strategies. Assessment occurs by having people indicate either the frequency or extent to which they manifest behaviors associated with an identified heuristic.

Testing

In testing, people are not asked to describe heuristics or the behaviors associated with these heuristics. Instead, the capability for applying heuristics is inferred based on peoples' responses to a series of test items. In one variation on this approach, the objective scoring approach, test items are developed such that the problems presented call for certain processing activities. Response options are structured to capture the application of heuristics linked to effective process application. In one study, test items were developed to measure selective encoding, selective comparison, and selective combination. It was found that gifted students differed from nongifted students in that they were better able to identify relevant information (selective encoding).

In the subjective scoring approach, problems (typically open-ended problems) are developed in a way that a variety of responses might be used to address the problem. Judges are then asked to review peoples' responses and assess the extent to which they reflect the application of certain heuristics. This approach is applied in scoring the divergent thinking tests commonly used to measure creativity by having judges evaluate responses with respect to three creative strategies: generating a number of ideas (fluency), generating unusual ideas (originality), and generating ideas through the use of multiple concepts (flexibility). In another illustration of this approach, army officers were asked to list the changes in peoples' lives that might happen if certain events occurred (e.g., What would happen if the sea level rose?). Judges scored these responses for heuristics such as use of a longer time frame, application of principles, and a focus on positive versus negative consequences. Use of longer time frames and application of principles were found to be related to both performance on managerial problem-solving tasks and indices of real-world leader performance, yielding multiple correlations in the 0.40s.

Conclusions

Clearly, a variety of procedures have been developed for identification and assessment of the heuristics people use in working on complex, ill-defined problems. Moreover, these procedures have proved useful in identifying heuristics, and measuring heuristic application, across a number of performance domains calling for complex cognition. What should be recognized, however, is that all of these approaches evidence certain strengths and weaknesses. The observational approach has typically proved most useful in heuristic identification. Experimental and psychometric methods are more commonly used to identify the impact of heuristics on performance and measure individual differences in heuristic application. Along similar lines, certain techniques subsumed under these three basic methods appear, by virtue of their assumptions, more appropriate than are others for addressing some questions, and measuring some heuristics. These observations are of some importance because they suggest that a comprehensive understanding of the heuristics involved in a certain type of performance will require a multimethod, multitechnique approach.

Although the kind of multimethod, multitechnique studies called for are not a simple undertaking, the evidence indicates that work along these lines will be worth the time and effort. Not only has identification of the heuristics involved in high-level cognitive performance proved critical in theory development, the information provided by these studies has provided new tools for developing and assessing peoples' performance capacities. Given the foundation of human performance in complex cognitive activities such as planning, decision making, and creative problem-solving, it can be expected that heuristic measurement will become an increasingly important aspect of social measurement over the course of the 21st century.

Hierarchical Linear Models

Jeff Gill

University of Florida, Gainesville, Florida, USA

Glossary

analysis of covariance model (ANCOVA) A varying intercept hierarchical linear model with the second-level effect fixed across groups.

between-unit model The component of a hierarchical linear model that describes the variability across the groups.

context-level variables Variables defined at the second or higher level of the hierarchical linear model.

empirical Bayes Using the observed data to estimate terminal-level hierarchical model parameters.

exchangeability The property of a hierarchical linear model that the joint probability distribution is not changed by re-ordering the data values.

expectation-maximization (EM) algorithm An iterative procedure for computing modal quantities when the data are incomplete.

fixed effects coefficients Model coefficients that are assumed to pertain to the entire population and therefore do not need to be distinguished by subgroups.

hierarchy The structure of data that identifies units and subunits in the form of nesting.

interaction term A model specification term that applies to some mathematical composite of explanatory variables, usually a product.

random coefficients regression model A hierarchical linear model in which the only specified effect from the second level is seen through error terms.

random effects coefficients Model coefficients that are specified to differ by subgroups and are treated probabilistically at the next highest level of the model.

two-level model A hierarchical linear model that specifies a group level and a single contextual level.

varying intercept model A hierarchical linear model with only one (noninteractive) effect from the second level of the model.

within-unit model The component of a hierarchical linear model that describes variability confined to individual groups.

Hierarchical linear models (HLMs) are statistical specifications that explicitly recognize multiple levels in data. Because explanatory variables can be measured at different points of aggregation, it is often important to structure inferences that specifically identify multilevel relationships. In the classic example, student achievement can be measured at multiple levels: individually, by class, by school, by district, by state, or nationally. This is not just an issue of clarity and organization. If there exist differing effects by level, then the substantive interpretation of the coefficients will be wrong if levels are ignored. HLMs take the standard linear model specification and remove the restriction that the estimated coefficients be constant across individual cases by specifying levels of additional effects to be estimated. This approach is also called random effects modeling because the regression coefficients are now presumed to be random quantities according to additionally specified distributions.

Essential Description of Hierarchical Linear Models

The development hierarchical linear model (HLM) starts with a simple bivariate linear regression specification for individual i :

$$Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i \quad (1)$$

which relates the outcome variable to the systematic component and the error term. The standard conditions for this model include the Gauss-Markov assumptions (linear functional form, independent errors with mean zero and constant variance, and no relationship between

regressor and errors), and normality of the errors (provided reasonable sample size): $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$.

Suppose, for example, that we are interested in measuring university student evaluations of faculty teaching through the standard end-of-semester survey. Then the outcome variable, Y_i , is considered the mean score for instructor i for a given class, recorded along with the explanatory variable, X_i , indicating years of teaching experience. In this example setup, the intercept, β_0 , is the expected score for a new instructor. Now, consider that this analysis is temporarily taking place only in department j . This means that Eq. (1) becomes:

$$Y_{ij} = \beta_{j0} + \beta_{j1}X_{ij} + \varepsilon_{ij} \quad (2)$$

There is no substantive change here; for the moment, the j coefficient is just a placeholder to remind us that we are studying only the j th department so far.

Now consider broadening the analysis to evaluate student evaluations of teaching across the entire university by looking at multiple departments. Although we expect some differences, it would be rare to find that there was no underlying commonality among the instructors. A more realistic idea is that, although each instructor has idiosyncratic characteristics, because he or she is teaching at the same university at the same point in time and being evaluated by the same student body there is a common distribution from which β_0 and β_1 are drawn. Actually, it would be unfair and inaccurate to calculate these means across all undergraduate majors at the university. It is well known, for instance, that sociology departments enjoy higher mean student evaluations than chemistry departments. So, now add a second level to the model that explicitly nests instructors within departments and index these departments by $j = 1$ to J :

$$\begin{aligned} \beta_{j0} &= \gamma_{00} + \gamma_{10}Z_{j0} + u_{j0} \\ \beta_{j1} &= \gamma_{01} + \gamma_{11}Z_{j1} + u_{j1} \end{aligned} \quad (3)$$

where all individual level variation is assigned to departments producing department-level residuals: u_{j0} and u_{j1} . The variables at this level are called context-level variables, and contextual specificity is the existence of legitimately comparable groups. Here, the example explanatory variables Z_{j0} and Z_{j1} are the average class size for department j and the average annual research output per faculty member in department j , respectively. Note that if we were interested in performing two nonhierarchical department-level analyses, this would be straightforward using these two equations, provided that the data exist. Of course, our interest here is not in developing separate single-level models; the two-level model is produced by inserting the department-level

specifications, Eq. (3), into the original expression for instructor evaluations, Eq. (2). Performing this substitution and rearranging produces:

$$\begin{aligned} Y_{ij} &= (\gamma_{00} + \gamma_{10}Z_{j0} + u_{j0}) + (\gamma_{01} + \gamma_{11}Z_{j1} + u_{j1})X_{ij} + \varepsilon_{ij} \\ &= \gamma_{00} + \gamma_{01}X_{ij} + \gamma_{10}Z_{j0} + \gamma_{11}X_{ij}Z_{j1} + u_{j1}X_{ij} + u_{j0} + \varepsilon_{ij} \end{aligned} \quad (4)$$

This equation also shows that the composite error structure, $u_{j1}X_{ij} + u_{j0} + \varepsilon_{ij}$, is now clearly heteroscedastic because it is conditioned on levels of the explanatory variable. Unless the corresponding variance-covariance matrix is known, and therefore incorporated as weights in the general linear model, it must also be estimated. Ignoring this effect and calculating with ordinary least squares (OLS) produces consistent estimators but incorrect standard errors because it is equivalent to assuming zero intraclass correlation.

Often the first-level expression describing the performance of instructor i in a given department, as specified by Eq. (2), is labeled the within-unit model because its effects are confined to the single department; the second-level expressions describing the performance of department j as a whole, as specified by Eq. (3), are labeled the between-unit model because they describe the variability across the departments. Looking closely at Eq. (4) reveals that there are three distinct implications of the effects of the coefficients for the explanatory variables:

- γ_{01} gives the slope coefficient for a one-unit effect of teacher experience in department j . This slope varies by department.
- γ_{10} gives the slope coefficient for a one-unit change in department class size in department j , completely independent of individual teacher effects in that department.
- γ_{11} gives the slope coefficient for the product of individual teacher experience by department and mean annual research output by department.

Because this set of variables contains both fixed and random effects, Eq. (4) is called a mixed model.

The fundamental characteristic of the multilevel data discussed here is that some variables are measured at an individual level and others are measured at differing levels of aggregation. This drives the need for a model such as Eq. (4) that classify variables and coefficients by the level of hierarchy they affect. Interestingly, a large proportion of HLMs in published work come from education policy studies. This is due to natural nesting of education data through the bureaucratic structure of these institutions. Other applications include studies of voting, bureaucracy, medical trials, and crime rates.

Special Cases of the Hierarchical Linear Model

There are several interesting ramifications that come from fixing various quantities in the basic HLM. The most basic is produced by setting the full β_{j1} component and the γ_{10} term in Eq. (4) equal to zero. The result is the standard ANOVA model with random effects:

$$Y_{ij} = \gamma_{00} + u_{j0} + \varepsilon_{ij} \quad (5)$$

In another basic case, if the second-level model defines a fixed-effect rather than random-effect model, ($u_{j1}, u_{j0} = \mathbf{0}$), then the resulting specification is just simple linear regression model with an interaction term between the instructor level explanatory variable and the department level explanatory variable:

$$Y_{ij} = \gamma_{00} + \gamma_{01}X_{ij} + \gamma_{10}Z_{j0} + \gamma_{11}X_{ij}Z_{j1} + \varepsilon_{ij} \quad (6)$$

This is one of the most studied enhancements of the basic linear form in the social sciences.

Another very basic model comes from assuming that the second-level model introduces no new error terms and there is also no interaction effect. Specifically, this means that we can treat the intercept term as a composite of a constant across the sample and a constant across only the j groupings:

$$Y_{ij} = (\gamma_{00} + \gamma_{10}Z_{j0}) + \gamma_{01}X_{ij} + \varepsilon_{ij} \quad (7)$$

This is routinely called a varying intercept model because the parenthetical expression is now a group-specific intercept term. If we add the second assumption that there is no articulated structure within the first term, that is, $(\gamma_{00} + \gamma_{10}Z_{j0})$ is equal to a single context-specific α_j , this is now the analysis of covariance model (ANCOVA).

Sometimes it is possible to take some specific parameter in the model and fix it at a known level. Thus, if substantive information at hand indicates that there is no variability to one of the γ terms, it is appropriate to fix it in the model. It is also possible to design a combination strategy such as to fix the slope coefficient ($\beta_{j1} = \gamma_{10} + \gamma_{11}Z_{j1}$) and let the intercept coefficient remain a random effect, or to fix the intercept coefficient ($\beta_{j0} = \gamma_{00} + \gamma_{10}Z_{j0}$) and let the slope remain a random effect.

Another common variation is to assume that $Z_{j0} = 0$ and $Z_{j1} = 0$, but retain the u_{j0} error term:

$$Y_{ij} = \gamma_{00} + \gamma_{01}X_{ij} + u_{j1}X_{ij} + u_{j0} + \varepsilon_{ij} \quad (8)$$

This model asserts that the j categorization is not important for determining the expected effect on Y_{ij} , but that there is an additional source of error from the categories. Hence, specifying the model with only one source of error is to miss a heteroscedastic effect. A specification of this type is typically called a random coefficients regression model.

Another related variation is to assume that the effect of the within-unit explanatory variable (years of teaching in our example) is uniform across departments. This is equivalent to setting $\gamma_{11}X_{ij}Z_{j1} = 0$, producing:

$$Y_{ij} = \gamma_{00} + \gamma_{01}X_{ij} + \gamma_{10}Z_{j0} + u_{j1}X_{ij} + u_{j0} + \varepsilon_{ij} \quad (9)$$

where sometimes $u_{j1}X_{ij}$ is also set to zero. The common name for this specification is the additive variance components model.

The General Structure of the Hierarchical Linear Model

The previously developed model is actually a substantial simplification in that typical models in social science research contain many more explanatory variables at both the within-unit level and the between-unit levels. It is therefore necessary to generalize HLM to incorporate more specification flexibility. First we recast Eq. (4) in matrix terms, such that the dimensional assumptions will be generalized to accommodate more useful specifications. We define a new β_j vector according to:

$$\beta_j = \begin{bmatrix} \beta_{j0} \\ \beta_{j1} \end{bmatrix} = \begin{bmatrix} 1 & Z_{j0} & 0 & 0 \\ 0 & 0 & 1 & Z_{j1} \end{bmatrix} \begin{bmatrix} \gamma_{00} \\ \gamma_{10} \\ \gamma_{01} \\ \gamma_{11} \end{bmatrix} + \begin{bmatrix} u_{j0} \\ u_{j1} \end{bmatrix} \quad (10)$$

which is just the vectorized version of Eq. (3). Therefore, it is possible to express Eq. (4) in the very concise form:

$$Y_{ij} = \beta_j' [1 \quad X_{ij}]' + \varepsilon_{ij} \quad (11)$$

This extra formalism is really not worth the effort for a model of this size; its real utility is demonstrated when there are more explanatory variables at the contextual level. Define k_0 and k_1 to be the number of explanatory variables defined at the second level for β_{j0} and β_{j1} , respectively. Thus far we have had the

restrictions: $k_0 = 2$ and $k_1 = 2$; but we can now generalize this dimension:

$$\beta_j = \begin{bmatrix} \beta_{j0} \\ \beta_{j1} \end{bmatrix} = \begin{bmatrix} 1 & Z_{j01} & Z_{j02} & \cdots & Z_{j0(k_0-1)} & 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 & 1 & Z_{j11} & Z_{j12} & \cdots & Z_{j1(k_1-1)} \end{bmatrix} \begin{bmatrix} \gamma_{00} \\ \gamma_{10} \\ \vdots \\ \gamma_{(k_0-1)0} \\ \gamma_{01} \\ \gamma_{11} \\ \vdots \\ \gamma_{(k_1-1)1} \end{bmatrix} + \begin{bmatrix} u_{j0} \\ u_{j1} \end{bmatrix} \quad (12)$$

The dimension of the matrix of \mathbf{Z} variables is now $(2 \times k_0 + k_1)$ and the length of the $\boldsymbol{\gamma}$ vector is $k_0 + k_1$, for any specified values of k_i that are allowed to differ. It is common, and computationally convenient, to assume that the error vector, u_j , is multivariate normally distributed around zero with a given or estimated variance-covariance matrix. Note that the row specifications in the \mathbf{Z} matrix always begin with a 1 for the constant, which specifies a level-one constant in the first row and a level-one restricted explanatory variable in the second row.

It is important to observe that because the constant in this model is part of the specification, the indices run to $k_0 - 1$ and $k_1 - 1$ to obtain the dimensions k_0 and k_1 . Also, when there was only one \mathbf{Z} variable specified in the second level of the model, it was sufficient to index simply by the subscripts j and either 0 or 1, as in the first and second equations of (3). However, now that there are arbitrary numbers for each second-level equation they must be further indexed by the third value—here, 1 to $k_0 - 1$ or 1 to $k_1 - 1$. Note that each group is no longer required to contain the same mix of second-level explanatory variables. This turns out to be useful in specifying many varying model specifications.

It is possible that there are also more first-level variables in the model (it is likely, in fact). To accommodate this, we must further generalize the defined matrix structures. Define the \mathbf{Z}_ℓ vector as

$$\mathbf{Z}_\ell = [1 \quad Z_{j\ell 1} \quad Z_{j\ell 2} \quad \cdots \quad Z_{j\ell(k_\ell-1)}] \quad (13)$$

for $\ell = 1$ to L coefficients in the first-level model, including the constant. Therefore the \mathbf{Z} matrix is now a $(L \times L)$ diagonal matrix according to:

$$\mathbf{Z} = \begin{bmatrix} \mathbf{Z}_1 & 0 & 0 & \cdots & 0 \\ 0 & \mathbf{Z}_2 & 0 & \cdots & 0 \\ 0 & 0 & \mathbf{Z}_3 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \mathbf{Z}_L \end{bmatrix} \quad (14)$$

where each diagonal value is a \mathbf{Z}_ℓ vector. This can also be fully written out as an irregular ℓ -diagonalized matrix, but it would be more cumbersome than the given form. Given the new form of the \mathbf{Z} matrix, it is necessary to respecify the $\boldsymbol{\gamma}$ vector as follows:

$$\boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\gamma}_0 \\ \boldsymbol{\gamma}_1 \\ \vdots \\ \boldsymbol{\gamma}_L \end{bmatrix} \quad (15)$$

where each $\boldsymbol{\gamma}_\ell$ is a column vector whose length is determined by the k_ℓ dimension specification. Putting these new structures together gives:

$$\beta_j = \mathbf{Z}\boldsymbol{\gamma} + \mathbf{u} \quad (16)$$

and:

$$Y_{ij} = \beta_j' [1 \quad X_{ij1} \quad X_{ij2} \quad \cdots \quad X_{ijL}]' + \varepsilon_{ij} \quad (17)$$

Thus, the HLM in this form allows any number of first- and second-level explanatory variables, as well as differing combinations across contextual levels. Note also that there is no restriction that number of individual units, n_j , be equal across the contexts (although this can make the estimation process more involved).

The final basic way that the HLM can be made more general is to add further levels of hierarchy with respect to levels. That is, it is possible to specify a third level in exactly the way that the second level was added by parameterizing the $\boldsymbol{\gamma}$ terms according to:

$$\gamma_{pq} = \delta_{0q} + \delta_{1q}W_{pq} + v_{pq}$$

where the p subscript indicates a second level of contexts ($p = 1, \dots, P$), and the q subscript indexes the number of equations ($q = 1, \dots, Q$) specified at this level (analogous to k at the lower level). In this specification, W_{pq} is a third-level measured explanatory variable and v_{pq} is the level-associated error term.

Obviously, the specifications can be made very complex at this level.

The other principle approach to modeling a third level is to specify a Bayesian prior distribution for the γ coefficients. These priors are typically assigned normal distributions, but this is not a restriction and many others have been used. As a consequence of linearity, the normal property then ripples down the hierarchy, making estimation relatively easy. This model, then, specifies hierarchies of linear hyperpriors, each of which has its own prior plus an associated matrix of explanatory variables, and only nodes at the highest level of the hierarchy have fixed hyperprior values.

Estimation of the Hierarchical Linear Model

No matter how complex the right-hand side of the HLM equation becomes, the left-hand side always consists of Y_{ij} , which is assumed to be normal, with mean equal to the systematic component of the model and variance from the collected error terms. If it were known that the error structure in the model was uncorrelated to explanatory variables, then it would be easy to estimate the coefficients with standard maximum likelihood or least squares approaches. Actually we know that, in general, the form of the errors is conditional on the levels of the explanatory variables because in Eq. (4) there is the term, $u_{j1}X_{ij}$. In addition, there are increasing numbers of dependencies as the model becomes progressively more complex and realistic.

If we knew for certain the form of the relationship between the regressors and errors, then it could be expressed through a weighting matrix and general least squares would provide consistent estimates of the coefficients and their standard errors. Unfortunately, this information is rarely available. The classic alternative is to specify a likelihood function and employ a maximum likelihood estimation of the full set of unknown parameters, including variances using Fisher scoring. This is often a cumbersome process, so many software implementations work with the profile likelihood—first estimating the higher order variance terms and only then fixing them in the likelihood function equation for the lower-level parameters. This tends to underestimate the magnitude of the higher-order variance terms because uncertainty is ignored in the first step, leading to overconfident model results. An improved process is to employ restricted maximum likelihood (REML) by integrating out the fixed-effects terms in the calculation of the profile likelihood and, after obtaining the lower-level parameter estimates, recalculating the higher-order variance terms conditional on these. However, the best

method is the quasi-Bayesian procedure, empirical Bayes/maximum likelihood (EB/ML). A fundamental principle of Bayesianism is that unknown parameters are treated as random variables possessing their own distributions which can be estimated as a consequence of applying Bayes's law. By analogy, we can consider the unknown HLM estimates as having their own distributions, conditioned on unknown quantities from the higher level of the model. Rather than stipulating explicit priors for the parameters, as a Bayesian would do, it is possible to use a prior suggested by the data, called empirical Bayes.

The expectation-maximization (EM) algorithm is essential to this estimation process and therefore warrants some description. EM is a flexible and often-used method for incomplete data problems; it is used to fill in missing information, given a specified model. The notion of what is "missing" is general here; it can be unknown parameters, missing data, or both. There are two basic steps. First, we assign temporary data that represent a reasonable guess to the missing data (expectation). Second, we proceed with maximum likelihood estimation of the parameters as if there now existed a complete-data problem (maximization). The algorithm is iterative in the sense that it is now possible to use these parameter estimates to update the assignment of the temporary data values with better guesses, and repeat the process. It can be shown that the EM algorithm gives a series of parameter estimates that are monotonically increasing on the likelihood metric and are guaranteed to converge to a unique maximum point under very general and nonrestrictive regularity conditions. The utility here is that the HLM with linear specifications and normal assumptions is a particularly well-behaved application of EM.

Detailed summaries of the EB/ML computational procedure for obtaining coefficient estimates and measures of reliability can be found elsewhere. The basic strategy is to obtain estimates of the variance terms using the EM algorithm and the joint likelihood function for the coefficients and the variances, plug these estimates into the top hierarchy of the model, perform maximum likelihood calculations as if these were the correct weightings, and update the estimate of the coefficients by using the mean of the subsequent posterior. This is a very general description of the procedure; there are many nuances that depend on the particular form of the model and configuration of the data.

Critical Advantages of the Hierarchical Linear Model

HLMs are a compromise between two opposite approaches to clustering. On one side, it is possible to simply pool all the observations and calculate an estimate of

the coefficients of interest as if the between-group effects did not matter. Conversely, it is also possible to aggregate the data by the groups and calculate the coefficient estimates on these aggregations as if they were the primary object of interest. The first approach ignores between-group variation and the second approach ignores within-group variation. It is possible that either of these approaches is entirely appropriate and reliable inferences can be obtained. Of course, if there actually are important differences by groupings, then neither will be correct. HLMs provide a method for producing models that explicitly recognize this distinction by incorporating the nesting of the data into the model specification.

HLMs also have several specific methodological advantages over standard linear models:

- Hierarchical models are ideal tools for identifying and measuring structural relationships that fall at different levels of the data generating procedure.
- Hierarchical models have virtually no limit to the dimension of their hierarchy.
- Hierarchical models directly express the exchangeability of units.
- Nonhierarchical models applied to multilevel data typically underestimate the variance.
- Hierarchical models facilitate the testing of hypotheses across different levels of analysis.
- Nonhierarchical models can be nested within hierarchical models, allowing a likelihood or Bayes factor test of the validity of the proposed hierarchical structure.

Although these reasons are compelling, it is only relatively recently that hierarchical models have been actively pursued in the social sciences. This is parallel (and related) to the attachment social scientists have for the linear model in general. What precipitated the change was the dramatic improvement in statistical computing that provided solutions to previously intractable problems. These stochastic simulation tools include the EM algorithm; Markov chain Monte Carlo techniques (MCMC), such as the Metropolis-Hastings algorithm;

and the Gibbs sampler, whereby an iterative chain of consecutive computationally generated values is set up carefully enough and run long enough to produce *empirical* estimates of integral quantities of interest from later chain values. Although these approaches are typically associated with Bayesian modeling, such iteration techniques are not *limited* to Bayesian or even hierarchical applications. They do, however, greatly help naturally occurring computational problems in these settings.

Highway Statistics

Alan E. Pisarski

Independent Consultant, Falls Church, Virginia, USA

Glossary

fatality rate The measure almost universally used in the United States is fatalities per 100 million miles of travel.

functional classification An engineering classification of roads based on their function (as opposed to their design characteristics).

international roughness index (IRI) A calculation of inches of deflection from the surface per mile of road; e.g., a rating of 150 = 150 inches of ruts measured over a mile.

lane-miles The number of miles of route multiplied by the number of lanes in the road. A four-lane 10-mile road contains 40 lane-miles.

miles of route The actual length of a system; sometimes called centerline miles.

pavement serviceability rating (PSR) A subjective professional measure of road quality on a scale of 1 to 5.

person-miles of travel The travel of an individual rather than a vehicle; two people in a vehicle going 10 miles equals 20 person-miles of travel.

ton-miles of travel The number of miles traveled by trucks multiplied by the cargo weight carried. One truck carrying 10 tons traveling 10 miles = 100 ton-miles.

travel time index (TTI) One of several measures of congestion, but perhaps the most typically used, measuring the ratio of peak-hour travel to off-peak travel. A TTI of 150 indicates that a 10-minute off-peak trip takes 15 minutes in the peak time.

vehicle-miles of travel (VMT) The total travel in miles summed for all vehicles; one vehicle going 10 miles equals 10 VMT.

Highways in the United States are many things—physical engineering artifacts of our culture; economic and social tools that serve our personal and business activities, needs, and preferences; and social products that have complex consequences, both positive and negative. All

of these are measurable, and it is through their measurement and description that society recognizes the roles played by the road system, appreciates the significance of the road system in daily life, and forms judgments on future transport needs and expectations. The road—vehicle dyad provides unparalleled mobility and accessibility to the American population.

Introduction

The highway is many things. Clearly, it is a physical object of considerable scope and dimension. Even if no vehicle ever traversed a highway, the description of the attributes and physical characteristics of the entire highway system, just in terms of its dimensions and design, would be a significant task. But an extraordinary variety of vehicles do use the system, and their performance, or the performance of the road serving them, is the object of a broad array of statistical mechanisms. The highway is an economic and social tool that carries prodigious quantities of people and goods to fulfill many economic and social needs; the highway is also a political tool, used to guide economic development to selected areas, to support military logistics, and to create social and economic interactions among regions to bind nations together.

As a societal artifact that interacts with the rest of the world both positively and negatively, in terms of the space it occupies, the highway is associated with deaths and accidents and has other social impacts as well. The vehicle fleet associated with the highway constitutes a world in itself, a world requiring statistical description and understanding—something akin to a demography of the automobile.

Dimensions of the System

The United States has a limited road system, if the system is calculated on the basis of road miles per square mile; on the other hand, the United States probably has the largest road system in the world. At the turn of the new millennium, the United States had almost 4 million miles of road. Although 4 million miles of road seems to be very large, it works out to slightly more than 1 mile of road per square mile of territory (0.69 km of road per square km of area), which, relative to many other countries, is quite limited. France, Germany, and the United Kingdom all have more than double that. This all goes to say that the United States is a very big country and large numbers are typical of almost any effort to describe or characterize its attributes.

The national mileage has actually grown little in the past century. In 1900, the earliest date for which statistics are recorded, the nation had just over 2.3 million miles of road. Less than 20 years later, by 1918, coverage had reached 3 million miles, and it has taken another 80 years to add another million miles of road. The physical nature of the road system has changed also. In 1945, about 80% of the road miles throughout the nation was unpaved roadway, consisting only of gravel or compacted dirt. It was not until 1977 that more than half of the nation's road system was considered paved. Today, the system is still more than one-third unpaved.

Of course, the capacity of the roadways has grown substantially, with the 4 million miles of road now having 8.25 million lane-miles, or slightly more than two travel lanes per mile of road on average. A lane-mile consists of one travel lane over 1 mile. A country road would likely be two lane-miles per mile of road, one in each direction. A major freeway can be 10 lane-miles per mile (five travel lanes in each direction). Statistics in this area have not been collected for long, but the data indicate that growth is not dramatic; in 1993, there were 8.15 million national lane-miles, with an increase of 100,000 miles from that year to the year 2000, or about 1% growth. Most of the lane-mile growth occurs in metropolitan areas, with rural areas often showing declines in lane-miles. The urban lane-mile growth is in large part a product of urban area expansion, in which existing roads are reclassified

from rural to urban, as well as a product of increased road capacity as lanes are added to existing streets and streets are built within new housing and commercial developments. Despite the typically wider roads in metropolitan areas, the vast majority of lane-miles, roughly two-thirds, is in rural areas.

System Ownership

According to the U.S. Bureau of the Census, roads in America are owned by approximately 36,000 units of government, utilizing almost every imaginable system of government organization for the management of the roads in the care of different units. Surprisingly, the national government owns few roads; typically these are only minor roads internal to federal lands. Table I, showing ownership of miles of road in 2001 for urban and rural areas, indicates the main entities that own roads in the United States. Although only approximately 20% of roads are under state control, these are often the major roads of the road system in terms of design characteristics and volume of use. The greatest portion of roads is under local control, including county, town, township, or municipal ownership and also including Indian tribes and public authorities especially created to operate roads. Over 3000 counties in America own more than 1.7 million miles of road, almost 45% of the total system in the country. Only about 3% of the road system is under federal control. The mileage of federal roads has tended to decline as roads on public lands are declassified or reclassified. It is also important to note that the road system is predominantly rural in location, with almost 80% of roads in rural areas.

Measures of Physical Condition

Road Condition

Pavement condition has historically been measured by a system called present serviceability rating (PSR), which ranked pavements from 1 (very deteriorated) to 5 (new or nearly new pavements). This rating was a subjective system based on engineering judgments, which, although sound, were capable of inconsistency

Table I Ownership of Roads^a

Jurisdiction	Rural		Urban		Total	
	Mileage	Percent	Mileage	Percent	Mileage	Percent
State	665,093	21.7	109,136	12.4	774,229	19.6
Local	2,286,969	74.5	765,633	87.3	3,052,602	77.3
Federal	119,270	3.9	2234	0.3	121,504	3.1
Total	3,071,332	100.0	877,003	100.0	3,948,335	100.0

^a Data from *Highway Statistics*, Federal Highway Administration (2001).

from place to place. More recently, the PSR has been replaced by a mechanical rating system called the international roughness index (IRI), developed by the World Bank; the IRI uses machinery to calculate the number of inches of cracks or other imperfections in a road surface. In this case, higher measures are worse. The ranges of comparative values between the two scoring systems are shown in Table II.

In addition to describing pavements in terms of the percentage good or very good, a recent extension is to calculate the volumes of traffic on those facilities so that the measure of percentage of traffic on poor pavements can be calculated. There are, of course, other measures of highway characteristics and condition. Those most used in national evaluations are lane width, which can range from 9 to more than 12 feet, and horizontal and vertical alignment. These are effectively measures of safety and measure the adherence to design standards. Alignments are graded on a code of 1 to 4, where 4 indicates frequent grades that impair visibility or curves that are unsafe for the prevailing speed limits.

Bridges

A system as large as the highway system of the United States inevitably would have a large number of bridges. Because of safety concerns, the number, characteristics, and condition of bridges are carefully monitored under federal law. The length threshold for bridges that are monitored is 20 feet. In 2000, there were somewhat more than 587,000 bridges in the National Bridge Inventory distributed functionally as shown in Table III. Like the road system, the number of bridges grows slowly, with about a 1% increase since 1996.

Bridge Condition

The bridges in Table III are grouped by functional class and area. The National Bridge Inventory reviews each bridge at least every 3 years and exhaustively

identifies and describes its characteristics. A recently introduced term in this evaluation methodology is "bridge deck area," which weights bridges by their size (length \times width); this evaluation is far more effective in terms of recognizing investment needs, compared to simply taking a count of bridges.

The two main distinctions made in bridge condition relate to bridges that are structurally deficient and those that are functionally deficient. A structurally deficient bridge is not necessarily one that is in danger of collapse, but it generally needs significant maintenance or rehabilitation. It may need replacement or it may have special speed limits or load maximums that inhibit use, forcing larger vehicles, such as school buses, to take more circuitous routes. Functional deficiency has more to do with a bridge that is inconsistent in its characteristics with the road that it serves, either in height, width, curvature, or other aspects. The best example would be a four-lane bridge on a six-lane roadway.

Because most bridges are on the local road systems, those systems are most likely to have the deficient bridges; however, the state bridges that tend to be larger and carry more traffic also carry the major portions of traffic that move over deficient bridges. Recent trends have shown significant improvement in structurally deficient bridges as a result of higher levels of funding and greater focus on the problem; deficiencies dropped from 120,000 bridges to 80,000 over the past 10-year period. Functional deficiencies have remained steady at roughly 80,000 bridges.

The Highway as a Service System

The System as Network

The great strength of the U.S. highway system is its interconnectedness, within the system and with other modal elements. Few places in the nation are located where desired trip destinations cannot be linked with origins with only minor levels of circuitry. It is difficult to describe or even measure the degree or character of this connectedness. There are a number of ways in which

Table II Pavement Rating Systems^a

Rating	PSR ^b	IRI ^c
Very good	≥ 4.0	< 60
Good	3.5–3.9	60–94
Fair	2.6–3.4	95–170
Mediocre	2.1–2.5	171–220
Poor	< 2.0	> 220

^a The ranges shown are for roads in general; interstate roads have a more stringent standard, with anything worse than an IRI of 170 deemed poor (an IRI of 170 = 170 inches in depth of cracks per mile). Data from *Condition and Performance Report*, Federal Highway Administration (2002).

^b PSR, Pavement serviceability rating.

^c IRI, International roughness index.

Table III Number of Bridges by Location on Functional System^a

Functional system	Rural bridges	Urban bridges
Interstate	27,797	27,882
Other arterial	74,796	63,177
Collector	143,357	15,038
Local	209,415	25,684
Total	455,365	131,781

^a Data from *Condition and Performance Report*, Federal Highway Administration (2002).

to represent the pervasiveness of the network; a composite of many of the measures is probably needed to understand the complete picture. The system interconnectedness can be expressed in terms of the areas covered, the populations, or other activities to be served (in a sense providing a weighting function for a pure area measurement), or it can also be expressed topographically in terms of measures of coverage and connectivity. The following list suggests ways in which to describe the network connectivity of the system.

1. Area: Miles of road per square mile.
2. Population: Miles of road per thousand population.
3. Vehicles: Miles of road per thousand vehicles.

These approaches actually provide measures of coverage density and might not adequately represent the network's true connectivity. A more effective measure of connectivity would consist of ways in which to describe the enforced circuitry imposed on travelers by a network. The rectangle shown in Fig. 1 can be seen to consist of a square with four sides meeting at four points. In a network representation, the sides would be called links and the points at which they meet would be called nodes. The nodes can be thought of as four towns connected by four roads, with an average ratio of links to nodes of one. If two new links (the diagonals) are added, the ratio of links to nodes goes to 1.5 and the average distance between nodes drops sharply. If a new node is seen to exist at the center of the square, then the two diagonal links can be considered as four links, resulting in a total of eight links serving five nodes, or a ratio of 1.6. Higher ratios indicate improved connectivity.

Circuitry can be measured as the distance that must be traversed on the network from an origin to a desired destination divided by the crow-flies distance between the two points. Sometimes the circuitry involved is imposed by land features such as lakes or mountains; in other cases, it might be simply the lack of roads that causes significant detouring from direct travel. Clearly, the diagonals in Fig. 1 reduce the circuitry between the nodes to be served in at least some of the cases. If in fact, the nodes are of

Figure 1 A network representation. The sides (links) connect at nodes. The ratio of links to nodes is 8:5, or 1:6. Higher ratios indicate improved connectivity.

different “sizes,” as measured in terms of population, industrial output, attractiveness, etc., then the average circuitry weighted by that measure would be quite different than an average that was derived assuming that all nodes were equal. Early transportation modeling used a formula related to a gravitation equation that weighted travel by the “size” of areas and the distances between them.

Another way in which to measure the robustness of the system would be to conduct hypothetical exercises in which a link is deleted; for instance, a bridge failure can be simulated and the effects on the circuitry of travel measured. This measures the redundancy incorporated in the system and may be an important measure of network effectiveness, in a military or emergency situation, for example.

Function

To understand the true nature and use of the road network as a system, it must be described based on function. A functional classification system has evolved over the years to provide a description of roads according to the function they perform in the overall highway system. There are three major groupings: (1) arterials, which are designed to serve longer distance travel, (2) collectors, which provide an intermediate function between local streets and long distance arterials, and (3) local roads, which primarily serve adjacent properties. As can be seen from Table IV, local roads that serve houses, factories, businesses, and farms constitute the largest share (more than two-thirds) of roads. All arterials constitute only about 11% of the road system, with the collectors making up the remainder. In urban and rural areas, there are subcategorizations within the three main functional groupings to permit more detailed description of specialized functions. The 46,000-mile-long interstate system constitutes the highest level of the functional system; although it accounts for only slightly more than 1% of

Table IV Distribution of Roads by Function^a

Functional system	Rural	Urban	Total
Interstate	0.8%	0.3%	1.2%
Other freeways/expressways	NA ^b	0.2%	0.2%
Other principal arterials	2.5%	1.4%	3.9%
Minor arterials	3.5%	2.3%	5.8%
Major collector	11.0%	NA ^b	11.0%
Minor collector	7.0%	NA ^b	7.0%
Collector	NA ^b	2.3%	2.3%
Local	53.5%	15.1%	68.6%
All	78.4%	21.6%	100.0%

^a Data from *Highway Statistics*, Federal Highway Administration (2002).

^b NA, Not applicable.

roads, it plays a great role in terms of function. There is a considerable degree of linkage between ownership and functional class. Almost all of the interstate roads and roads designated “other principal arterials” are owned by state agencies. Even minor arterials are predominantly owned by states, especially in rural areas. As expected, local roads are owned by local governments, particularly counties in rural areas and municipalities in urban areas. Collectors are more varied in terms of ownership.

The National Highway System

Historically, all roads other than those designated “local” in both rural and local areas, or “minor collectors” in rural areas, were identified as federal-aid highways, indicating that they were eligible for federal financial aid. In 1991, the U.S. Congress established the National Highway System (NHS), a system of nationally significant highways, replacing the previous federal-aid highways concept. The NHS consists of the 46,000-mile interstate system, created in 1944 (the Eisenhower National System of Interstate and Defense Highways), and another 113,759 miles of existing roadway consisting almost exclusively of principal arterials, for a total system of 160,093 miles at present, about 4% of the nation’s roads, but almost 44% of vehicle miles of travel. As expected, most of the system, about three-fourths, is in rural areas, and almost 95% of it is state owned. It should be noted that the NHS consists of the redesignation of previous facilities and is not a system of new roads. Only about 3500 miles of additional road will eventually be created, to constitute the full system of 163,611 miles. [Table V](#) summarizes the road mileage and travel activity associated with the NHS. Although the NHS constitutes only slightly more than 4% of the road system, it in fact accounts for about 6% of national lane-miles. Almost all of the interstate portion of the NHS is four lanes or more with full access control, with only about 1000 miles with four lanes without access control and another 1000 miles, mostly in Alaska and Puerto Rico, with less than four lanes. Almost two-thirds of the other noninterstate NHS mileage is three lanes or fewer.

Intermodal Connectors

An important aspect of the NHS is that the U.S. Congress recognized in its designation process the two separate

roles of national-level highways. The first role is the through-travel, long-distance function, in which highways may be the sole form of transport or may compete with other modes of transport; the second is the service function provided by highways, as the access mode to most other modal alternatives. Although the mileages involved in serving these connection points (terminals, ports, etc.) are very limited, they are a critical part of the nation’s transportation system. It is estimated that about 1200 miles of road serve the nation’s freight terminal facilities. In total, more than 1400 passenger and freight terminal points are served by the NHS.

The Strategic Highway Corridor Network

The strategic highway corridor network (STRAHNET) is designed to serve military needs, including access to bases and connection to major ports for mobilization purposes. This entire system consists of 61,000 miles of road, 45,376 of which is interstate highway and another 15,668 miles is noninterstate.

Volume of Use of the System

At some time in the next 6 years, reauthorization by Congress of the surface transportation program the nation’s highway system will pass a dramatic milestone. The level of highway use will reach 3 trillion vehicle-miles of travel (VMT). (A vehicle-mile equals one vehicle traveling a distance of 1 mile; the sum of vehicle-miles is referred to as the VMT.) As the 20th century began, the (motorized) annual vehicle-miles of travel in the United States was about 100 million miles of travel. It took until 1968 to reach the level of 1 trillion miles of VMT in a year, in a nation in which the population was approaching 200 million. At that time, the share of travel between rural and urban areas had arrived at about a 50/50 split. It took only another 20 years for the road system to reach 2 trillion VMT per year, and the regional shares of travel had reversed from 1962, with 40% rural and 60% urban shares. By 2000, the level of travel was at 2.75 trillion VMT, and is expected to reach 3 trillion in the period 2004–2007; this equals a period of roughly 17–18 years for the increase to the third trillion. The long-term trend is summarized in [Table VI](#).

Table V National Highway System Mileage and Travel, 1998

<i>System^a</i>	<i>Mileage</i>			<i>Travel miles ($\times 10^6$)</i>			<i>Percentage of total travel</i>		
	<i>Rural</i>	<i>Urban</i>	<i>Total</i>	<i>Rural</i>	<i>Urban</i>	<i>Total</i>	<i>Rural</i>	<i>Urban</i>	<i>Total</i>
Interstate	32,910	13,424	46,334	252,317	377,840	630,157	9.6	14.3	23.9
Other NHS	85,616	28,143	113,759	214,824	315,243	530,067	8.1	11.9	20.1
Total NHS	118,526	41,567	160,093	467,141	693,083	1,160,224	17.7	26.2	43.9

^a NHS, National Highway System.

The rates of growth of VMT per decade have declined in each decade following the extraordinary levels of the 1950s, when travel grew by approximately 57%. In the 1960s, the rate of growth dropped to 48%, and then to 38% in both the 1970s and 1980s, and down to roughly 28% during the last decade of the century. However, the actual miles traveled has continued to increase dramatically in each decade, from an increase of about 0.16 trillion VMT in the 1950s to 0.6 trillion new VMT in the last decade of the century. Although such growth seems prodigious, against a background of increase in population of approximately 25 million per decade and a similar number of new vehicles, it appears more comprehensible.

VMT Fleet Mix

The predominant level of growth in travel is attributable to the personal vehicle, responsible for over 92% of travel. This varies significantly by area, comprising only 88% of rural travel and 95% of urban travel. Single-unit and combination trucks comprise almost 3% and 5%, respectively, of overall vehicle travel. Truck travel is greatest in rural

areas, comprising more than 11% of travel and almost 21% of rural travel on the interstate system. In fact, combination vehicles alone, consisting of tractors and trailers or semitrailers, account for more than 17% of travel on rural interstate highways. Moreover, the truck share will continue to grow. Growth rates by vehicle on the rural interstate show 3.2% annual growth for personal vehicles from 1987 to 1997 and 4.2% and 4.4% growth for single units and combination unit trucks, respectively. Urban interstate travel showed almost identical annual growth rates of about 3.9% for all vehicle types in the same period.

Functional Classification Mix

The growth in travel has not been distributed evenly across the highway system in either rural or urban areas. Although growth has been substantial almost everywhere over the past 10 years, it is most predominant for the interstate and other high-level arterial travel. Total percentage growth rates in the different elements of the system are shown in Table VII. The 10-year travel growth rate was 30% for the total system, with growth for urban

Table VI VMT Milestones^a

<i>Year</i>	<i>VMT</i>	<i>Event</i>
1900	100 million	First year of recorded VMT
1905	1.24 billion	First year of recorded billion VMT
1924	105 billion	First year of recorded 100 billion VMT
1936	0.25 trillion	First year at quarter-trillion VMT
1952	0.50 trillion	First year at half-trillion VMT
1962	0.76 trillion	VMT split, rural 60%/urban 40%
1967	0.96 trillion	Rural/urban VMT split reaches 50/50
1968	1.0 trillion	First year at 1 trillion VMT
1988	2.0 trillion	First year at 2 trillion VMT
1988	2.0 trillion	VMT split, rural 40% urban 60%
2000	2.75 trillion	100-year mark
2005 (est.)	3.0 trillion	Expected third-trillion VMT year

^a VMT, Vehicle-miles of travel; based on calculations by the author.

Table VII Travel Growth Rates (1988–1998) by Functional System

<i>Functional system</i>	<i>Travel growth</i>		
	<i>Rural</i>	<i>Urban</i>	<i>All</i>
Interstate	39%	46%	43%
Other freeways/expressways	—	43%	43%
Other principal arterials	49%	22%	31%
Minor arterial	10%	34%	24%
Major collector	12%	—	12%
Minor collector	17%	—	17%
Collectors	—	33%	33%
Local	29%	24%	26%
Total	27%	33%	30%

^a Based on calculations by the author.

and rural systems at 3 percentage points above and below the national average, respectively. In both rural and urban areas, travel on collectors and local roads was below or just at the national overall level, whereas interstate travel growth was more than 10 percentage points above the average. Other freeways and expressways and other principal arterials in rural areas also saw similar levels of growth in travel, often in the 40% and higher range. Only urban principal arterials deviated from the pattern.

As a result of these growth trends, the shares of travel showed even further redistribution toward the high end of the system in both rural and urban areas. From 1980 to 1998, rural interstate travel grew from 20% of rural travel to 24%; in combination with other principal arterials, their overall share grew from 40% to over 47%, with all other functional classes declining in share. In urban areas, interstate travel grew from less than a 19% share to almost 23% of urban travel, and in combination with other freeways and expressways rose from 28% to 35% of the volume from 1980 to 1998. When taken with other principal arterials, this is close to 60% of all travel. The growth trends discussed previously emphasize the importance of the national highway system. As noted earlier, the NHS constitutes about 4% of the road system and now accounts for over 43% of all travel, with about 24% on the interstate and 20% on the other NHS components.

Expected Future Trends

The national annual VMT growth rate over the 20-year period from 1980 to 2000 was 2.99%. Given the slowing of many of the factors of travel growth, an annual growth rate for the 20-year period from 2000 to 2020 of about 2.1% per year is forecast. This varies by area with a rural growth rate of 2.26% and an urban rate of 1.96%. The determinants of travel growth, such as population increase, new households, new driver's licenses, etc., may be decreasing, and part of the forecasts are based on the hope that increasing congestion will cause shifts in transit

use or other alternatives and will lessen demand for overall highway travel.

Measures of Condition and Performance

In recent years, as the levels of perceived congestion on the road system have grown, the sophistication of the processes of measuring system performance has grown as well. Although there is still no single adequate definition or measure of congestion, the ability to describe the system's performance has improved, primarily as a result of the work of the Federal Highway Administration (FHWA) and the Texas Transportation Institute. An important facet of understanding has been recognition of the need to identify the depth, extent, and duration of congested travel. Depth measures the severity of congestion; extent measures the range of coverage of the congestion, measured by the number or percentage of roads or riders affected; and duration measures the temporal distribution of the congestion.

Early measures included a volume/capacity (V/C) ratio figure; in a simple sense, the V/C measured how "full" a road segment or road system was. A level of service (LOS) measure accompanied the V/C ratio, defining how certain ratios affected the driving experience. The LOS measure was a letter grade ranging from A (the best) down to F (for failing), graded at traffic standstill levels. In recent times, traffic engineers have felt the need for lower grades or subcategories of grades within F. The characteristics of the letter grades are summarized in [Table VIII](#) (note that there are no quantitative boundary measures between the grades). Often the grades were accompanied by photographs, giving the viewer a sense of what the grade looked like on the road. A more recent restructuring of terms has led to the use of a volume/service flow (V/SF) ratio, which is the ratio of the traffic actually using a facility during the peak hour and the theoretical capacity of that

Table VIII Grading System for Traffic Congestion^a

<i>Grade</i>	<i>Description</i>
A	Describes primarily free-flow operations; vehicles are almost completely unimpeded in their ability to maneuver within the traffic stream and the effects of incidents are easily absorbed
B	Also represents reasonable free-flow in which speeds are generally maintained; ability to maneuver is only slightly restricted
C	Flow still at or near free-flow speeds; ability to maneuver restricted and tension increases; incidents cause local deterioration of service
D	Speeds begin to decline with increasing volumes; freedom noticeably restricted; minor incidents cause queuing
E	Operations at or near capacity; operations volatile, with any disruption causing waves of reaction; both physical and psychological comfort is extremely poor
F	Breakdown in flow; queues formed and lower volumes of flow produced

^a Data abstracted by the author from the *Highway Capacity Manual 2000*, Transportation Research Board (2000).

facility to accommodate the traffic. For example, a V/SF ratio of 0.8 corresponds to a LOS of grade D (Table VIII).

Recent observations of actual experience in highway traffic have actually raised the level of theoretical capacity by 10–15%, from 2000 vehicles/hour to as high as 2400 vehicles/hour. While recognizing actual behavior, this change, at a minimum, creates a discontinuity in measurement and, in fact, may be ratifying an increasingly unsafe set of conditions. Historical measures of traffic congestion have focused on the so-called peak hour in which the highest levels of traffic movement occurred. As most people know, the peak hour is now more of a peak “period” in which congestion is likely to occur. This has confounded measurement in that as traffic conditions have worsened, traffic has spread out, with people and goods traveling both earlier and later. Thus, it might be found that the share of total travel in the peak hour has declined, or just held steady, as congestion has worsened. As a result, peak-period-based measures have diminished in utility. For example, the percentage of peak hour traffic exceeding the V/SF threshold at which congestion begins

(V/SF = 0.8) actually shows a decline for urban interstates from 1995 to 2000.

Perhaps the most fundamental measure of congestion is the total volume of travel per lane-mile of road, described as daily VMT (DVMT) per lane-mile. DVMT on urban interstates has grown from 11,300 vehicles per day to 15,300 from 1993 to 2000. By this measure, things are certainly deteriorating. Because this measure tells us nothing about the distribution throughout the day; two roads with the same values of DVMT per lane-mile, but differing temporal distributions of traffic, could conceivably have very different congestion patterns. The broad measures of highway travel growth are shown in Fig. 2.

Among the new measures developed to address the changing nature of travel congestion are those shown in Table IX. Note that these measures are all measures of the facility and its flow. This is different than measuring the effective service provided to individual trips of individual travelers. It is conceivable that measures of system flow could show decline while individual travel was improving as a result of shifts in locations, modes,

Year	Vehicles	Drivers	Miles of road	VMT
1950	100	100	100	100
1955	127.4	120.1	103.2	132.169
1960	150.2	140.4	107.0	156.853
1965	183.7	158.4	111.4	193.758
1970	220.3	179.3	112.6	242.187
1975	270.3	208.7	115.8	289.764
1980	316.7	233.6	116.5	333.326
1985	349.0	252.3	116.6	387.342
1990	383.7	268.5	116.7	467.983
1995	409.6	283.9	118.1	528.765
2000	458.9	307.1	118.8	600.131

Figure 2 Main trends in highway activity. ♦, Vehicles; ■, drivers; ▲, miles of road; x, vehicle-miles traveled (VMT). Data for selected years from *Highway Statistics*, published by the Federal Highway Administration.

routes, etc.; the most direct user measure is, for instance, average travel time. This information is collected by the Bureau of the Census for work trips and by the National Household Travel Survey (NHTS) of the FHWA for all trips. These averages can improve while the facility-based measures decline. The census measured an increase in work trip travel times of only 40 seconds from 1980 to 1990 but observed a ≥ 2 -minute increase from 1990 to 2000.

There are many other measures of congestion that express various aspects of congestion's attributes. The

studies of the Texas Transportation Institute (TTI) have been notable in this area; TTI has published a series of annual urban mobility reports since 1982. Their very practical measures have increased as their research has progressed. Much more work needs to be done to arrive at exhaustive measures that are readily understood and applied uniformly. Rolf R. Schmitt of the FHWA has sought to develop theoretically comprehensive measures of congestion attacking all aspects of the topic; his early structure for congestion measures is shown in [Table X](#).

Table IX Selected Highway Performance Measures in Use^a

<i>Measure</i>	<i>Approach</i>	<i>Purpose</i>
Average speed	Direct measure of speeds on a facility	Most direct measure of changes in facility service
Travel time index or percentage additional travel time	Ratio of congested travel time to typical off-peak times	Depth measure; measure of loss of time in the peak (140 = 40% more travel time)
Annual hours of delay	Total annual hours delayed in traffic per driver, or per adult, or per capita	Depth \times extent measure; accumulated loss of time for the year; provides cost value
Percentage of system congested	Percentage of roadway lane miles operating at less than free-flow speed	Extent measure; percentages of road system affected by congestion
Percentage of travel congested	Percentage of urban daily traffic on principal arterials moving at less than free-flow speed; same as preceding measure weighted by volume	Extent measure; e.g., 40% of total travel was under congested conditions!
Buffer or reliability index	Measure of amount of extra time needed to assure on-time arrival	A measure of variation in speeds and travel times

^a Data from *Condition and Performance Report, Federal Highway Administration* (2002), and *Urban Mobility Report, 2003, Texas Transportation Institute* (2003).

Table X Theoretical Structure for Highway Performance Measures^a

<i>Measure</i>	<i>Concept</i>
Geographic accessibility	Are the origins and destinations linked by the transportation system?
Architectural accessibility	Do the origins and destinations have physical barriers for part of the population?
User cost	Do the origins and destinations have economic barriers for part of the population?
Temporal availability	Is the transportation system available when people want to travel?
Best travel time	How long does it take to get to the desired destination under the best conditions?
Expected travel time	What is the usual expected time to get to the destination?
Buffer time	How much time do people add for a trip or shipment in anticipation of variability in expected travel-time to reach the destination when they need to be there?
Nonoptimal time	How much longer than the best travel time does the usual or scheduled trip take because of routing, speed restrictions, expected delay, etc.?
Tardiness	How late are people and goods when buffer time is exceeded?
On-time performance	How often do trips and shipments reach their destinations by the usual expected time?
Capacity	How many travelers and shipments can be moved over the transportation system under optimum conditions?
Congestion	When and where are the number of trips and shipments that are actually accommodated less than the maximum possible because capacity has been exceeded by the volume of traffic?

^a Data from R. R. Schmitt, presentation to the North American Statistical Interchange, April 2002.

Highways as an Element in Society

There is an extraordinary number of ways in which highways interact with society, and each has significant ramifications. The impacts include both positive and negative attributes and can be arrayed into three broad categories, economic, social, and safety/energy/environmental. Although the impacts of roads on the land began well before the United States was a nation, the most important impacts of highways ultimately derive from the inception of the great role of the internal combustion engine.

Vehicles

A key measure of the relationship between vehicles, highways, and society is the number of vehicles/household or vehicles/1000 population. In 1910, at the start of the auto age, there were 200 people/vehicle in the United States; 5 years later, this was already down to 40 people/vehicle. By the 1930s, the entire population could be seated in the front and back seats of all of the existing vehicles, and by the 1950s, the entire population could be accommodated in the front seats alone. In 2001, the total motor vehicle fleet exceeded 230 million vehicles; with a population on the order of 285 million, this was a comfortable 1.24 people/vehicle. The vehicle fleet now not only exceeds the number of drivers in the population, it exceeds the number of the total adult population. In many of the recent past decades, vehicle production exceeded population increase.

Other measures of the vehicle/population relationship include the percentage of persons over 16 years of age with drivers licenses, the average number of vehicles per household, the distribution of households by vehicles owned or available for use, and the number of households with no vehicles. Among adults, the United States is near saturation regarding licenses; the same can be said for households, for total number of vehicles. However, these levels are significantly lower among minority groups, which will be a significant source of future growth in vehicle acquisition and travel miles. A key statistical measure of mobility is the number and percentage of households without vehicles in a society highly oriented to mobility. Surprisingly, the number of households without a vehicle has remained at about 10 million for 40 years, and the number of households with one vehicle has remained at about 30 million, but, of course, both are a significantly declining percentage of all households. All growth has occurred in the two- and three-vehicle households. Figure 3 depicts this trend over the past 40 years.

Household Highway Expenditures

Transportation is of great value to American households, as amply demonstrated by spending behavior. A key

Figure 3 Number of households by number of vehicles owned. ♦, No vehicles; ■, one vehicle; ▲, two vehicles; x, three or more vehicles. Data from the decennial censuses of the U.S. Bureau of the Census.

measure to monitor is the share of total household spending going to transportation. On average, American households spend about 19% of their total expenditures on transportation, or about \$7600 per year in 2001, with both the amount and the percentage of spending rising with increasing incomes. Of this amount, more than 96%, all but about \$300 of total spending, is oriented to vehicles and road travel. The percentage of expenditures going to transportation has risen slightly over the decades.

Human Purposes

In considering local road travel, particularly when associated with congestion, the tendency is to think of work travel. In fact, work travel is a small ($\approx 20\%$) and declining share of all travel. The share of personal travel accommodated by the road system is prodigious. For work trips, the personal auto accounts for over 92% of trips, with transit and "other" accounting for less than 4% each. Even then, most of the trips via buses and walking or biking are also on roads. For a number of trips for other purposes, such as social/recreational travel or school/church or family/personal business, rail-related usage is far less, as compared to work travel, but walking trips increase.

Long-distance travel (trips over 100 miles) is similarly oriented to the personal vehicle. The personal vehicle accounts for more than 80% of long-distance travel; with intercity bus travel added, the highway share rises to 83%. Even for business travel, the auto predominates for all trips under 1000 miles round trip.

Freight Flows

Americans tend to neglect the role of freight transport in their lives. More than 11 billion tons of freight, valued at \$7 trillion, moved in 1997. Measured in ton-miles (moving 1 ton of freight 1 mile), total freight movement was on the order of 2.66 trillion ton-miles. The predominant share of each of the three measures (value, tons, and ton-miles) of freight movement is by highways: 82% of value, 70% of tons, and 42% of ton-miles.

Travel Activity Categories

Categories that are used to structure uses of highways are given in [Table XI](#).

Consumption

Highways are great consumers of resources, including land, steel, concrete, and petroleum, but perhaps the most important element of consumption is time. It has been argued that human beings have tended to spend about 1 hour or so per day in travel since the beginning of civilization. Today, the averages exceed an hour and most of the time spent in travel is spent in autos or trucks. The National Household Travel Survey (NHTS) indicates that the average time spent driving is 66 minutes on weekdays and 54 minutes on weekends, and the time spent in a vehicle driving or as a passenger is closer to 70 minutes per day.

Table XI Travel Activity Categories

<i>Category</i>	<i>Description</i>
Commuting	
Other resident travel	School, work-connected business, personal business, shopping, visit friends and relatives, social/recreational, medical/dental, other
Visitor travel	Overnight visitors, same-day visitors, business travel
Services	Telephone, gas, electric, cable TV
Public vehicles	Government/military, police, fire, ambulance/emergency, refuse, road construction/maintenance
Urban goods movement	Couriers, store delivery, home delivery, office delivery, factory delivery, services/repair, construction
Through-passenger travel	Business, social/recreational, visit friends/relatives
Through-freight travel	Agriculture, construction/manufacturing, wholesale/retail, import/export

Safety

Preliminary estimates indicate that the 2002 road-related fatality count rose to 42,850 from 42,116 in 2001. This was a sharp setback; fatalities had been declining as a function of reduced rates of fatalities from crashes and the rate of crashes. Total nonfatal crashes declined as did the number of persons injured in 2002. The highest levels of fatalities occurred in 1969 and in the early 1970s, when for several years fatalities exceeded 55,000; this number dropped sharply over the years to a nadir of 39,000 in 1992, the last time the number was below 40,000. It has been rising sporadically since then.

Measurement of safety is a complex procedure. The tendency is to focus on the absolute numbers of fatalities and of persons injured, but the analytical focus is often on the rates of crashes and fatalities. Among the key measures are the fatalities per million population, fatalities per 100,000 vehicles or per 100,000 drivers licenses, and fatalities per 100 million miles of travel. All of these measures have shown marked improvement over the past 30 or so years. For example, the fatality rate per 100 million miles of travel is less than half of what it was in 1980. Current annual fatalities at 1980 rates would exceed 90,000. The key monitoring question is whether in any given year the rate of improvement in fatalities is sufficient to compensate for the rate of growth in travel. These measures will vary sharply from country to country and can be very misleading, given levels of motorization and levels of management of traffic.

Environmental Concerns

Although road water runoff affecting water quality, noise pollution affecting nearby populations, and habitat impacts are concerns stemming from road use and development, the key environmental concerns related to road use have been those related to air quality. Air quality has been measured over time by focus on four pollutant categories; these are volatile organic compounds (VOCs), oxides of nitrogen (NO_x), carbon monoxide (CO), and particulate matter under 10 μm in diameter (PM10). Lead emissions, a major national concern in the 1960s and 1970s, were totally eliminated because of changes in gasoline formulation by the mid-1980s.

The focus on air quality is in five key areas: share of pollutants generated by transportation, total tons of pollutants emitted, percentage change in emissions, exceedances (of air quality standards) per monitor, and index measures of trends. By almost all of these measures, air quality has been improving dramatically and will continue to do so. Measured against 1970, on-road vehicle emissions are down by the following percentages: VOCs, almost 60%; carbon monoxide, 43%; and PM10, almost

20%; only NO_x is up by 16% as a result of sharp increases in the diesel truck fleet. Carbon monoxide exceedances per monitor are down from 25 per monitor in 1975 to 0.1 in 2000. In all cases, transportation is doing better at improvement compared to the other sources of pollution. In many cases, off-road gasoline engines used for lawn mowing, boating, skimboarding, etc. have shown dramatic increases in emissions.

History of Business Performance Measurement

K. J. Euske

Naval Postgraduate School, Monterey, California, USA

L. A. Zander

Naval Postgraduate School, Monterey, California, USA

Glossary

cash flow Cash receipts minus cash disbursements.

economies of scale The reduction in the cost of producing goods and services because of increasing size of the producing organization.

effectiveness A measure of the relationship of outputs to goals or objectives.

efficiency A measure of the relationship of inputs to outputs.

performance Behavior that leads to a measured value outcome in the future. It is context specific.

therbligs A set of actions defined by Frank and Lillian Gilbreth for use in time and motion studies.

This history of performance measurement focuses on the development of performance measurement in commercial organizations over the past 500 years. As would be expected, performance measurement over the centuries has been directed at providing stakeholders with a picture of their organization. As the model of business and technology shifted, so did the need for the information to understand the performance of the organization. Models that are viewed as having significant defects today, such as return on investment, did provide useful information for the organizations for which they were designed. There is a continuing challenge to develop a measurement system that effectively and efficiently captures organizational performance in a timely fashion. The highlights of the evolution of performance measurement covered here exemplify changes to performance measurement that have occurred over the centuries. Other examples could have been used. The examples chosen, in the

authors' view, capture the spirit of the times and the evolution of performance measurement.

Early Measurement Systems

Luca Pacioli is probably best known for his contributions to accounting. The ideas and processes described in his *Summa de Arithmetica, Geometrica, Proportioni, et Proportionalita* from 1494 are still applied by many in the accounting profession today. However, he can also be characterized as a pioneer in the area of performance measurement. The *Summa* also includes discussions of the topic of performance measurement as well as internal controls, such as numbering and dating ledgers, journals, and memorandums. In addition to describing the double-entry accounting system, Pacioli led businessmen through the necessary steps to account for all of their transactions. He identifies three things that are required to operate a successful business. First, there must be some sort of market need or justification for the endeavor. Second, the businessman must be a good accountant and mathematician. Third, the affairs of the businessman must be arranged systematically so that he may understand the business at a glance. Fundamentally, this means that the businessman must have an orderly record of the performance of the business. For the merchants of the time, this meant understanding the gain or loss for any particular venture. Pacioli described the specific entries required to recognize a profit or loss. Basic financial measures provided a means to evaluate the performance of the individual enterprise.

From the period of Pacioli into the 18th century, businesses tended to be family-run organizations; their primary focus in the area of performance measurement centered on the calculation of profit and loss for projects undertaken. The owners were staking their assets on specific endeavors. The fundamental question was whether the investment (i.e., running the family business) generated sufficient cash flow to continue the venture.

As transportation and technology improved, the focus on the management and measurement of performance evolved. In the 18th century, Josiah Wedgwood, faced with the competition in the pottery industry, realized that the old methods of manufacturing and employee management would no longer suffice. He sought alternative approaches to managing his operations. Wedgwood, through his systematization of production, division of labor, and disciplining of labor, is one of the pioneers of English factory organization. Wedgwood appointed foremen and managers and established what would now be defined as workgroups, or individual workers specializing in each area of manufacturing, from making the pottery through painting. As the organization continued to grow, Wedgwood created the *Potters' Instruction of 1780* to define rules and regulations for manufacturing along with guidance for the foreman regarding rewarding employees and reprimanding employees who were not performing according to expected standards. Additionally, Wedgwood paid piece rates and had bonus schemes to stimulate productivity. His innovations provided a basis for measuring performance at the operational level.

About 40 years after *Potter's Instruction* was printed, one of the first uses of the term "accountability" appeared in a report published for the Springfield Armory. The 1819 report addressed innovations in two specific areas: (1) processes used for manufacturing and inspecting production work and (2) the use of double-entry bookkeeping for every transaction by the employee, related to the manufacturing of items within the armory. The specific transactions recorded information about the physical amounts and value of material used as well as the amount and value of scrap and good inventory received at the end of the workday. In 1834, the Ordnance Department of the Springfield Armory published its own official document, *Ordnance Regulations*. Included in this publication were two objectives related to accountability and management structure: (1) the careful delineation of lines of authority and communication (2) setting standards of uniformity for accounting and manufacturing practices. Daniel Taylor, a West Point graduate who wrote the document, introduced into the manufacturing process within the Armory a new standard for performance measurement and discipline. Taylor's innovations at the Springfield Armory have been traced to studies conducted at West Point under the guidance of Sylvanus Thayer to establish a merit system for student evaluation. Taylor, a student at West Point

just prior to the arrival of Thayer, was a part of the transition to a system of grading students and holding them accountable for their performance. It has been proposed that Taylor adapted the accountability and performance measurement ideas from West Point to the armory.

Late 19th—Early 20th Century

As the 19th century came to a close, the U.S. Congress identified a need to eliminate the restraints on trade and competition in the United States. To address the issue, Congress passed the Sherman Anti-Trust Act of 1890. The act was established to protect trade and commerce against unlawful trusts and monopolies. The act also influenced performance measurement. As Thurman Arnold noted in *The Bottlenecks of Business*, when the act was first passed, many interpreted it to be an attack on big business, purely based on their size, perhaps even prohibiting organizations from taking advantage of mass production or distribution. However, there were those who saw the Sherman Anti-Trust Act not as simply a tool to use against any large organization, but rather as a tool to address abuses that might result from the economic power of large organizations. Thurman W. Arnold, who held the office of the head of the Anti-Trust Division of the U.S. Justice Department, took the position that it was not size in and of itself that needed to be controlled, but rather the use of market power to unreasonably restrain trade.

From a production point of view, if organizations could not use their power to restrain trade, competition was more likely to flourish. Given the potential for competition, the leaders of large organizations faced the need to be more competitive. One way to do so was to find more efficient ways to produce their goods and services. Economies of scale became increasingly important. The measurement of performance now more than ever was a necessary part of managing a business. The continuing advances in technology and distribution systems helped transform the manufacturing environment.

With the changes came problems. One was determining performance expectations for individual workers. Frank B. Copley, in his book *Frederick W. Taylor*, explains how Taylor's theory of scientific management resulted from his attempts to address the problem of the appropriate amount of work that any given person ought to complete on any given day with the right tools and materials. Taylor had published a book in 1911, *Scientific Management*, in which he described his methods of gathering and providing to management the knowledge that had traditionally been in the domain of the workers. The process by which he did this included recording and tabulating data and, when appropriate, identifying the relevant rules, laws, and mathematical relationships.

Taylor's work introduced the concept of time standards for processes as well as the need for a standard set of tasks to be completed. A difficulty in using his method of managing the work being performed lies in the ability to collect meaningful data. Getting the workforce to provide information that was surely going to affect their piece-rate system was no easy task. In addition, the machinery might not function properly, or could break down altogether. Taylor applied common sense to decide on which acts to focus to yield the largest return. The focus was on the measurement of performance of the task or tasks that would most likely have an impact on the overall production process, rather than on the measurement of everything.

The standards developed by Taylor were based on a scientific method of gathering data and mathematical formulas, and as such provided a control mechanism to manage the unit. Taylor saw the need for both financial and nonfinancial measures. The blend of information from the time studies, as well as the cost data, provided a set of information that could be used to measure the performance of a given production unit. Taylor's view of cost accounting was that it was not useful unless it was combined with the accurate measurements of the work performed.

In a book written in 1964, *Efficiency and Uplift*, Samuel Haber discussed the establishment in 1911 of the Taylor Society; this group of Taylorites, an informal but exclusive group of individuals, included Frank Gilbreth and Henry Gantt. Both men would soon be cast out of the Taylor Society for their additions and revisions to the "scientific management" way of thinking. Haber describes how Gilbreth concentrated his efforts on the "scientific" aspect of Taylor's work. In 1912, Gilbreth introduced the motion-picture camera as a means of obtaining more exact measurements of work performed by an employee in the manufacturing process. Taylor refuted the process by claiming that it was only an aspect of scientific management, undoubtedly good for investigating the minutiae of motion. Early on, Taylor approved of the experiments, but later he became concerned that the concentration on motion studies was part of a more grandiose scheme and that Gilbreth's focus neglected the broader scope of scientific management.

Gantt's attempt to introduce revisions to the scientific management approach included introducing a focus on social reform and attempting to get at inefficiency in work methods by looking at management, not just the workers. Taylor found these ideas to be unacceptable. Taylor's approach to the work in the factory centered on the problem of setting the tasks of the worker. Gantt, on the other hand, argued that the place to attack inefficiencies was not with the laborer, but with management. Most of Gantt's innovations in the area of management came from his search to set performance standards for management

similar to those set for the workers—using a stopwatch. Idleness of man or machine was an indication of management malfeasance. In Gantt's system, costs associated with idleness were not added to product. They were deducted directly from profits. This approach was designed to have a direct effect on those individuals in a management role and to focus performance measurement at a higher level of the organization.

During the same period of time that Taylor was developing his work in scientific management, and continuing after Taylor's death in 1915, Alexander Hamilton Church wrote articles with a focus on areas that included accounting, management, and performance measurement. Richard Vangermeersch, in his authoritative book, *Alexander Hamilton Church* (1988), describes how the foundation of Church's writings centered on the increasing complexity found in the manufacturing environments, focusing on the control of the operation. In the first work that Church published, he concentrated on the increased competition and the necessity for coordination and quick presentation of results. For control to be a reality for Church, inputs and financial results needed to be both forecasted and compared after the fact. Church recognized that scientific management had been around for decades, but also realized that the evolution of this concept was certain to take place as industry continued to go through changes. His view was that scientific management was more a set of principles than a system, and that it provided a means to view the entire production process. Church argued that because scientific management focused only on the human element of management but did not address issues such as capital and labor, it was not a complete system. Vangermeersch traces L. P. Alford's work with Church to develop what they viewed to be the scientific art of management, which focused on more than just one system. In 1912, Alford published an article titled *The Principles of Management*, which presented the foundation for their views. Three basic principles of management were presented:

1. Systematic use of experience.
2. Economic control of effort.
3. Promotion of personal effectiveness.

Each principle was to be measured and analyzed by leadership in conjunction with the workgroups. The resulting information provided a means to capture the performance of the workgroups.

The early 1900s also brought about a systematic identification of critical performance variables; with the publication of a return-on-investment model, Donaldson Brown, working for DuPont at the time, formulated a model to analyze the various components of return on investment. The model provided for a comprehensive series of financial indicators. Brown was later moved to General Motors, a company experiencing a significant

upturn in the market in terms of performance. General Motors (GM) was faced with the problem of managing product variation while maintaining production standardization. Ford Motors, on the other hand, lagging behind in the market, sacrificed product differentiation for production volume. While GM measured performance using the model developed at DuPont, Henry Ford had little consideration for the evaluation of financial performance of Ford Motors. Not only did he not develop measures to evaluate such performance, he appeared unconcerned about return rates or other financial measures. His focus was on nonfinancial measures tied directly to the shop floor. This difference in the approach to measuring performance continued for years, not only across organizations but also within organizations. Essentially, Ford was looking at causality from the perspective of a process-based model. GM had what can be described as a results-based model that was more remote from the actual production process. In a 1993 field study of highly successful organizations, Euske and co-workers found that a key midmanagement role was translating or finding a way to tie the top-level financial measures to operational measures of performance.

In the environments in which Brown operated, return on investment was a useful tool. Return on investment, both in nominal and in discounted forms, was a useful form of measurement for organizations that experienced the kind of growth and prosperity that GM saw during the early 1900s. However, return on investment as a measure of performance has a number of weaknesses that are well documented in the literature.

Middle to Late 20th Century

By the mid-1940s, everyone from engineers to social scientists was studying various aspects of control, including performance measurement. Norbert Wiener, a mathematician, coined the term “cybernetics” as a theory of control systems based on communication. It was the work of a number of individuals, including W. Ross Ashby and C. West Churchman, that expanded the idea to complex systems. Their work uses the decision as the unit of analysis. The decision variable then becomes an important element in the system design for performance control (SDPC) model.

The SDPC model, using cybernetics and systems theory as its basis, can be described as a model for guiding the actions of organizational planners using the following seven phases:

1. Identifying the goal: Defining the variables and parameters.
2. Formulating the strategy: Composing the controlled and uncontrolled variables.
3. Organizing the structure: Decomposing the dependent and independent controlled variables.
4. Training the decision makers: Amplifying regulatory capacity over the dependent and independent controlled variables.
5. Coordinating the firm: Recomposing the dependent and independent controlled variables.
6. Monitoring the environment: Synchronizing the controlled and uncontrolled variables.
7. Valuing the performance: Evaluating the variables and parameters.

For the SDPC process to be effective, it must be part of an ongoing planning cycle, continuously applied to the organization. Of particular interest is the last phase of the SDPC process, which addresses the need to evaluate the past performance of the system and the value of that information as it applies to future applications. This phase requires reliable data from various sources. Given a systems theory basis for the SDPC process, the data gathered, once analyzed, can be used as part of an overall evaluation of the entity. First, the data can be used to ensure that the design and decision processes are working properly. Second, the data provide information to stockholders for determining the appropriate resources to allocate to specific processes or systems. Finally, the data can be used to communicate results to the nonstockholders regarding the performance of the organization. Although designed within a systems theory framework, SDPC relies heavily, but not exclusively, on accounting data.

The use of financial data was important during this period not only in models such as SDPC, but also in the return-on-investment model. One variation of the return-on-investment model that had been used for decades was residual income. Although the use of the measure had waned during the latter part of the 20th century, during the 1990s, the use of residual income experienced a resurgence in the form of economic value added (EVA), promoted by Stern Stewart & Co. in publications such as G. Bennett Stewart's *The Quest for Value*.

Return on investment and SDPC proved very useful through the mid-1900s. However, problems began to arise with the use of shorter-term financial measurements. Managers realized that during difficult times, when sales were on the decline and margins were not as acceptable as they had been, profit and return on investment targets could still be met by working a little harder in the finance office. For example, the discretion that existed for the timing of revenue and expense recognition for the current accounting period could affect the outcomes measured by the accounting system.

A different approach addressed the problem of the short-term focus and the ability to manipulate financial measures. In this approach, the focus on performance measures shifted toward nonfinancial measures.

Measures that focused on an organization's strategy and evaluated areas such as research, development, and manufacturing became increasingly important in the 1980s and 1990s. As an example, a company might choose to measure productivity information in order to become more efficient in the manufacturing process, thereby becoming more competitive in the marketplace. Other approaches recognized the need for flexibility in both design and manufacturing and the need to develop ways to measure product design implications as part of the overall research and development process.

The introduction of both financial and nonfinancial measures had the potential to impose on an organization the overwhelming task of trying to manage too many different measurements. Nevertheless, the approach offered the opportunity to capture multiple aspects of performance. However, at any one point in time, it is likely that only a few of the measures would be significant to an organization. The need for a mix or balance of measures was not a new idea. The *Tableau de Bord* used by the French at least since the early 1900s is just such a mix of measures.

The 1990s saw a continuation of the discussion of the relevance of both financial and nonfinancial measurements, but with an emphasis on the employee's role in improving the organization, based on data gathered in the measurement process. In *Relevance Regained* (1992), Johnson, focusing on the global marketplace, argued that if an organization is to be successful, it is essential to capitalize on the potential of the employees and to eliminate any performance measures or other management information that do not support behavior congruent with the imperatives of global competitiveness. Johnson stated that the imperatives for a globally competitive organization create an environment that allows employees to use their skills and talents to the fullest. The globally competitive organization creates an environment such that employees can then begin to understand how the entire organization impacts the way that customers view performance, and to understand their individual responsibilities to meet those customer needs.

The different models that appeared during the 1990s incorporated both financial and nonfinancial measures. For example, in 1991, Lynch and Cross introduced the performance pyramid. The pyramid contained four levels of objectives and measures to link strategy and operations by translating strategic objectives from the top down and measures from the bottom up. The top level of the pyramid is the vision for the organization as stated by the senior management of the company. The second level contains objectives for each business unit in terms of markets and financial data. The third level represents the core processes supporting the organizational strategy, with tangible objectives and priorities as they relate to areas such as customer satisfaction and productivity.

Finally, the base of the pyramid represents the conversion of the objectives into specific criteria, such as quality and cycle time for each department or organizational component. The Lynch and Cross model enables the members of the organization to communicate to employees those measures that are important and also provides for an understanding of how those measures relate to the objectives of the organization.

In 1992, Kaplan and Norton popularized a tool developed at Advanced Micro Devices (AMD). The tool was designed to provide managers with the information they deem necessary to be successful in today's business environment. Kaplan and Norton, on the opening pages of their book, *The Balanced Scorecard*, argued that "the Balanced Scorecard translates an organization's mission and strategy into a comprehensive set of performance measures that provides the framework for a strategic measurement and management system. The scorecard measures organizational performance across four balanced perspectives: financial, customers, internal business processes, and learning and growth." The approach to develop a performance pyramid and balanced scorecard are slightly different. Although both models provide for input from employees at all levels of the organization, the balanced scorecard has more of a top-down approach, compared to the pyramid.

As business and technology continue to shift, the need for information to understand the performance of organizations will continue to change. The evolution of performance measurement is a continuing effort to model performance in a fashion that helps the stakeholders understand the organization.

History, Social Science Methods Used in

Allan J. Lichtman

American University, Washington, DC, USA

Glossary

cliometrics The marriage of metrics with Clio, the muse of history, usually applied to the use of theory and quantitative methods in economic history.

content analysis The application of formal, replicable methods to studying manifest and latent patterns found within texts, including written documents and artifacts such as paintings, coins, films, and buildings.

counterfactual history An answer to a “What If?” question that uses theory and mathematical analysis to assess what might have happened absent particular events, trends, or innovations.

ecological regression The use of regression methods to draw inferences about the behavior of groups from aggregate units in which group members are included.

event history analysis Methods for analyzing life-cycle data such as birth, death, marriage, and divorce that involve few events over extended time periods and for which individuals are traced only for part of their life course.

exploratory data analysis The search for unsuspected regularities and relationships in historical data without testing hypotheses derived from predetermined theory.

game theory Models for analyzing a strategic response to situations in which the outcomes of an individual's or group's decisions are affected by the strategic calculations and choices of others with different and conflicting goals.

Geographic Information Systems (GIS) A computerized system for integrating, analyzing, and displaying digitized maps and other spatial-based data.

postmodernism A view of history that questions whether truth about the past is attainable, no matter how rigorous the methodology used. It suggests that rather than an objective record of the past, historians have only texts or discourses subject to limitless interpretation.

record linkage Computerized methods for recreating life histories by identifying and connecting individuals found in such multiple records as census reports, parish registers, and tax rolls.

time series analysis Methods for analyzing time-dependent data, in which the value of a variable at a particular time, such as spending by governments, is dependent on values at past times.

In the 1960s, historians began to draw extensively on social science methods to recapture the daily experiences of ordinary people, reinterpret history from the bottom up, and reconsider major interpretative questions through the use of quantitative data and verifiable methods of analysis. Since that time, historians have deployed increasingly sophisticated techniques adapted to the special challenges of historical study. Although historians using social science methods have not produced grand new theories of human behavior or come to dominate studies of the past, their work makes an indispensable contribution to every field of history.

History and Social Science

Historians draw on the precise quantitative methods of social science to fill gaps in the historical record, answer causal and interpretive questions about the past, and test theories of human behavior. Methods used by historians range from the simple counting and sorting of data to inferential statistical methods such as multiple regression analysis and quantitative analytic tools such as game theory. The use of social science methods has been influential in shifting the focus of much historical study from the deeds of great men and women to the lives of ordinary people and the challenges they confront in daily life. Through such interdisciplinary procedures historians have studied the masses as well as the elite and day-to-day events and the dramatic episodes of the past. The use

of social science methods has opened up the once-hidden history of women, minorities, and poor people who left little or no documentary record of their own. It has cast new light on historical controversies and subjected theories derived from the disciplines of social science to the test of historical experience. However, critics have charged that social science methodology robs history of its human drama, replaces great deeds with the humdrum routine of daily life, condemns historians to arcane specializations, and forces an inherently contingent past into a Procrustean bed of preformed theory.

Origins of Social Science History

Quantitative social science history gained momentum in the 1960s and early 1970s as part of a New History movement that sought to reinterpret history from the bottom up, not the top down; to replace impressionistic, intuitive approaches with formal, verifiable methods of analysis; and to supplant historical narratives with the development and testing of hypotheses. New historians looked to supplement traditional historical sources (letters, diaries, and government documents, for example) with quantifiable sources of information (such as birth and death certificates, census records, business ledgers, ship manifests, and election returns) and to apply rigorous methods of content analysis to wrest hidden meanings from texts. They sought to achieve temporal and cross-cultural comparisons of experience across time and place and to look beneath the headline events of an era to discover the history that is latent rather than manifest in people's experience, such as changes in family size and structure. Their work also had the political objective of giving voice and agency to peoples whose experience was hidden in documentary records, but recoverable through scrutiny of quantitative data from the past.

The new history also reflected changes in social science, which was becoming more self-consciously methodological, abstract, and quantitative. "And still they come," wrote the poet W. H. Auden of the 20th century, "new from those nations to which the study of that which can be weighed and measured is a consuming love." Some new historians, in the words of one pioneering practitioner, Lee Benson, even anticipated that historians guided by quantitative social scientific methods would escape time-bound experience and "participate in the overall scholarly enterprise of discovering and developing general laws of human behavior."

Pragmatically, the development of high-speed computing and machine-readable databases accelerated the pace of work in quantitative social science history in the 1960s. Even the costly and unwieldy mainframe computers available at the time, with hours of turnaround time for a single job, let historians process far more data and

apply more sophisticated statistical techniques than in earlier years. By the 1970s, historians were increasingly adept in using programming languages such as FORTRAN, COBOL, and BASIC, as well statistical software applications such as the Statistical Analysis System (SAS) and the Statistical Package for Social Sciences (SPSS), both of which remain in widespread use. Quantitative social science history, because it often requires the compilation and analysis of large bodies of data, led to the rise of government-supported machine-readable data archives—the quantifier's equivalent of manuscript repositories. In the 1960s, aided by funding from the National Science Foundation, the Inter-University Consortium of Political and Social Research (ICPSR) at the University of Michigan began compiling an extensive computerized base of quantitative political and social data that included election returns, survey results, legislative roll calls, and census compilations. By the 1990s, historians had available many hundreds of digital databases covering broad time periods and diverse geographic regions, and they also had desktop computers more powerful than the unwieldy mainframe computers of earlier years. Historians and social scientists also joined together in major collaborative projects that once were unusual in a solitary profession such as history. These included, for example, the Philadelphia Social History Project in the United States and the Cambridge Group for the Study of Population and Social Structure in Britain.

New journals dedicated to publishing work in quantitative social science history helped establish the legitimacy of such interdisciplinary work during the 1960s and 1970s. These included the *Journal of Social History* (1967), *Historical Methods Newsletter* (1967), the *Journal of Interdisciplinary History* (1970), and *Social Science History* (1976). In 1975, a small group of American scholars from history and social science disciplines formed the Social Science History Association (SSHA), dedicated to "encouraging the selective use and adaptation in historical research of relevant theories and methods from related disciplines, particularly the social sciences." The ICPSR and the Newberry Library in Chicago began offering instruction on quantitative applications in history and by the 1980s, an International Commission for the Application of Quantitative Methods in History was holding workshops and sponsoring programs at the meetings of the International Congress of Historical Sciences. Historians outside the United States formed organizations similar to the SSHA and founded several European-based journals dedicated to new historical methods, including *Historical Social Research* (Germany), *Histoire et Mesure* (France), and *History and Computing* (Great Britain). By the 1970s, mainstream historical journals were also publishing considerable historical research based on social science methods. According to a study by John Reynolds, from 1975 to 1981 work in social

science history equaled approximately 28% of the research articles published in five major national historical journals in the United States.

Social science history gained prominence and luster through path-breaking work by early practitioners that commanded respect and attention in the profession. Economic history was first among the historical research fields to embrace quantitative social science methods. Perhaps the most notable among the early new economic historians was Robert Fogel. In 1964, with his work *Railroads and American Economic Growth*, Fogel challenged the widely held belief that railroads had been essential to the economic growth of the United States in the 19th century. To test this thesis, Fogel contrived a counterfactual model of a U.S. economy based not on railroads but on an extensive system of canals. Using available documentary data and assumptions drawn from neoclassical economic theory, Fogel estimated the rate of growth under the canal system and concluded that the canals in his hypothesized model would have proven almost as efficient as railroads and that economic growth would not have substantially slowed in the absence of railroads. Fogel's approach to economic history—the development of specific hypotheses about past economies, the testing of hypotheses through counterfactual modeling, and the reliance on quantitative methods and economic theory—became hallmarks of a new economic history that participants termed cliometrics. Much of the work in cliometrics is informed by variants of rational choice theory, which posits that markets and other human institutions arise from purposive, goal-seeking behavior by rationally calculating individuals. Some economic historians, however, including Douglas North (who shared the Nobel Prize with Fogel in 1993), stress the importance of economic and social institutions, bringing economic analysis more closely in line with historical experience, although at the expense of elegant formal models applicable in principle to diverse historical circumstance.

A decade after publication of Fogel's study of railroads, he and co-author Stanley Engerman stunned the world with *Time on the Cross* (1974), which used the techniques of cliometrics to argue that slavery was an efficient, profitable, and relatively humane system of labor. Slaves, the authors found, were well housed, clothed, and fed and were rarely beaten, sexually exploited, or forced to abandon their families. Moreover, they contended that slavery was profitable to slave owners, farms using slaves were more efficient than farms using free labor and the slave was "harder-working and more efficient than his white counterpart." These remarkable conclusions flowed from the application of computer-assisted inferential analysis to numerical data culled from probate records, plantation documents, slave-market registers, and census figures. The authors, for example, used techniques borrowed from demography and population genetics to

approximate (from census tallies of mulatto slaves and the current genetic composition of American blacks), the proportion of slave children sired by white fathers. Their work posited that the destruction of the profitable system of slavery after the Civil War accounted for declining economic standards in the South, and that post-bellum racism, not slavery, explained the present-day problems of African Americans in the United States. Prior to the publication of *Time on the Cross*, the social scientific revolution in history had largely taken place below the threshold of public awareness. Now a historical study using sophisticated mathematical analysis and social science models influenced policy debates and penetrated popular culture, setting off arguments pro and con in the press, innumerable reviews, and conferences devoted to debating the authors' methods and conclusions.

Economic history—often practiced by scholars such as Fogel with training in economic theory—remains the sub-discipline within history with the most extensive and sophisticated use of social science methods. The work of the cliometricians (most located in economics rather than history departments) came to dominate the field of economic history. The percentage of pages in the *Journal of Economic History* devoted to cliometric articles rose from approximately 6% in the 1950s, to more than 30% in the 1960s, to nearly 80% in the 1970s, and to slightly more than 80% in the 1980s. In 1993, Fogel and fellow cliometrician Douglas North won the Nobel Memorial Prize in economic studies "for having renewed research in economic history by applying economic theory and quantitative methods in order to explain economic and institutional change."

In social history, scholars associated with the *Annales School* of French historiography (founded several decades earlier) gained acclaim during the 1960s through painstaking efforts to achieve the total history of communities by reconstructing quantitatively their economic and demographic structure, material culture, and even mentalities or characteristic perceptions of the world. Much of this work relied not on advanced statistical techniques but on the simple compilation of data from previously unexploited sources such as church registers, court records, and tax rolls. The era's most prominent *Annales School* historian, Ferdinand Braudel, initiated a new kind of history in which clashes among rulers, struggles for economic advantage, and strife on the battlefield faded before more fundamental forces of longer duration: the physical environment, prevailing economic and social structures, and entrenched cultural practices and beliefs. "The history of events," Braudel wrote in the preface to *The Mediterranean and the Mediterranean World in the Age of Philip II*, which gained international attention when published in revised form in 1966, was the history of "surface disturbances, crests

of foam that the tides of history carry on their strong backs.”

In England, quantitative research on family structure shattered the long-cherished presumption that people lived in extended multigenerational families rather than nuclear families until the upheavals of the Industrial Revolution. Work by Peter Laslett and his associates on reconstructing family structure from local records showed that the nuclear family predominated in England long before the onset of industrialization. His findings indicated that for several centuries before industrialization married couples were expected to establish independent households, separate from elderly relatives. Studies conducted by John Hajnal at about the same time found different family patterns in eastern Europe, with a younger average age of marriage than in the West and a high incidence of complex extended and multifamily households. Later scholarship has modified but not overturned Laslett's conclusions, showing that his data failed to identify the common presence within households of lodgers, boarders, and servants, some of whom may have been family members.

In the United States, social historians led by Stephan Thernstrom examined the validity of the Horatio Alger myth of social mobility in 19th century America. Thernstrom's 1964 work, *Poverty and Progress*, a case study of the town of Newburyport, Massachusetts, between 1850 and 1880, examined the extent to which upward social mobility—defined not only through occupational advance but also the acquisition of savings accounts, land, and homes—was a reality for ordinary workers. Thernstrom drew on the data reported in the enumerator's schedules for four decennial federal censuses, city directories, and tax records to trace changes in the lives of laborers, finding that over a span of 30 years only a small minority of his sample succeeded in moving into nonmanual occupations and less than 25% amassed at least \$1000 in property. Stories of rags to riches in the United States, his work and subsequent research suggest, were more myth than reality.

Lee Benson, with his 1961 book on politics and voting patterns in New York state during the era of Andrew Jackson in the United States, expanded the use of interdisciplinary methods into political history, a field once dedicated to the study of statesmen, laws, and institutions. His findings challenged the popular belief that President Jackson led an egalitarian Democratic party, drawing its support largely from the working class, in contrast to the rival Whig party with its base among more affluent voters. Through studying popular voting in relatively homogeneous communities, he found that rich communities did not vote differently from poor communities and that voting alignments often remained stable over relatively long periods of time. Differences in popular voting among communities, he found, were based not on

economic class but on ethnic origin and religious affiliation. Benson explained his results by drawing on interest group theory, suggesting that different ethnocultural groups in early-19th century America regarded one another as negative reference groups and responded accordingly in their political allegiances. Benson's work had a profound influence on other political historians, including Ronald Formisano, Robert Kelley, Richard Jensen, and Paul Kleppner, who developed a broad ethnocultural interpretation of 19th century American political history. The ethnocultural thesis focuses on the quantitative study of popular voting, arguing that at least until the 1890s voters divided their political allegiance according to their commitment to “pietistic” religious and cultural values that sought to use government for moral reform or to “ritualistic” values that rejected coerced morality and stressed commitment to church rituals and beliefs.

Beyond popular voting, the new political historians also transformed our understanding of legislative politics through the quantitative analysis of roll-call votes. W. O. Aydolette in a 1963 article used Guttman scaling techniques to examine patterns in voting by members of the British Parliament in the 1840s on such weighty matters as repeal of the Corn Laws, the Chartist petition for voting rights, adoption of income taxes, and the imposition of duties on imported livestock. He found that two scales largely explained the voting patterns of many hundreds of Parliamentarians on numerous, seemingly diverse issues. His findings refuted prevailing class-based interpretations of political conflict and showed instead the importance of ideological and party divisions in the 1840s. By the 1970s, Aydelotte's pioneering work had led to similar studies of legislative voting in the United States, Denmark, France, and Mexico. Especially influential was Joel Silbey's 1967 work on congressional voting in the United States in the 1840s and early 1850s. He found that even as the controversy over slavery escalated, it was largely party loyalty not sectional origin that shaped and organized congressional behavior. Voting in Congress, moreover, closely correlated with the positions taken by parties in newspaper editorials, campaign speeches, and partisan texts.

Development of the Field

During the past 25 years, historians have deployed increasingly sophisticated techniques designed to deal with special challenges of historical study. Political and social historians have sought means for circumventing the ecological fallacy—the false presumption that relationships that prevail among aggregate units such as nations, states, provinces, counties, wards, and precincts correctly describe relationships among the groups contained within the units. For example, a correlation

between wealthy counties in 1920s America and counties that voted predominantly Republican does not prove that affluent individuals necessarily tended to vote Republican. Likewise, higher suicide rates in heavily Protestant compared to heavily Catholic countries in 19th century Europe do not necessarily mean that Protestants were more likely than Catholics to commit suicide. To overcome this vexing problem, historians, who often lack data on individuals, turned to the technique of ecological regression, initially developed by sociologist Leo Goodman in the 1950s. This technique uses least-squares regression derived from aggregate-level data to model the underlying behavior of groups contained within the aggregate. In the 1970s, Allan J. Lichtman and J. Morgan Kousser were among the first historians to use ecological regression methods. Lichtman's study of the American presidential election of 1928 documented a powerful pro- and anti-Catholic response to Catholic Democratic candidate Al Smith and showed that, contrary to prior assumptions, voting in 1928 did not foreshadow the later New Deal coalition. Kousser's work documented the processes by which white redemptionists in the American South disenfranchised African Americans. Lichtman and Kousser's historical research also had practical implications because they were called on to testify as expert witnesses on voting behavior, political fairness, and minority political opportunities in scores of redistricting and voting-rights cases litigated in federal and state courts.

Lichtman, Kousser, and others also used multiple regression analyses to disentangle the impact on voting of such variables as race, religion, class, ethnicity, and urban-rural residence. Historians have since routinely used such analyses to study the variables that influence such phenomena as the birth weights of babies in early 20th century Europe, school attendance rates in 19th century Canada, the productivity of 17th century English agriculture, and rates of migration in modern developing nations. Historians have also turned to techniques such as probit, logit, and log-linear analysis to study data that fail to meet the statistical requirements of standard regression methods. They have, for example, used log-linear models to reexamine earlier work on social and economic mobility in the United States and Europe and to estimate change and stability in rates of intermarriage among racial and ethnic groups in Latin America.

Beyond the analysis of cross-sectional historical data such as voting in a particular election, historians have drawn on the special methodology of time series analysis to analyze chronologically organized data, where the value of a variable at a given time is dependent on values at earlier times—for example, spending by governments, deaths from certain kinds of disease, and rates of incarceration. These methods enable historians to discover trends, periodicity, and breakpoints within data

independent of seasonal and other fluctuations. Historians have used methods of time series analysis to estimate the periodicity of smallpox epidemics in Europe, the frequency of industrial disputes in Great Britain and the United States, and age and gender patterns in the trans-Atlantic slave trade.

Through time series analyses, researchers have also explored interpretations of events called turning points in history. Researchers using interrupted time series analysis, for example, found that Franklin Roosevelt's New Deal of the 1930s failed to alter political and economic trends begun during the previous decade and that the Industrial Revolution produced less discontinuity in European economic life than previously suspected. In contrast, economic historian Claudia Goldin used both time series analysis and cross-sectional statistical analysis of data from American states to demonstrate that use of the birth control pill had a major impact on the educational, career, and marriage decisions of young women in the United States. New procedures for analyzing time series data, in addition, allow historians to explore how changes over time in historical circumstance affected relationships between variables—for instance, differences in the effects of social movements on policy-making during various stages in the life cycle of a regime.

Historians have used event-history methods to analyze data on people's life cycles, such as birth, death, marriage, and divorce, that are not amenable to standard methods because they involve few events over extended time periods and include individuals who cannot be traced for their full life course because they have moved, they have been inexplicably dropped from the records, or record-keeping ceases prior to their death. Event-history methods code data not according to the occurrence or nonoccurrence of events but to survival time prior to the event, and the methods measure not the number of individuals experiencing an event (e.g., marriage or the birth of a child) but the number of person-years prior to the occurrence of the event. Maximum likelihood methods can be applied to life tables to disentangle the effects of explanatory variables on such duration-dependent events. The analysis may include time-fixed variables such as age differences between married couples or time-changing variables such as the birth or death of a child. In a 1990 study of early modern Japan, Laurel L. Cornell used event-history methods to establish that divorce rates for peasant women were higher than once believed and that age differences at marriage, the lack of children, and the presence of a woman's mother-in-law all increased the likelihood of a marriage ending in divorce. Political historians of 19th century Britain have used event-history analysis to trace the voting history of individuals from poll books that recorded people's names and votes, demonstrating, for example, that the predictability of future from past voting (an indicator of party loyalty) increased

significantly after the Reform Act of 1832. The methods of event-history analysis can also be applied to events that occur at the level of groups, organizations, or even nations, such as strikes, racial rioting, policy decisions, and technological innovation.

Historians, working individually and in team projects, have recreated life histories through the computerized linking of records such as census reports, parish records, tax rolls, and land registers. Such work, once laboriously done by hand, can now be conducted through algorithms and programs that probabilistically identify and connect the same individual cited in multiple records. These procedures are designed to overcome such problems as transcription errors, multiple spellings of names, name changes, commonly used names, compound names, abbreviations, and obscure handwritten entries. The prodigious labor required by even computer-assisted record linkage has promoted collaborative work. For decades, the Philadelphia Social History Project has worked on integrating databases to reconstruct ordinary life in Philadelphia for much of the 19th century. The Connecticut Valley Historical Demography Project has studied life cycles in Massachusetts towns from 1850 to 1910 by linking census reports on individuals with municipal death records. Teams of researchers have long been working on linking the rich sources of historical information on individuals available in the records of Scandinavian nations.

Through exploratory data analysis historians discover unsuspected regularities and relationships in historical data without testing hypotheses derived from predetermined theories. Exploratory methods, as demonstrated by the path-breaking work of John Tukey in 1977, are appropriate for historical data that do not satisfy the requirements of interval or ordinal scaling; are not linear in form; do not derive from independent, random sampling methods; suffer from selection bias; cannot be replicated; and contain gaps, dips, and extreme values or outliers. They also give quantitative specificity to historians' impressionistic notions about past trends and events without requiring the assumption that fixed relationships prevail among variables in different times and places. Tukey's innovative procedures rely on the graphical presentation of information to disclose the central tendency of data, reveal anomalies, and classify phenomena according to various attributes. Other methods derive from pattern-recognition techniques used, for example, in geophysics and medical diagnosis.

The use of Geographic Information Systems (GIS) for exploratory data analyses has led to the sophisticated spatial analysis of historical issues. These systems integrate, analyze, and display digitized maps and other spatial-based data on matters such as birth, marriage, and death; race; popular voting; protest demonstrations; economic activity; occupational patterns; home ownership;

and transportation networks. Studies based on GIS reveal aspects of the past concealed in nonspatial forms of analysis and help resolve one of the central dilemmas of quantitative historical inquiry—changes in the geographic base for which statistics are collected. Major collaborative GIS projects include the Great Britain Historical GIS Project, China in Time, the United States County Boundary Files, and the worldwide Electronic Cultural Atlas Initiative. Historians have used GIS to study topics such as local migration patterns, geographic distributions of books and other sources of information, transportation networks, language use, political allegiance, local economic development, and demographic histories.

Historians have modeled past behavior using insights from game theory, which analyzes strategic responses to situations in which the outcome of any individual's decisions are affected by the actions of others with different and conflicting goals. Given this situation of strategic interdependence, decision makers cannot predict the consequences of their actions without considering the actions of others. Games can be cooperative or noncooperative, zero-sum (e.g., winner take all) or amenable to differential payoffs for all players involved. They may involve limited or unlimited numbers of actors and varying degrees of uncertainty. The rules of the game specify the resources and strategic options available to players. Critical to game theory are its notions of strategy (each player's plan of action for maximizing payoffs) and of equilibrium (an outcome in which no player can unilaterally improve his payoff provided that other players stick to their chosen strategies as well). Peter Z. Grossman, for example, applied game theory to studying acts of political terror by the state, using the classic one-shot, *n*-person prisoner's dilemma game to analyze decisions made by detainees during Josef Stalin's bloody political purges in the 1930s. Under this scenario, the optimal individual strategy for prisoners is to cooperate with interrogators in implicating other suspects in order to avoid the worst possible outcome—death for noncooperating prisoners implicated by any one of an indefinite number of other known and unknown detainees. However, Grossman demonstrated that prisoners could alter this strategic equilibrium by changing the terms of the game through efforts to implicate their interrogators. Now, a prisoner is no longer playing only against other prisoners but also against the state and its agents, who have no consistent optimal response. He concluded that this rule-changing strategy raised the costs of the purge to authorities and ultimately limited its scope and impact.

Historians have applied game theory to other situations, including the allocation of resources by political campaigners and decisions made by legislators, kings, and religious leaders. A 1998 compendium of game-theoretical studies of history, *Analytic Narratives*, applies

game theory to major historical issues in an effort to prove the truth of noted mathematics scholar James R. Newman's claim that "Games are among the most interesting creations of the human mind, and the analysis of their structure is full of adventure and surprises." The work included in this volume explores the rise and fall of the International Coffee Organization in the 20th century, the sources of sectional balance in American politics prior to the Civil War, the development of political institutions under the French and British monarchies and in the commune of Genoa during the late medieval period, and the policies for conscripting men for war in 19th century Britain and the United States. These analyses demonstrate that game theory can illuminate issues central to understanding national and international histories.

In the 1990s, political scientists Keith Poole and Howard Rosenthal achieved a revolutionary breakthrough in studying the history of legislative roll-call voting, including the difficult question of how to compare voting patterns across time periods with changing issues, party systems, and constituencies. Using multidimensional scaling methods to analyze more than 16 million roll calls in the American Congress since 1789, they found that political conflict can be modeled according to the ideological positions of legislators on just one or two dimensions. The first and most important dimension corresponds roughly to liberal-conservative differences on government intervention in and regulation of the economy. The second dimension roughly measures positions on race and civil liberties. Poole and Rosenthal have generously made their data available on the Web, including ideological scores for each member of Congress that are comparable over time. Their results indicate that ideology is more important than constituent influences in shaping congressional voting, that realignments in congressional voting result from the replacement rather than the conversion of legislators, and that congressional voting became both more ideologically polarized in the late 20th century than in earlier years and largely one-dimensional because positions on economic and social issues fell into line for both parties (e.g., legislators who voted for generous welfare programs also voted for civil rights laws and against restrictions on abortion). Their scales can be used to study the polarization between parties and regions, the effects of elections on congressional voting patterns, and correlations between liberal-conservative ideologies and voting on particular issues. Scholars have extended Poole and Rosenthal's methodology to study the history of roll-call voting in legislative bodies outside the United States.

Although interdisciplinary historians have not achieved Lee Benson's dream of formulating new laws of human behavior, their work has challenged the universalistic assumptions of social science theories. Historians, for example, have questioned the application of rational

choice theory to contexts in which nonmarket values and institutions predominate and people act according to tradition, altruism, ideology, religious belief, or prejudice and subordinate their own interests to common group goals. Scholars of literacy have challenged linear theories of the relationship between literacy and modernization and called attention to forms of literacy other than alphabetic discernment: oral and numerical abilities, spatial awareness, visual acuity, and aesthetic sensibility. Political historians have contested the regularities of critical election theory, a construct of political science that posits that electoral systems respond to unmet public needs through periodic critical or realigning elections that alter the balance of partisan power, reshuffle coalitions of voters, and introduce policy and institutional change. Historians have also cast doubt on the thesis that modernization marked a sharp transition from societies with high fertility and unregulated birth rates to societies with low fertility and controlled reproduction. Historical demographers have found that patterns of fertility were more variable than previously assumed, that preindustrial societies effectively used traditional methods for regulating birth, and that in many cases fertility rates rose, not fell, during the early stages of industrialization. Historians have in addition discovered that there is no single path to industrialization but, rather, that economic development can follow multiple paths ranging from abrupt economic take-offs to a gradual diffusion of technologies and market systems.

Historians have deployed social science methods to address issues once amenable only to informal interpretation. Methods of social network analysis map and measure networks of individuals, groups, and organizations, discerning often hidden patterns in the dissemination of information and influence and uncovering the causes of stability or collapse. Event structure analysis provides computerized models for drawing on a historian's expertise to derive explicit, replicable models of narrative explanations. It forces the historian to distinguish between what is central and what is incidental to an explanation, and it provides a basis for more abstract formulations applicable to other concrete situations. Economic historian David Galenson achieved new insights into artistic creativity by applying cliometric methods to the analysis of prices at art auctions and reproductions of artistic works in textbooks. He found that artistic productivity follows two distinctive patterns, represented by the archetypes of Picasso who achieved a quick, conceptual breakthrough early in life and of Cezanne who refined and developed his art gradually over time through trial and error and achieved his most valued work late in his career.

Most prolifically, historians have used refined methods for the content analysis of texts, including written documents, and material creations such as paintings, coins, churches, and homes. Content analysis is a global term describing a body of formal, replicable methods

of data coding and numerical analysis that supplants or supplements the impressionistic reading of texts. Historians have used methods of content analysis to study the appearance of words and phrases in documents or the spatial display of objects in paintings. For example, social historians have studied the arrangement of subjects in family portraits to document changing representations of age, hierarchy, and gender. More complex applications include the discovery of hidden structures of meaning implied by the relationship among concepts in a text and the cognitive mapping of mental structures reflected in a text. For example, scholars have used methods of content analysis to map the concepts and relations that structured the responses of American opinion leaders to the Cold War and its aftermath. Content analysis may illuminate particular issues such as the response of business publications to New Deal reforms or the grievances expressed by Frenchmen petitioning the regime on the eve of the French Revolution. It may also be applied to broad societal trends. A study of front-page stories in major American newspapers throughout the 20th century, for example, disclosed an increasing depersonalization as generalizations and statistical findings replaced a focus on individuals, anecdotes, and inferences from examples. Historians and social scientists worldwide have used content analysis of sources such as newspaper articles and police reports to document across space and time the occurrence, duration, size, and grievances of protest events (e.g., riots, revolutions, and demonstrations) and the various societal responses (e.g., cooptation, repression, and infiltration).

Reaction and Response

The rise of quantitative, social science history in the 1960s generated debates between equally passionate opponents and champions of this new approach. American colonial historian Carl Bridenbaugh in his 1963 presidential address to the American Historical Association entitled "The Great Mutation," warned, "The finest historians will not be those who succumb to the dehumanizing methods of social sciences, whatever their uses and values, which I hasten to acknowledge. Nor will the historian worship at the shrine of that Bitch-goddess, QUANTIFICATION." Bridenbaugh and other traditionalists worried that arcane statistics about people in the mass would supplant the imaginative reconstruction of individual experience and that writing about the past would take on the hypothesis-testing form of scientific papers, sacrificing the explanatory and expressive power of the historical narrative. They feared that history would assume the barren abstractness of science and lose its capacity for conveying to a broad audience the hopes and dreams, agonies and accomplishments of individuals in times and places different from

their own. And history reduced to science, in their view, would no longer cast light on such human preoccupations as freedom and social order, democracy and authority, tradition and innovation, faith and reason, and pluralism and unity.

The most zealous of the early practitioners of quantitative social science history gave little credence to such cautionary tales. Instead, they expected their new methodologies to sweep the field, rendering obsolete the old-fashioned, impressionistic approach to historical evidence and analysis. They believed that more precise and theoretically informed history would revitalize the profession, establish a reliable base of knowledge and theory, suggest intriguing new lines of inquiry, and recover the hidden history of invisible and suppressed peoples. Emmanuel Le Roy Ladurie of the *Annales School* declared in 1967 that the "historian of the year 2000 would be a programmer or would not exist." Although work based on quantitative social science methodology became part of mainstream history during the 1970s and 1980s, it never achieved the dominance predicted by Le Roy Ladurie and other early practitioners. Reynolds's study of major American journals showed that the publication of such work peaked at approximately 30% during the 1980s and fell to about 25% during the first half of the 1990s.

This decline reflects the failure of the historical profession to incorporate expertise in social science methods into the teaching of professional historians and the indifference, if not outright hostility, of younger cohorts of historians following the "cultural turn" aimed at recreating the cultural meaning of past events from the perspective of participants and through approaches not amenable to formal methods of analysis. Recent trends in historical scholarship have also revitalized explanation through narratives rather than hypothesis and an understanding of past time through what is sometimes termed the thick description of events. Also influential are postmodern ideas, which question whether truth about the past is attainable, no matter how rigorous the methodology used. In this view, instead of having an objective record of the past, historians have only texts or discourses that are subject to interpretation and reinterpretation without any objective means for adjudicating among them. Historical work is itself a discourse that may or may not be persuasive, exciting, or compelling, but does not correspond to any concrete verifiable reality. Historians cannot transcend their subjectivity and their own time to produce an objective account of the past. Rather, historians produce a plurality of histories or discourses, shaped not just by historical texts, but by ever-shifting present-day values, conventions of language, intuitions, and prevailing theories of human behavior. There is no finality to historical study—the triumph of one historical discourse over another is always unstable, contingent, and subject to

change based on unpredictable, nonobjective criteria. Although postmodern history seems the polar opposite of quantitative social science history, both approaches reflect the common political objective of giving recognition to previously marginalized individuals such as women, poor people, and nondominant racial groups. By equalizing interpretations of texts, postmodernists sought to free subordinated people from the power exerted by mainstream culture and recover for posterity their values and ways of life.

Paradoxically, postmodernist critiques cooled the fires of conflict between traditional practitioners and interdisciplinary historians. Postmodernism questions not just the application of social science methods to history, but also any logically governed, evidentially based study of the past. Traditionalists and social scientific historians both agree that despite wide latitude for interpretation, historical work remains constrained by logical and empirical methods that have stood the test of critical review by generations of scholars. Both camps have also come to recognize that the application of quantitative methodology and theoretical models supplements, not supplants, traditional forms of historical study.

If work in quantitative, social scientific history has not come to stand like a Colossus over the field, it has nonetheless made and continues to make indispensable contributions to studying the human condition in past times. Historians cannot today address such diverse issues as economic development, labor relations, family life, migration, social mobility, crime and policing, health and mortality, state-building, legislative and electoral politics, literacy, protest movements, and warfare without taking into account the questions, findings, and inferences of work in quantitative social science history. Social science historians, in turn, have come to acknowledge the limitations of their methodology as applied to a field in which humans are both the subject and object of study, replicable experimentation is precluded, data are limited and time-bound, and important questions are not amenable to scientifically verifiable answers.

Most practitioners of quantitative social science history have resisted the impulse to reduce their discipline to another social science, remaining aware that history, like the god Janus, faces toward both social science and the humanities. Rather than abstracting universal propositions from past events they follow Thoreau's precept that "He is not a true man of science who does not bring some sympathy to his studies, and expect to learn something by behavior as well as by application." The practitioners of quantitative social science methods are participating with other historians in studying human experience as bounded by time and place, stretching our imagination to grasp conditions and challenges different from our own. Students of interdisciplinary history

appreciate the continuing importance of recreating individual experience, interpreting the meaning of past ages, and crafting narratives accessible to nontechnical readers. The best of what is still called the new history combines social scientific and traditional methods of inquiry and communicates its findings in clear and vivid prose that brings home to broad audiences an understanding of their heritage and experience, something that the finest historical scholarship has always done.

Household Behavior and Family Economics

Yoosik Youm

University of Illinois at Chicago, Chicago, Illinois, USA

Glossary

bargaining model An economic model that treats the division of household labor as the result of bargaining between spouses who have different and even conflicting interests.

comparative advantage in market sector A spouse has a comparative advantage in market sector if and only if his/her marginal product ratio of market sector (vs. housework sector) is greater than that of the other spouse.

density-of-friendship circle The proportion of the actual number of friendship ties among a spouse's friends out of the maximum possible number of friendship ties.

doing gender A process of creating and maintaining gender identity by rendering oneself accountably masculine or feminine through everyday activities.

gender theory A model under which the division of household labor is not the result of rational behaviors but instead derives from the process of creating and maintaining gender identity in everyday life.

neoclassical model This economic model assumes that the division of household labor is the result of a couple's harmonized behavior that aims to maximize shared unitary utility: people do housework voluntarily in order to maximize the aggregate consumption of the household.

network approach A sociological approach that pays special attention to how a couple's personal network ties affect the division of household labor. The division of household labor is the result not only of spouses' individual attributes, but also derives from the patterns of their social ties.

power-dependency theory This sociological theory assumes that the division of household labor is the result of a couple's power relationship, which is determined by resource discrepancy.

threat point Minimum welfare level if no agreement can be reached in bargaining. The spouse with the higher threat point has a bargaining advantage when a couple makes decisions about the division of household labor. A threat point is typically measured by options (or resources) outside the relationship.

Recent theoretical debates in the social sciences have dealt with how to obtain the proper measures of household behaviors, especially the division of household labor. In the field of economics, the neoclassical and the bargaining paradigms, in particular, have emerged. Until the early 1990s, most economists treated a household as one economic unit based on common preference assumptions. Although this approach gained popularity, especially because of convenient data acquisition at the household level (instead of the individual level), bargaining models have now been developed that treat the family as a collection of individuals with different utilities. In the field of sociology, instead of focusing only on individual attributes of family members, gender theory and the network approach emphasize that household behaviors are the products of interactions between individual family members. Based on these theoretical developments, the focus here is on examining various measurement issues, such as proper levels (for individuals and couples), data collection methods (survey, observation, and emotion sampling methods), and measurement indices (comparative advantage, options outside, and network properties).

Introduction

The following discussions examine diverse theoretical debates and measurement issues concerning one of the most well-studied examples of household behavior, the division of household labor. Diverse approaches have been developed to explain a persistent empirical puzzle: whether employed or not, women do most of the housework. Numerous studies have found that employed married women in the United States do about twice as much

housework as employed married men do. The division of household labor has attracted theoretical interest because it provides an excellent empirical test of theories on intrahousehold resource/power distribution. Discussion of measurement issues herein is in line with theoretical developments in social sciences: special attention is paid to providing a brief summary of measurement concerns that are most relevant to evaluating and developing theoretical issues, without trying to provide an extensive list of measurement issues. In the following two sections, theoretical debates in social sciences are briefly introduced.

Economic Approaches: Neoclassical vs. Bargaining

In economics, two competing paradigms have been established to explain how the division of household labor is determined. Neoclassical economic theory, especially as exemplified by Gary Becker's work, argues that the partner with comparative advantage in the market (for example, the higher wage rate) will specialize in paid work and the other partner will specialize in housework, in order to maximize shared unitary utility. In sharp contrast to the assumption of unitary utility of the family members, a group of economic models has adopted the bargaining approach; developed by John F. Nash, this model states that the division of household labor is the result of bargaining between spouses who have separate and even conflicting interests. According to bargaining models, the person who has a bargaining advantage (normally the one who has more resources outside the marriage/cohabitation) will specialize less in housework.

Until the early 1990s, most economists treated the household as one economic unit in which family members behave as if they share one common utility, or at least as if they agree on every economic activity. This "common preference" (or unitary utility of the couple) is guaranteed by consensus or altruism. Different terms are used to describe this approach: neoclassical model, common preference model, unitary model, or consensus model. The approach has gained popularity based on typical economic consumption data that are usually reported at the household level. It has also allowed economists to analyze household data with relative ease by putting aside the theoretical task of showing how individual preferences are aggregated at the collective household level (the so-called preference aggregation problem). Becker provided the seminal theoretical basis for this approach: as a possible mechanism to ensure the unitary utility of the household, he paid attention to "care." In his well-known "rotten-kid" theorem, he proved that even if only one of the members is taking care of meeting the

needs of the others, so that his/her preference depends on the others' utility function, every family member (including a rotten kid) would try to maximize the joint family utility. Now, under the assumption that couples try to maximize their shared consumption in the household, Becker proved that no more than one family member would specialize in both market work and household work if all family members have different comparative advantages. Please note that the theorem is valid no matter what family members' income levels are. Even if both spouses have high income from paid work, there will be still positive gains from specialization as long as it is based on comparative advantage and their goal is to maximize their unitary utility. In conclusion, under the neoclassical approach, the person with a comparative advantage in the market will allocate time mainly to the market sector and the other will spend time mainly on housework, thus maximizing their shared utility (or aggregate consumption).

Although Becker avoids the preference aggregation problem by assuming "caring" (or altruism), the issue over who has the last word (or ultimate power) in the household is not solved. A caring person (or a parent) must have the ultimate power in the household in order that the rotten kid theorem is valid. It disregards the fact that the family is also often the place for conflict and struggle. In economics, many different approaches have been developed to treat the family as a collection of individuals with different utilities and to show how the aggregated outcome emerges from different and even conflicting utilities. As one major approach, bargaining models assuming a cooperative game between two persons have been proposed for the intrahousehold division of labor and thus the division of household labor is the result of bargaining between two persons with separate utility. As the solution of the basic Nash bargaining model expects, a higher threat point (i.e., the minimum welfare level if no agreement can be reached between the players, divorce or break up being the payoff in this case) always decreases housework and increases paid work. There have been several efforts to elaborate the Nash bargaining model—for example, by replacing an external threat point with an internal one. Such efforts attempt to explain intrahousehold decisions without relying on the assumption of a single household utility function. In sum, according to bargaining models, a person with a higher threat point will specialize in paid work and the other person with a lower threat point will specialize in housework.

Many empirical results have challenged the unitary utility argument, especially by showing that family members do not appear to pool their income. But most empirical results can be interpreted in accord with both camps, and thus cannot be judged as conclusive rejections of the neoclassical approach. However, many now believe that the burden of proof should be shifted onto those who argue for the unitary utility of the family.

Sociological Approaches: Macro vs. Micro

In the search for mechanisms that are responsible for the persistent sexual division of household labor, diverse sociological attempts have been proposed and examined at different levels of analysis. Macro studies successfully turn attention to social systems such as capitalism or patriarchy as a cause for society-level oppression of women that is manifested in the sexual division of labor. In the opposite direction of this Socialist/Marxist feminism, micro research highlights individual-level attributes of spouses, such as resource level (or resource gap between spouses). Power-dependency models in sociology (or exchange theory, or a resource-dependency theory) that correspond to bargaining models in economics have focused on the power of each spouse as determined by their relative resource level, such as income, occupation prestige, or education: more power produces less housework hours. Also, some studies focus on gender-role attitudes of individual spouses.

Although many studies have focused on either macro (society) systems or micro (individual) attributes, some attention has been paid to interactions within families or between a family member and his/her social intimates, such as friends, kin, and neighbors. Gender theory is one of the few approaches that put interactions in the center of the research. In contrast to the old concept of gender role, which is supposed to be learned through socialization and to remain internal to the individual mind as fixed form, gender has been conceived as constituted by a set of behavioral displays or sex-specific ways of appearing, acting, and feeling, all of which serve to establish or reaffirm categorical identity. This notion of gender display has been further elaborated and advanced by developing the concept of “doing gender,” which is displaying gender by making use of discrete, well-defined bundles of behavior. This behavior is necessarily insufficient to generate and maintain gender identity in society, because the “bundles” cannot simply be endlessly plugged into the continuum of interactional situations to produce recognizable enactments of masculinity and femininity. To be successful, marking or displaying gender must be finely fitted to ever-changing situations and constantly modified or transformed as the interactional occasion demands. Doing gender includes the ongoing task of rendering oneself accountably masculine or feminine in everyday life, and thus, although it is individuals who do gender, the enterprise is fundamentally interactional and institutional in character, for accountability is a feature of social relationships and its idiom is drawn from the institutional arena in which those relationships are enacted.

The network approach is another sociological approach that focuses on the interactions of family

members as an essential mechanism for determining the division of household labor. Whereas gender theory focuses on symbolic interactions based on normative constructs and institutional settings, the network approach examines structural interactions based on quantitative measurements of the social networks that create and maintain gender differences. Elizabeth Bott's ethnographic study based on 20 couples in London is considered to be one of the first major network studies to reveal that the degree of segregation in the role-relationship of husband and wife varied directly with the connectedness of the family's social network. Bott found two ideal typical families based on several network properties of couples. Three major network characteristics of the *first type* of family are the focus of discussion here. In this family, the couple took it for granted that the husband would have some recreation with men away from home and the wife had separate relationships in which her husband did not expect to join; there was little shared free time. Second, the husband had male friends as the main members of his network, whereas the wife had relatives or neighbors; the husband and wife had very few mutual friends. Third, although the total network of both spouses was sharply divided into the husband's network and the wife's network, within each network, there was a high degree of connectedness between members, independent of the couple: this represents a very dense friendship circle. This type of family is strongly associated with a highly segregated conjugal role-relationship: the husband and the wife believe that there should be a clear-cut division of labor between them and they actually carry out their internal domestic tasks in a very separate way. This fits the picture of traditional families: husbands spend time with their buddies while wives do housework, chatting with their relatives or neighbors.

The *second type* of family has an opposite network structure. First, joint entertainment of friends is a major form of recreation for both the husband and the wife; much free time is shared. Second, nearly all of the husband's friends and the wife's friends are joint friends with the husband and wife. Third, it is not usual for a large number of the family's friends to be in intimate contact with one another independently of their contact with the family: this represents a sparse friendship circle. In this type of family, although there is a basic differentiation between husband's role as primary breadwinner and the wife's as mother of young children, the division of labor is flexible and there is considerable sharing and interchange of tasks.

The associations were explained by differential pressures from the couples' different patterns of networks. In the first type of family, each spouse is strongly embedded in his/her own external networks and thus each spouse is very sensitive to his/her respective social ties (rather than to each other). Because each spouse's external ties are

strongly separated, spouses will have a very separate role. In sharp contrast to this, in the second type of family, the strongest influence on each spouse is self-derived, rather than being derived from social intimates. These partners are much more flexible in their roles and meet their own specific needs without strong monitoring or pressures from their kin and friends. The network approach has extended its theoretical horizon by either being incorporated into the wider theme of autonomy or being integrated into a non-cooperative game-theoretic model through a cohesion (rather than autonomy) mechanism between spouses.

In the following sections, measurement issues are discussed in two parts: first, how the division of household labor can be measured as dependent variables, and second, how main causal factors assumed by various theoretical standpoints can be measured.

Measuring Issues 1: Division of Household Labor

Measuring Units

One of the most widely studied data sets on the division of household labor, the National Survey of Families and Households (NSFH), has revealed that there are systematic interspouse reporting discrepancies on the reported amount of housework time. The NSFH asked each spouse to estimate their housework hours and their spouse's hours ("How many hours do you and your spouse spend on the following tasks?"). In general, both husbands and wives tended to report more hours for self than they reported for their spouses, and the discrepancies were greater for the husband's self-reported hours. Given this kind of discrepancy, it is desirable to measure housework hours at a couple level instead of an individual level: couple-matched data asks for combined housework hour estimates. This is important especially because many studies reveal that the discrepancy is systematically affected by normative attitudes, relational quality, and demographic characteristics. As long as traditional surveys are used to measure housework hours, however, even couple-matched data can suffer from validity issues—i.e., reported hours can be different from actual hours. This leads the discussion to the next issue, measuring instruments.

Measuring Instruments

Many studies have found that direct questions tend to lead to overestimation of housework hours. Given that observing housework would be prohibitive for large-scale representative data, one of the attractive alternatives might be a time-diary method. In time-use studies employing this method, respondents are asked to complete a diary of

hours spent on various activities. Especially when people are involved in multiple housework tasks simultaneously (e.g., doing laundry while taking care of a baby), it is hard for them to later recall precisely the hours they spent on each activity; time-diary entries are more reliable compared to retrospective self-reports. The time-diary can be also effective in studying the emotions or feelings people go through during performance of specific housework tasks. Experimental sampling methodology (ESM) developed in psychology studies attempts to collect random sampling of behavior, thoughts, feelings, and experiences in real-life situations. Respondents are provided with a questionnaire booklet in which they record their behavior, thoughts, or feelings when they are beeped by a randomly activated pager. This instrument is especially useful when the interest is in normative constructs around specific housework; for example, some housework tasks are considered "male-work" and thus husbands can maintain and even strengthen their masculinity by doing those specific types of housework. The time-diary method and ESM will be accurate to the extent that diary time and day are representative of the general pattern of everyday activities.

Measuring Issues 2: Factors Responsible for the Division of Household Labor

Measuring Units

Most economic analyses and many sociological approaches to study the division of household labor use individual-level attributes such as income, wage rate, education, occupational prestige, and gender-role attitudes to measure comparative advantage, threat point, resources that define power, or normative attitudes as units of measurement. In contrast, some sociological approaches, including gender theory and the network approach, have paid attention to the interaction properties of couples, based on the premise that measurement units cannot be reduced to each individual spouse's attributes. Given that each approach (focusing on the individual vs. the couple) has gained empirical support from various studies, to obtain solid conclusions in empirical research, the ideal would be to include both units of measurement.

Measuring Objects

Depending on the theoretical approach of a research project, what to measure will be different. Three primary quantitative measurements for the selected approaches relate to comparative advantage, threat point, and network.

Comparative Advantage

To provide an exact operational meaning of comparative advantage as it is used in neoclassical economic theory, it is necessary to examine the equation of the aggregate assumption of household assumed in Becker's original formula. An aggregate consumption Z of the household of a husband and wife is as follows:

$$Z = Z(x, t_h^i) = Z[\alpha(wt_p^m/p_x) + wt_p^w/p_x, \beta(t_h^m) + t_h^w].$$

This formula of aggregate consumption is composed of market goods (x) and household goods (t_h^i , represented by the effective amount of housework hours), and both the man and the woman produce both types of products. The amount of goods consumed is the sum of goods earned due to the man (αw is the wage rate, t_p^m is the amount of time spent on paid work by the man, and p_x is the price for goods) and due to the woman (wt_p^w/p_x). Household goods also derive from the man's housework hours (βt_h^m) and from the woman's housework hours (t_h^w). The husband has a comparative advantage in the market sector relative to the woman if and only if

$$\frac{\partial Z / \partial t_p^w}{\partial Z / \partial t_h^w} < \frac{\partial Z / \partial t_p^m}{\partial Z / \partial t_h^m},$$

which means that $\alpha > \beta$ in the previous equation. The husband has a comparative advantage in the market sector if and only if the marginal product ratio in the market sector (vs. the housework sector) for the husband is greater than the marginal product ratio in the market sector (vs. the housework sector) for the wife. However, to measure the marginal product ratio for each spouse is not straightforward because a valid, reliable price for housework is not available. Under the assumption that marginal product in the housework is the same for each spouse, wage rate can be used as a proxy for the comparative advantage. However, even obtaining wage rate is complicated because there are people who do not currently work (or even never work). For those people, it is possible to use an estimated wage rate based on factors such as years of schooling, estimated years of job experience, gender, and race.

Threat Point

The concept of the threat point came directly from classical Nash bargaining model. The Nash bargaining outcome is the solution to the maximization problem: $\text{Max}(u_1 - d_1)(u_2 - d_2)$, under the condition that $u_1 + u_2 = u$, where u_1 and u_2 are the payoffs to the two individuals, respectively, and d_1 and d_2 are threat points, or the minimum welfare level if no agreement can be reached between the players. The solution can be derived as $u_1 = 1/2(d_1 - d_2) + 1/2u$ and $u_2 = 1/2(d_2 - d_1) + 1/2u$. It can be easily confirmed from this solution that higher threat points always increase payoffs (or paid work instead of

housework, in this case) once the other partner's threat point is given. The threat point for the bargaining of the division of household labor can be options outside the relationship (e.g., expected welfare in the case of divorce or break up). It can also be conceptualized as including options inside the relationship (such as lower housework production due to shirking).

To measure the threat point (or options outside the relationship), it is possible to use either subjectively perceived options or objective indices for options outside marriage, such as education level or income level. For example, some studies used the respondents' subjective assessment of whether their lives would worsen or improve were they not married. For example, the following question in the NSFH was used to measure the relative power in the relationship: "Even though it may be very unlikely, think for a moment about how various areas of your life might be different if you separated." Unfortunately, there is not enough empirical data to confirm that this kind of direct question correctly measures the options outside the relationship.

Alternatively, it is possible to use income or education level as a proxy for options outside the relationship. However, this also suffers from one problem: the resource level of an individual spouse (nor even the resource gap between spouses) does not accurately measure options outside marriage. Threat in bargaining comes not directly from the bargainers' resource gap but from the availability of alternative options in the case of dissolution. Even if a woman has significantly less education (or wage potential) than her husband has, if she can find a better husband with a higher wage (compared to the current husband) who will spend more time on household chores, she can demand more housework from the current husband. Simple measures of resource level (either in absolute or relative terms) have limitations in gauging potential welfare in the case of dissolution. Potential welfare depends on critical parameters of the marriage market, such as age, physical attractiveness, earning capacity, and occupational prestige; these will work for each gender in different ways.

Before moving on to a discussion of network measures, it is important to clarify a difference between neoclassical economics and bargaining theory with respect to their treatment of the wage rate. In bargaining models, an increase in wage rate always decreases housework hours, but such an increase would not matter in neoclassical economics as long as it does not change the status of comparative advantage.

Network Measures

Although network approaches do not yet have unified theoretical propositions and thus there is not full agreement on what kind of effect each network property has on the division of household labor, it is possible to identify

three major network dimensions that are crucial to the mechanisms responsible for the division of household labor: sharing free time, mutual friends, and density-of-friendship circle. First, the extent to which spouses share free time is easily measured either by direct questioning in a traditional survey format or by experimental sampling methodology. Second, mutual friends can be measured either in absolute sense (total number of mutual friends) or in relative sense (the proportion of mutual friends). The proportion of mutual friends of the couple can be calculated as follows:

$$N_m / (N_h + N_w - N_m),$$

where N_m is the number of mutual friends and N_h and N_w are the number of friends of husband and wife, respectively. The denominator represents number of pooled friends of couples. This measure varies from 0, when spouses have no mutual friends, to 1, when all the friends are mutual friends.

The third measure of importance is the density-of-friendship circle for each spouse. This can be calculated as follows: $n/[N(N-1)]$, where N is the total number of friends (not counting the spouse) and n is the number of friendship ties between friends. The denominator is the possible maximum number of friendship ties between N persons and the numerator is the actual number of friendship ties. This measure varies from 0 (if among the spouse's friends, nobody is a friend to anybody) to 1 (when everybody is a friend to everybody).

Human and Population Genetics

Gerty J. L. M. Lensvelt-Mulders

Utrecht University, Utrecht, The Netherlands

Glossary

behavior genetics The study of the inheritance of behavioral characteristics.

chromosome A structure that carries the genes and is found in pairs in the cell nucleus of humans.

deoxyribonucleic acid (DNA) A nucleic acid polymer that is the basic hereditary material, located within the chromosomes.

genotype All characteristics that an individual has inherited, whether or not they are manifested.

individual differences The relatively persistent differences in behavior between members of the same population.

nature–nurture debate The never-ending debate about the relative importance of inheritance and the results of upbringing on the mature phenotype.

path analysis A statistical procedure used to divide covariation between variables into separated components or path.

phenotype All displayed characteristics of an individual.

quantitative trait locus linkage (QTL) The search for the loci of specific genes, where each locus is the location of a gene on the DNA string.

This article focuses entirely on human genetics. It contains a short overview of the two most important branches of human genetic studies, molecular and population genetics. A bibliography and relevant Web sites are included for the interested reader who wants to study this topic more thoroughly. The content of the current nature–nurture debate in science and society is discussed and the basics of the analysis of mapping the human genome are explained. This article also includes a brief introduction to population genetics. The future directions of human genetics and the scientific challenges that geneticists will face are discussed. This article concludes

with a discussion on the ethical issues that surround research into human genetics.

Genetics in Society and Science

The Nature–Nurture Controversy

One of the oldest debates in the social sciences is whether humans are social or biological creatures. This debate can be visualized as a giant seesaw in time. At one end, there are the biological explanations of human behavior, such as evolutionary theories, the influence of genetic factors, and theories that stem from brain research. On the other end, there are the social explanations of behavior, such as cultural differences, upbringing, and learning processes. In the past, biological and social explanations always seemed mutually exclusive, with one approach overriding the other, depending on the “zeitgeist.” For instance, from the 1950s to the 1970s, the seesaw totally skipped to social theories of human behavior. Most social scientists will remember the strong statements in favor of social explanations made by the early behaviorists from their introductory courses. In the 1990s, the seesaw reversed and the scientific and social climate became more in favor of biological explanations of human behavior. These days, the nature–nurture debate flares again, due to increased insights into the heredity of behavior. Researchers, policy-makers, and the lay public are starting to worry about the implications that the outcomes of genetic studies will have for society. What will be the social consequences of the genetic diagnosis of traits such as intelligence, criminality, or sexual orientation? These are important questions because genetic research is becoming a major field within different sciences. The debate is now about how this new knowledge can be celebrated and how it can be prevented from being misused.

Strange as it seems, behavior genetics has the qualities necessary to bridge the gap between exclusively biological and exclusively social explanations of human behavior, because behavior genetics are rooted in biology. Biologists have always acknowledged the fact that even the most inherited behavior can exist only in the context of the environment. The results of new research in behavior genetics have convincingly showed that biological mechanisms can no longer be ignored. However, contrary to what many seem to think, behavior geneticists are not exclusively interested in genetic effects on individual differences; they are just as interested in the influence of social effects.

The Genetic Study of Individual Differences

The influence of genes on everyday behavior can be studied at two levels. At the microlevel, geneticists are trying to identify pieces of DNA associated with particular behavior; for instance, the mapping of chromosome 20 has elucidated a great deal about leukemia, diabetes, and childhood eczema. At the population level, behavior geneticists seek to understand both the genetic and environmental contributions to individual variations in behavior. The way that genes cause complex behavior is still quite unknown, but it is known that complex traits almost always involve multiple genes, which makes the mapping of such traits a very difficult exercise. Luckily for behavior geneticists, it is not necessary to unravel all the secrets of the genome before judgment can be passed on the causation of behavior. It is possible to attribute behavior to broad causes such as genetic or environmental effects, without understanding all the details of this causation. As Loehlin stated in 1992: "One can be perfectly able to drive a car without understanding the way the engine works."

Human Genetics

Terms and Definitions

The assumptions of behavior genetics are based on the rules of Mendelian inheritance and the knowledge of DNA as the bearer of genetic information. The nucleus of a human cell nucleus contains 46 chromosomes; 23 are inherited from the father's sperm and 23 from the mother's ovum. Every chromosome consists of two strings of DNA. Genes are small segments on these DNA strings that carry exactly one piece of information. The location of a gene on the DNA molecule is called a locus and the complementary sites on both strings are called alleles. Heterozygotes have different alleles on each string. Genes are thus the unit factors of heredity that are at

the basis of behavior. However, genes do not underlie behavior in a direct sense. Genes are considered templates for the synthesis of amino acids—the building blocks of proteins, which exert their influence on behavioral structures and processes via the nervous system and the production of behaviorally relevant hormones and neurotransmitters. The whole inherited set of genes on all chromosomes is called the genotype, as opposed to the phenotype, which is defined as the whole of observable characteristics and traits of a person.

Most complex traits, especially those traits that are of interest for behavioral scientists, are controlled by the combined action of multiple genes. This multiple regulation increases the possibility of individual differences and makes the variety in human genotypes incredibly large. Research in behavior genetics suggests that variation in diverse characteristics such as intelligence, personality traits, obesity, criminal behavior, and health depends to a considerable extent on genetic factors.

Mapping the Human Genome

The study of the location of individual genes on the genome is part of the domain of molecular genetics. This article does not provide a detailed tutorial on the laboratory techniques of molecular genetics, but does give a brief explanation of how genes are traced. Genes are traced with the aid of DNA markers. DNA markers make it possible to localize genes that are related to behavioral traits without the necessity of understanding the gene product. DNA markers are polymorphic sequences of amino acids with a known location. There are two main strategies for identifying and locating genes, linkage and association, where linkage is concerned with the localization of genes and association is concerned with identifying genes. Classical linkage techniques use large pedigrees of related individuals to search for genes that are related to a certain trait. The rationale behind linkage is that carriers of a trait or disorder should share markers that are close to the disease locus and that are not shared with noncarriers. The coinheritance of the trait and DNA markers is used as a sign of linkage between the gene and the trait. A problem with linkage techniques, especially in sib-pair-based techniques for complex traits, is that they often lack the statistical power to detect true linkage, because human pedigrees are small and only some of the individuals are infected.

Association is the other method used to detect linkage. Unrelated individuals from large populations are used to map the gene associated with the trait. The idea behind association is that carriers should share the associated gene with other unrelated carriers. Power is not a problem for association studies, because it is easy to increase the sample size of unrelated individuals. The drawback of association studies is that they can be used to map only

candidate genes that are associated with the trait prior to the study.

Mixed designs that include linkage as well as association are also used, in which additional different families are studied in concordance. Mixed designs combine the strengths of both designs into a more powerful gene detection system.

Population Genetics

Explaining Variability in the Population

Behavior Genetic Research

The focus of population genetics is the explanation of differences in behavior between individuals in a certain population. Behavior geneticists try to increase the understanding of the genetic and environmental causes of these differences. To accomplish this, research methodology and statistical methods to analyze genetic informative data were developed. The research field of behavior geneticists is very broad, encompassing the disciplines of medicine, psychology, and biology.

Genetic Factors Affecting Behavior

The phenotype, the whole of the observable traits of an individual, develops under the influence of different genetic and environmental factors. Within behavioral genetic analysis, three genetic effects are distinguished: additive effects, dominance effects, and the effects of epistasis. Genetic effects are additive insofar as they add up; an additive effect is thus the sum of the average effects of individual alleles (father has fair hair, mother has dark hair, offspring's hair will be in between). Dominance is the nonadditive interaction of alleles on a single locus or intralocus interaction. This concept is well known from Mendelian studies on the color of peas. Epistasis is the interaction of an allele with alleles on other loci, called interlocus interaction.

Environmental Factors Affecting Behavior

The environment in its broadest sense covers the total of the external input to the behavioral processes. As such, it is a very broad concept, including biochemical factors such as nutrition, physical factors such as temperature, and family factors such as child-raising practices or the influence of sibling rank order on development.

The environment can affect behavior in two ways. First, it can make individuals who differ genetically become more alike in their behavior. Culture and parental upbringing practices are instances of such influences. Upbringing makes children in a family behave more similarly than could be expected on the basis of their genetic resemblance. The greater the extent to which an environment is shared, the more individuals will become alike.

In genetic studies, the environmental effects that make individuals more alike are found under the headers shared, between family or common family environmental effects.

The environment can also have the opposite effect: it can make individuals that share the same genotype more different from one another. For instance, when a member of an identical twin pair is involved in a traumatic accident, this can have a lasting effect, making this person more anxious in everyday life than her or his co-twin. The unique experience of the accident has altered the phenotypic relation between these twins; it has made them more different than could be expected on the basis of their identical genotype. This effect of the environment is called the unique, within-family, or idiosyncratic environment effect. In the remainder of this paper, the expression "common environment" is used for environmental effects that make people more alike and the expression "unique environment" is used for all the environmental effects that make them more unique.

The Behavior Genetic Design

Conducting Twin, Family, and Adoption Research

To analyze the differential impact of genotype and environment on individual differences, data are needed from genetically informative individuals. The comparative study of complex behavior within twins, siblings, and family members affords such an approach. The twin design is the most classic design in behavior genetic research and it is based on the fact that there are two kinds of twins: monozygotic or identical twins (MZ) and dizygotic or fraternal twins (DZ). MZ twins share the same genotype; they are genetically (nearly) identical. Because of this, observed differences between MZ twins are assumed to be environmental in origin. DZ twins share 50% of their genes; they are genetically related as first-degree siblings, but they share the family environment to a greater extent than siblings usually do. Differences between DZ twin pairs can be genetic as well as environmental in origin. By comparing the phenotypic similarity of MZ twins with that of DZ twins, researchers conduct a kind of natural experiment to investigate the effects of heredity and environment on behavior.

Assumptions for Conducting Family Studies

Before examining the analysis of family data, three assumptions must be discussed: the equal environment assumption, the assumption of nonassortative mating, and assumptions about correlations and covariations between genes and environment.

The equal environment assumption (EEA) assumes equality of trait-relevant environmental experiences among MZ and DZ twins. Research shows that MZ twins share their environment to a larger extent than

DZ twins, which seems to violate the EEA. MZ twins more often go to the same school and wear the same clothes and as adults they practice the same sports, share their hobbies, and meet each other on a more regular basis. But does this influence similarity? A study executed to test the EEA for the Big Five personality traits showed that although the EEA was violated this did not influence the phenotypic resemblance between MZ co-twins for trait-relevant behavior. No significant correlations were found between levels of shared environmental experiences and the intraclass correlations of MZ twins. More extensive sharing of the environment did not make the twin pairs significantly more equal on these traits.

The second assumption is that no assortative mating is allowed for the observed variables, because this will lead to a greater genotypic similarity of siblings than can be modeled. Assortative mating is the tendency of like to mate with like. There are theories that assume that people seek partners with the same attributes as well as theories that state that “opposites attract.” However, for most behavioral traits, assortative mating tends to be slight, although for a few traits, such as intelligence and social attitudes, it can be substantial. The effects of assortative mating can be included in genetic models and its effects on other parameters can be estimated.

The last assumption is that behavior genetic analysis techniques do not allow for interactions or correlations between genes and the environment. It was Plomin who introduced the concepts of gene–environment interactions and correlations. Gene–environment interactions refer to genetic differences in sensitivity to experiences. For example, neurotic and emotionally stable children may not differ much in general adjustment when they are both reared in a warm supportive environment, but may grow apart on the emotional stability scale when they are reared in a harsh and cold environment. Since twin analysis assumes a linear relation between the observed phenotypes and their underlying genetic and environmental variables, interactions should not occur.

Genotype–environment correlations are defined as the extent to which individuals are exposed to environments as a function of their genetic propensities. There are three genotype–environment correlations: passive, evocative, and active. Passive correlations occur because genes are not randomly distributed over environments. Children share genes as well as environment with their family and can thus passively “inherit” environments that match their genetic structure. Evocative correlation refers to the experiences of a child resulting from reactions of other people to its genetic propensities. For instance, people tend to act more favorably to more beautiful children, giving them more positive experiences, which is thought to enhance self-esteem later in life. Active correlations occur when children (and adults) actively select, modify, and construct their environments.

Correlations and interactions between genotype and environment are more often the case than not and therefore the assumptions about the occurrence of interactions and correlations are often violated. But this is not as disrupting as it was in the past, given that appropriate multivariate model estimation techniques allow for interaction and correlation. For instance, including parents of twins in the classical design allows the estimation of cultural transmission and genotype–environment correlation.

Methods for Analyzing Twin Data

The Classic Approach: Comparing Intraclass Correlations

Behavior genetic studies estimate which part of the total variance of a trait can be attributed to genetic effects and which part of the variance can be attributed to environmental causes. The proportion of the variance explained by genetic effects is called the “heritability coefficient.”

In the classic twin approach, the difference between the intraclass correlations of the MZ and DZ twin pairs is used to estimate the heritability coefficient. The intraclass correlation is a specific type of correlation that takes into account the fact that twin pairs are not independent of one another; ICC are based on ANOVA analysis. The difference between the intraclass correlations of MZ and DZ twins is doubled to estimate this heritability coefficient

$$h^2 = 2(r_{\text{MZ}} - r_{\text{DZ}}).$$

An h^2 of 0.5 for a certain trait, for instance, “emotional stability,” means that 50% of the total variance in this trait in a population can be explained by differences in the genetic makeup of its individuals. It is very important to have a precise understanding of the meaning of h^2 . The h^2 applies only to a population studied in its own environment; therefore, it can change as a result of changes in the population. It is also important to understand that the heritability coefficient is a descriptive statistic of a trait in a population and as such does not apply to individuals. And last but not least, for many traits h^2 is not stable over the life span; it changes with age during development. Intelligence, for instance, is more influenced by the genotype when a person becomes older than in childhood. It is important to keep an open mind toward the effects of the environment on differences in behavior. An h^2 of 0.5 also means that 50% of the variance is explained by causes other than differences in the genotype. These causes are environmental in origin. In the scientific literature, both effects on behavior should always be mentioned. It is odd that in the public debate these environmental effects are so often overlooked.

Path Analysis for Twin Research

Behavior genetics uses quantitative genetic analysis as a tool. Quantitative genetic analysis is the theoretical

basis for the statistical analysis of variation in populations. The statistical tool is more commonly known under the names “structural equation modeling” or “path analysis.” Model estimation has many advantages over the classic approach. The graphical reproduction of structural models is very helpful for making the assumptions of the twin design more explicit (see Fig. 1). Using path models makes it possible to test different models against each other and to opt for the model that best fits the data. The fit of the model can be expressed in goodness-of-fit statistics and the estimates for genetic and environmental effects are given together with their standard errors.

Many different complex and multivariate models are already commonly used, but here quantitative genetic analysis using the most basic univariate model for genetic analysis is illustrated. This model can easily be extended to multivariate and longitudinal designs as well as designs that go beyond the twin design and investigate the more complex genetic and environmental relationships between different relatives.

Figure 1 represents the simplest path model for MZ and DZ twins reared together. The genetic theory as outlined above is reflected in the model. By convention, the observed or dependent variables are drawn as rectangles and the latent, independent variables are shown as circles. Single-headed arrows are used to define causal relations or paths and double-headed arrows are used to define covariances. Also by convention, uppercase letters are used to define the latent variables and lowercase letters are used to represent the paths and double-headed arrows. An example from research on extraversion is used to illustrate the model. Extraversion is one of the Big Five personality traits. It is associated with active, impulsive, and social behavior, where people who exhibit high levels of these behaviors are called extraverts and people who

exhibit low levels of these behaviors are called introverts. The variables in the squares are the observed levels of extraversion for twin 1 and co-twin 2. The latent variables (circles) come from behavior genetic theory. E stands for the unique environment and by definition random error is incorporated in E; A stands for the additive genetic effects, D stands for the effects of dominant genes and epistasis, and C stands for the effects of the common environment. The covariation between both genetic effects is defined for MZ as well as for DZ twins; where MZ twins show a correlation of 1, they are of the same genotype and DZ twins show a correlation of 0.5 for additive genetic effects and 0.25 for dominance effects.

Since quantitative genetic analysis has a strong regression component, the model can be also defined from its underlying regression structures

$$P_1 = eE_1 + aA_1 + dD_1 + cC_1,$$

and

$$P_2 = eE_2 + aA_2 + dD_2 + cC_2,$$

where P_1 and P_2 are the phenotypes of two co-twins. As can be derived from the regression equation, the phenotype is assumed to be a linear function of the underlying genetic and environmental effects. The total variance of the observed measure is composed from the factor loadings as:

$$V_p = a^2 + d^2 + c^2 + e^2.$$

In the classical twin study that uses twins that are reared together, C and D cannot be modeled in one analysis, because then they become confounded and the model cannot be identified. Using this path diagram, different models can be tested. First, the simplest model that takes only the unique environmental and additive genetic effects into account is examined. In the second step, this model can be extended with common environmental or dominance effects, depending on the difference between the intraclass correlations of the MZ and DZ twins in the sample. When the intraclass correlation of the MZ twins is less than twice the intraclass correlation of the DZ twins, a model that allows for common environmental effects is chosen, because the DZ twins resemble each other more than could be expected on the basis of their genotype alone. When the intraclass correlation of the MZ twins is larger than twice the intraclass correlation of the DZ twins, a model that allows for dominance effects is chosen, because the DZ twins differ more than could be expected from theory. Finally, a model that excludes every genetic effect, the CE model that states that all individual differences are attributable to environmental effects, can be chosen.

Using these three models, the way that models are compared and tested is discussed here. In Table 1, the

Figure 1 Univariate path model for genetic analysis of twins reared together. Extrav1, level of extraversion for twin 1. Extrav2, level of extraversion for co-twin 2. E, unique environmental effects. A, additive genetic effects. D, effects of dominance and epistasis. C, effect of common environment.

Table I Results of a Univariate Quantitative Genetic Analysis on Extraversion

	<i>Model</i>		
	<i>AE</i>	<i>ACE</i>	<i>CE</i>
χ^2	3.086	2.405	3.524
<i>df</i>	4	3	4
<i>P</i>	0.544	0.439	0.423
V_A	0.47	0.13	
V_E	0.53	0.56	0.58
V_C		0.31	0.42
NFI	0.98	0.98	0.98
AIC	7.086		7.524

Note: AE, model includes additive genetic and unique environmental effects. ACE, model includes additive genetic and unique and common environmental effects. CE, model includes only environmental effects. V_A , phenotypic variance explained by genetic effects. V_E , phenotypic variance explained by unique environmental effects. V_C , phenotypic variance explained by common environmental effects. NFI, normed fit index for large samples. AIC, Akaike's information criterion.

path estimates, as well as the goodness-of-fit measure (here, the normed fit index), are given. In the study here examined, the intraclass correlation for MZ twin pairs was 0.5 and for DZ twin pairs it was 0.39, which could be an indication of common environmental effects.

These results show that a model that incorporates only additive genetic and unique environmental effects has a nice fit ($\chi^2/df < 1$; NFI = 0.98). From the data, it can be seen that 47% of the variance in extraversion levels in the population can be attributed to additive genetic effects and 53% of the total variance can be attributed to unique environmental effects. But is this the best-fitting model or has the shared environment also had a significant effect on the development of the trait? To address this question, a model that includes additive genetic effects, unique environmental effects, and common environmental effects needs to be tested. To accomplish this, one degree of freedom must be sacrificed. This model also fits ($\chi^2/df < 1$; NFI = 0.98), but does it fit significantly better compared to the more parsimonious AE model? When models are nested, the likelihood ratio test is used to solve this question. As goodness-of-fit measure, the χ^2 values are obtained. The difference between χ^2 values can be interpreted as a measure for the significance of path C, $\chi^2_{AE} - \chi^2_{ACE} = 0.681$, which is not large enough to compensate for the loss of one degree of freedom. Thus, the model including common environmental effects does not explain the data significantly better than the first model with only additive and unique effects.

The next model tested does not assume any genetic effects on the trait, only environmental effects. This model also seems to fit the data ($\chi^2/df < 1$). Because this model (CE) is not nested in the first model (AE),

it is not possible to compare both models using a likelihood ratio test. When models are not nested, the model with the smallest Akaike's information criterion (AIC) is considered the best model, because AIC is a measure of the parsimoniousness of a model. Therefore, it can be concluded that a model with only additive genetic and unique environmental effects suffices to explain the data.

Future Directions

The Future of Molecular Genetics

Genetic linkage methods with complex inheritance are based on allele sharing between related pairs. As described above, one way to identify the specific loci involved in the development and expression of traits is the use of quantitative trait loci linkage. In the past, the results of QTL have not always been reliable; contradictory outcomes have been seen and there were many problems with the replication of earlier findings. This has led to much criticism of QTL. In turn, this has led to international cooperation and the development of standardized protocols, which will enhance the possibility of finding genetic regions linked to susceptibility of disorders. In the future, the methods for QTL will become more refined and the statistical analysis more powerful in order to detect true linkage and to decrease the number of false-positive outcomes. It will also become possible to determine confidence intervals small enough to become meaningful. To increase the possibility of finding true linkage, related phenotypes can be studied in concordance using selected samples. For instance, in the search for genes linked to diabetes mellitus-related traits glycemia, obesity, blood pressure, and insulin secretion can also be tested.

The Future of Population Genetics

Increasingly more complex and comprehensive models and even more extensive international cooperation will characterize the future of population genetics. Multivariate analysis and the establishment of twin registers have made it possible to start longitudinal studies into different complex traits and diseases. It is expected that these new insights will lead to increased knowledge of the genetic etiology and environmental contributions to behavioral traits and disorders.

Multivariate analysis also makes it possible to study the genetic relationships between different traits. For instance, the simultaneous analysis of asthma, hay fever, dust allergy, and eczema data showed that there are common environmental and additive genetic influences for all four symptoms of atopy, which means that

they have one or more genes in common. The same multivariate models are being used to study the relationship between personality traits and physiological variables, such as the relation between levels of sensation-seeking and cardiovascular reactivity measures.

Genetic analysis and its statistical methods have become so approachable that the twin-only design can be easily extended to other genetically related individuals such as parents and siblings. Adoption studies with twins and siblings reared apart are carried out to obtain greater insight into the combined effects of heredity and environment. Adoption designs will make it possible to identify specific influences of the environment, unconfounded by heredity, and to analyze genotype–environment interactions and correlations. Several types of adoption designs can be used to study the emergence of behavior, such as designs including measures of several different family relationships, e.g., biological parents and their adopted-away offspring, twins separated early in life, spouse correlations, biological and adoptive parent–offspring correlations, and sibling correlations.

And finally, the latest trend is to incorporate specific genetic loci in model-fitting, the so-called biometric model-fitting analysis. The aim of these studies is to gain knowledge about how much of the genetic variance is accounted for by some small set of candidate loci. On the other hand, these models can also provide information about the types of shared environmental effects that influence behavior. For instance, in the study of schizophrenia, specific environmental factors that result in discordance among identical twins are already the subject of extensive investigation.

Ethical Issues

Behavior genetic studies draw a lot of controversy, because the results of such research can have far-reaching political and social implications. Among the topics that are frequently studied are socially sensitive issues such as the genetics of intelligence, homosexuality, and criminal behavior. What does it mean if 75% of the variance in intelligence in a population can be explained by genetic differences between individuals? This type of outcome from international comparative studies evokes a lot of controversy because it seems to collide with the “just world” hypothesis and the thought that all people are born equal. Intelligence may be a fuzzy concept and it is not known exactly what intelligence is, but everyone has some notion that it is an important attribute in society and that those blessed with it appear to be better off. The problem here is that it is not clear enough to the lay public, and to many scientists too, what these outcomes represent. Researchers and the media have not always presented new findings with the necessary care and have

not explained carefully enough what these results do and do not mean. One of the tasks of genetic researchers therefore lies in bringing greater clarity to what research on behavior genetics can achieve and what it cannot achieve. The major emphasis on the heritability coefficient has created an idea of genetic determinism at the expense of the environmental outcomes of behavior genetics. Most conditions are determined by multiple causes and therefore also depend on environmental influences. Behavior genetic methods can be used to elucidate such intermediary environmental influences and thus provide a richer explanation of behavioral differences in intelligence.

At the microlevel, genes are studied in DNA studies. The aims of this field of research are to elucidate the mechanisms of gene action and to map the human genome. The mapping of features as diverse as schizophrenia, criminality, and alcohol addiction raises questions about the implications that this knowledge will have for society. What are the social and political implications of the media bulletin that “a gene for violent criminal behavior has been discovered”? Does this mean that violent criminal behavior is inherited and that “violent criminal behavior” is written indelibly in the genes, determining behavior? What should be the consequences of this discovery for society? Is violent behavior suddenly a disease? Should those who commit violent crimes be hospitalized and cured? What should the implications be for the legal system? Should there be genetic screening for violent behavior and ultimately some form of prenatal genetic engineering? These are important issues but they cannot be solved here. In May 2003, a conference was held on these social issues on the occasion of the termination of the Human Genome Project. The topic of the conference was how genetics researchers should engage in a more open dialogue so that the public can become better informed, while those involved in science hear the nature of political and public concerns. Researchers in the field should be aware of the importance of these issues and the responsibilities that come with working in a new and exciting research field. Fortunately, most researchers are.

Human Growth and Development

Michel Ferrari

University of Toronto, Toronto, Ontario, Canada

Chandi Fernando

University of Toronto, Toronto, Ontario, Canada

Glossary

change Any physical, psychological, or institutional alteration, without concern for direction or value.

development A process of growth that includes increasing complexity and dynamic directionality over time; typically, but not always, used to refer to a positive change.

electroencephalogram (EEG) A measurement the electrical activity of the brain.

evolution A process of biological growth that includes increasing complexity and dynamic directionality over time; typically, but not always, used to refer to a positive change.

gross domestic product (GDP) The value of the total final output of all goods and services produced in a single year within a country's boundaries.

gross national product (GNP) GDP plus incomes received by residents from abroad minus incomes claimed by nonresidents.

growth An increase in size of the physical body, of knowledge, or of an institution.

individual differences Variation among individuals on all dimensions, as measured by psychometric tests. The study of such differences has been a major focus in the psychology of intelligence and personality and in behavior genetics.

magnetoencephalography (MEG) The measurement of the magnetic activity of the brain, usually conducted externally.

The relations between growth and development are complex, especially because these two words have several, partially overlapping meanings. For our purposes, growth refers to an increase in size of the physical body, of knowledge, or of institutions, whereas development refers to

a process of growth that includes increasing complexity and dynamic directionality of growth over time. Growth and development need not imply progress; a cancer tumor is a growth and one can develop a physical or mental illness.

Physical Growth and Development

Physical growth refers to changes in the body (such as height, weight, or hormonal changes) that are the result of maturation, environmental experiences, or some interaction between these two factors. It also involves neurological and sensory development, such as increased visual acuity and mastery of motor skills.

Developmental Milestones (Psychometric Measurement)

The oldest quantitative measures of human growth and development, emerged in the mid-nineteenth century through the work of Quételet. He measured the physical growth of members in a population and calculated statistical norms for the "average man" of different groups (racial types) of people, characterized by measurements of moral and physical qualities. These then came to be considered not just averages, but real ideal or abstract features of these populations. Similar work continues in studies of milestones of "normal" human growth and development that track, for example, the average age at which a person is expected to begin sitting, standing, walking, smiling, grasping, sensory acuity, or later

physical changes that accompany puberty, as well as those that occur across the life span into old age. This approach implies a maturational view of physical development. The Bailey Motor Scale, for example, measures quality of movement, sensory integration, motor planning, and perceptual motor integration in infancy. Likewise, tests of bone density measure potential bone loss in old age. Similar kinds of measurement are implicated in assessments of obesity in the population and other measures of health.

Brain Development

Early attempts to understand the development of human brain structure relied on the effects of accident or illness conducted postmortem. However, more recent neuroimaging technologies allow growth generally, and brain activity specifically, to be examined dynamically in living subjects as early as infancy and even during embryogenesis. These include technologies that are less invasive, such as positron emission tomography (PET) scans, magnetic resonance imaging (MRI), and techniques such as magnetoencephalography (MEG) and electroencephalogram (EEG). Studies have examined both large-scale structures such as the spine and internal organs and small-scale structures such as neuronal growth and cell assemblies. Different areas of the brain develop at different times during embryogenesis and ontogenesis. The frontal lobes, for example, develop late compared to more primitive structures such as the brain stem, cerebellum, and limbic system.

Brain growth is influenced both by environmental variables such as nutrition and by learning experiences. Malnutrition negatively affects brain growth, as it does all other aspects of physical development. On a more positive note, learning can increase brain development. For example, a study of London cab drivers found that they have a bigger hippocampus (an area of the brain implicated in memory) than do other Londoners, presumably reflecting their need to remember the many streets of London. And, in general, studies show that learning increases the areas of the brain devoted to particular tasks, often by recruiting neurons from other areas of the brain through new connections and not through the growth of new neurons.

Cognitive Growth and Development

Cognitive growth and development refers to the growth and development of knowledge through experience. Such growth and development can involve information processing needed in planning, attention, or memory, as well as development of expertise in particular knowledge

domains. Theorists disagree over whether cognitive development occurs gradually or in stages.

Psychometric Measures of Mental Development

Galton continued the psychometric line of work of Quételet (anthropometry) by extending it to consider individual differences in psychological characteristics, such as those that characterize genius or mental deviance. Galton took these variations to be biological variations that reflected an evolutionary trend toward the greater improvement of the human race, which was hereditary in families. Measures of this hereditary genius included measures of fame, basic skills, and reaction times. Recent work in this vein has been done by Simonton, who shows, using similar statistical methods, that career age and early productivity are the best indicators of exceptional performance within a profession.

The most popular psychometric measurement of cognitive growth is the IQ test, the most famous developed by Binet and Simon at the beginning of the twentieth century. Spearman used a similar logic to measure what he called *g*, or the basic capacity of individuals to learn. Such tests are the basis for assessments of learning disabilities and giftedness in many content domains.

Galton also held the view, common then, that the different races and different genders differed in their intellectual capacity. The less-evolved races were thought to have less higher-order ability or capacity for abstraction. It is an idea that continues today in books such as *The Bell Curve*, which Gould has effectively challenged in his own book *The Mismeasure of Man*. Although no longer considering evolution to imply progress, evolutionary psychologists are also working in the same spirit as Galton.

Learning and Expertise

Dissatisfied with psychometric norms, which document but do not explain cognitive growth, researchers have measured changes in information-processing capacity (e.g., attentional or memory capacity). Some researchers adopt a maturationist explanation for the observed increases in information processing. Others, such as Ericsson and Sternberg, believe that such changes reflect a growth in expertise. The measurement of growth in expertise is made by comparing the differences in representations and strategies exhibited by experts versus novices, and by comparing the differences in self-regulation and practice habits (deliberate practice of elements and self-explanation) of the greatest experts and most gifted students versus regular experts and students. Assessments by Chi have shown that deep misconceptions can persist even after extensive training if novices do not

experience a radical conceptual change and adopt the expert theory in that knowledge domain. The assessment of conceptual change and level of expertise consists of inferring the implicit or explicit representations required to explain patterns of individual problem solving. A unifying position that explains cognitive growth in a way that combines biological variability in basic abilities and the level of expertise proposes that observed skill results from a synthesis of individual differences in capacity and sustained personal efforts to master cultural material that exercise those capacities. Assessments of ability are made through tests of fluid (culture-free) and crystallized (culturally learned) intelligence. Measures are also made of successful life-span adjustments as individuals compensate for their weaknesses and optimize their strengths; for example, elderly individuals rely on documents or others to help recall a forgotten name as their fluid memory ability declines in old age.

Human Evolution

The facts that some individuals learn particular kinds of information better than others and that people can suffer specific cognitive deficits, such as aphasia, have undermined support for Spearman's *g* and suggest instead that the human mind is modular, that is, that people of all ages exhibit a profile of abilities. These profiles can be established by psychometric tests and also from performance criteria.

Evolutionary psychologists such as Pinker argue that human growth is best understood in terms of the evolution of the human species. This evolution produced a certain biological body that has a basic human nature characterized by modules. This view relies on cross-cultural comparisons of social organization and neurological studies of the effects of brain damage. Evolutionary psychologists mainly rely on an adaptation or design theory regarding the fit between human development and the environments in which we evolved. Support for modules are also provided by infant studies in which innate understandings (e.g., that physical objects are solid) are found to be present from birth and are assumed to be necessary for acquiring later knowledge and skills in the world.

In related work, behavior geneticists such as Plomin have tried to isolate specific genes associated with particular adaptive and maladaptive behaviors (e.g., aggression) or cognitive capacity (e.g., intelligence). These ways of measuring human development presume that human nature is largely set for the species, with individual variations. Individual growth and development, in this view, are analogous to playing the hand one is dealt in poker. Some people are dealt the genetic equivalent of a royal flush and are almost assured to be geniuses, whereas others are given a hand that has no face cards

and are mentally deficient; however, most of us have a few good cards and need to play well to win. In other words, our choices may matter, but it is the biology that we inherit that specifies what our smart choices will entail if we want to make the most of our potential abilities.

Stages

Historically, the measurement of children's increasing expertise or ability, especially their ability to understand mathematical and logical relations, has been shown to exhibit structural reorganization characterized by stage-like shifts. This position is usually associated with Piaget, who used a clinical method to observe and interview children about their explanations of events in studies designed to highlight a certain feature of the world (e.g., children's understanding of the conservation of weight or volume). Typically, four main stages are proposed: sensorimotor, preoperational, concrete operational, and abstract propositional (these stages have been given different names by different theorists). The measurement of children's problem-solving behavior and their justifications for particular solutions show an advance through these four stages of understanding in a fixed sequence. Whether this sequence is unique to Western culture or is universal has been disputed but, according to Piaget, the sequence must remain the same—even if not everyone will achieve the most abstract levels of understanding in a given domain.

Neo-Piagetians such as Case, Fischer, and Demetriou have continued in this theoretical tradition. Case shows that children need to master certain core ideas in a domain such as mathematics (which he calls central conceptual structures) before their understanding can advance in that area. Fischer (using, e.g., Guttman scaling) documents that cognitive development can progress along alternative pathways; thus, in learning to read, people can arrive at a comparable level of skill by different routes. Socially supported learning generates an optimal level of functioning and leads to the quickest progression through these stages compared to typical independent performance. Measurements of ability under conditions of increasing social support, called dynamic testing, are increasingly advocated; such assessments reflect what Vygotsky called the zone of proximal development (ZPD). Demetriou has also used statistical techniques to measure the contributions of basic abilities to the development of different levels of knowledge in particular areas of skill (e.g., verbal and spatial areas).

Recent microgenetic assessments of people learning a new task have shown that individuals recapitulate the same levels of understanding, whether they are children or adults developing knowledge over their life span. Surprisingly, this recapitulation can occur many times as individuals construct their understanding of the new

task or knowledge domain. Characteristic of microgenetic measurements are multiple measures of performance over a short period of time during the learning of something new. Growth modeling statistics and other methods can be used to assess microgenetic and life-span knowledge development.

In this view, our knowledge is constructed through our biology and our cultural experience jointly, and it greatly depends on our own actions and efforts to master particular kinds of tasks.

Social and Emotional Growth and Development

Another main area of human growth and development is social and emotional development. Social and emotional development refers to the development of personality and the concept of self. It includes at least implicit reference to the ideal ends of development that orient the kind of knowledge people strive to master, including spiritual development and the development of wisdom. Another important topic is how children develop in their social interactions to others. These topics have been measured in a variety of ways, from psychometric assessments to narrative methods.

Personality Development

Personality

In the Galtonian psychometric tradition, personality structure has been measured through factor analytic techniques. These have uncovered what is commonly called the big five-factor structure (openness to experience, conscientiousness, extroversion, agreeableness, and neuroticism). Observational measures also identify differences in temperament that are clearly visible in infants and continue through childhood and adulthood. Other measures examine the extent to which personality embodies multiple, and possibly conflicting, social scripts (e.g., mother and office worker) that individuals fulfill to different degrees. Personality, when considered through narrative methods, becomes synonymous with studies of the self.

Self

Many measurement approaches have been used to study self-concept (e.g., questionnaires, analyzing statistical differences between groups of different ages, and clinical interviews looking for structural reorganization of knowledge). Clinical interview measures of self show that infants first see themselves in terms of their physical features and behaviors. Children later see themselves through isolated concrete events that have occurred in their lives leading to ideas about unique psychological

abilities or group affiliations. Only in adolescence do people understand themselves through abstract assessments of the type of person they are or through an integrated in a life story. In this respect, these findings echo those found for cognitive development generally in the work of Piaget and others.

Recent work inspired by that of Bruner has begun to examine self as a narrative. Narrative measures suggest that conceptions of self-growth and development involve considering the self as an actor striving toward goals, using resources (including friends and allies) to overcome some sort of trouble or obstacle. Heroic narrative involves overcoming the obstacles to right a wrong or to achieve an even better state of affairs; tragic narrative involves a failure to do so. As such, narrative approaches necessarily imply cultural conceptions of a good life.

Spirituality

Moral Development

Related to self and development, many attempts have been made to measure moral development. These approaches often use a logic similar to that of Piaget, advancing in stages. The most famous of these is Kohlberg's six stages of moral development: preconventional (stage 1, obedience and punishment orientation; stage 2, individualism and exchange), conventional (stage 3, good interpersonal relationships; stage 4, maintaining the social order), and postconventional (stage 5, social contract and individual rights; stage 6, universal principles). These stages were inspired by Piaget's early work in this area. Research in this area often uses scenarios such as the Hans dilemma (in which Hans must decide whether to steal a drug he cannot afford to save his dying wife) to determine level of moral development. Similar to the work of Piaget, Kohlberg's model relies on the different patterns of response and justifications for particular answers that are considered more developed. These stages have been challenged by Gilligan who proposes an ethics of care rather than one of duty. Recent work on moral development has measured the increasing differentiation of domains of moral knowledge (as assessed through both statistical measures and narrative accounts of personal meaning). In this view, the three main domains of social reasoning are moral reasoning about justice, rights, and welfare; conventional reasoning about rules by authority or traditions; and personal-choice reasoning about duties and responsibilities. Some have also assessed the moral self, that is, the characteristics and narratives through which individuals come to understand themselves as moral beings who must take strong social and political action.

In a different vein, Baltes and Sternberg have measured wisdom, defined either as expertise in the fundamental pragmatics of life (Baltes) or a tacit knowledge of

how best to achieve equity or balance among competing interests (Sternberg). Wisdom is measured by analyzing people's answers to scenarios about difficult life situations, especially those involving some sort of negotiation. An alternative view sees wisdom as caring about community and about personal legacy in the face of death. This approach has been inspired by Erikson and is often documented through narrative analysis of people at the end of their lives. McAdams, following Erikson, emphasizes the importance of generativity within life narratives and has shown how measures of generativity correlate to those of general well-being throughout the life span. Buddhist psychologists such as Varela adopt a more radical form of this view in which wisdom involves abandoning fixed habitual responses in favor of a creative response afforded by the specific life situation that an individual is engaged in.

Spiritual Development

Moral development in psychology is assessed in a manner that implies that such development is secular; however, similar approaches have identified spiritual development—the way that people understand their relation to God or to mystical experiences—as underpinning their deepest moral aspirations. For example, Fowler's stages of faith, also modeled on Piaget's stages, document this sort of development. Assessments have been made of mystical experiences and near-death experiences, which rely on narrative methods to assess what is most meaningful and enduring in transformative experiences. These approaches use techniques and analytic strategies often associated with literary studies, such as narrative analysis and character studies. However, statistical methods such as questionnaires have also documented the prevalence of different kinds of spiritual experiences at different ages. For example, children as young as 6 years old have had the experience of a divine presence; mystical experiences of a union with all things is rarer and does not seem to occur before adolescence.

Linked Lives

Human growth and development is not merely a characteristic of isolated individual but of individuals in communities and in families. Cultural differences are not divorced from physical and cognitive aspects of growth and development; rather, they both express and contribute to them in turn. Cohort studies by Elder of the effects of broad cultural events (such as the Great Depression and World War II) show that lives are linked, especially within families, where the actions of parents can have a profound impact on the later lives of children (e.g., a parental decision to abandon their farm to move to the city will transform the lives of their children).

Bronfenbrenner and, more recently, Rogoff have emphasized this point in cultural and ecological models of human development. According to Bronfenbrenner, individuals are embedded in micro, meso, exo, and macro contexts. Rogoff conceptualizes each of these in terms of different planes of analysis, all of which contribute to growth and development. Rogoff documents how participation in social groups changes as individuals grow and develop, going from the periphery (for novices) to the center (for experts).

Culture

Cultural development involves both differences in how cultures conceptualize growth and development and the development of knowledge and artifacts across generations within cultures. Measurements of cultural development include statistical indications of the quality of life and of economic prosperity.

Self-Ways

Work by Bourdieu and Markus shows that individuals interact in groups in ways that conform to an implicit structure unique to specific cultures (e.g., patterns of gift giving), the existence of which participants may deny. These differences are critical to personal assessments of self-worth and a good life, as well as to evaluations of wisdom or maturity. Such cultural expectations are not fixed but are communicated from generation to generation through the institutional practices and narratives within which human life unfolds—whether or not those practices are made explicit. For example, Nelson and her colleagues have shown that the way parents coconstruct the meaning of autobiographical events with children is critical to how children in different (sub)cultures construct their own autobiography. Cultural differences between American and Asian families, for example, have been shown through differences in conversations about self and events, with Asian families include more social actors as integral to their autobiographical narratives.

Knowledge Building

Not only do individuals grow up and develop within social groups and establish their identity within them, cultures and institutions develop technologies (artifacts and practices) that become integral to their ways of life and that are essential to understanding human growth and development. An obvious example is the advance in neonatal care that saves thousands of lives in developed countries. A more problematic issue is the possibility that parents can abort a fetus identified as having a disability

or, in the near future, perhaps to alter it through genetic engineering. Along similar lines, eyeglasses and pace-makers have been a boon to quality of life, even extending life, but the possibility of enhancing memory or altering mood through drugs such as Prozac or lithium—and the pharmaceutical industry's stake in developing and promoting such drugs—has profound and problematic implications for human growth and development. Science fiction writers already conceive of developing and improving human nature through marrying the human form and artifacts. In the real world, companies such as Bell Canada have begun to assess whether, for example, wearable computers can improve the work capacity of their technicians.

More abstractly, knowledge itself can be said to develop within a particular culture, the clearest example being the development of mathematical knowledge from Babylonian to modern times. Many argue that knowledge building is precisely the capacity that we foster in education and that such activity is essentially creative. Knowledge building can be supported by artifacts such as Knowledge Forum, a networked collaborative learning environment for schools developed by Bereiter and Scardamalia. Computer simulations and computer modeling are other powerful tools for knowledge development.

Economic Development

In addition to knowledge, there are also indicators of economic growth and development that are taken to indicate the prosperity of nations. Economic development is measured by indicators such as the gross domestic product (GDP) and gross national product (GNP), whereas other measures (e.g., indicators of levels of pollution) target the sustainability of that development or quality of life (e.g., social satisfaction, the amount of disposable income, and level of unemployment).

Seligman, Diener, and Keating all suggest we need indicators of happiness and well-being for citizens as well as of economic prosperity. Diener has measured happiness within various cultural populations using standardized questionnaires. Likewise, Keating has done international comparisons to show that health (and especially, disparities in health among the rich and poor) is an indicator of the overall economic success in different countries.

Particular forms of government are often measured, and we can say that a country is developing into a democracy or a dictatorship by the state of the political institutions, or the level of freedom of the press, within that society. These measures cannot be divorced from ideologies about development and related views about Utopia, or where development ideally should be heading. For Keating, we also need to consider how political, economic, and social conditions interact dynamically with neurobiological differences among children to create

the particular habits of mind that characterize them as individuals and, by extension, the forms of life that constitute the culture. Such development may be typical, but it can also be atypical, and to this we turn next.

Atypical Development

Our discussion of growth and development has so far focused on typical development, but we close with a few words on atypical growth and development. It almost goes without saying that all the measures mentioned previously can also be used to document atypical cases. For example, brain imaging technologies are also used to measure human growth in the sense of growth of tumors and other abnormalities in children and adults or the deterioration of the brain in Alzheimer's and Parkinson's disease.

Medical Biography

Medical biographies are an interesting way of measuring physical growth and development. For example, a recent study of the course of illness of U.S. president Franklin Delano Roosevelt questions a long-held view that he had polio. His specific symptoms and the sequence and timing of them in his life (e.g., that he fell ill at the age of 39) make it more likely that he was a victim of Guillain-Barré Syndrome, an autoimmune disorder (although, in any case, the cure for either was not developed until decades later). Similarly, the trajectory of the prognosis of particular diseases can be measured through clinical epidemiology, with important implications for social policy; for example, the trajectory of illness is very different in cases of cancer and cases of organ failure, such as chronic obstructive pulmonary disease (COPD).

Cognitive Differences

Cognitive development can also deviate from the norm. It can be accelerated, or it can be delayed. This logic is what still underpins labels learning disabled and gifted, commonly considered to represent two standard deviations above or below the norm. This approach also highlights alternatives to the norm, for example, attention-deficit hyperactive disorder (ADHD) or autism. Recent work uses different assessments of learning disability and giftedness that are not based on psychometric testing but rather on performance (e.g., Gardner's proposed multiple intelligences); nevertheless, the implicit logic of all of these studies is that extraordinary individuals produce work that is outside the normal range expected within the population. Measurement has also considered alternative pathways to development in atypical cases, for example the work of Karmiloff-Smith on Williams

syndrome and its near genetic variants, which highlights the importance of individual development within specific environments even in genetically atypical cases.

Developmental Psychopathology

The importance of individual development is emphasized within developmental psychopathology, in marked contrast to clinical and empirical measurement models of disability. Within the clinical model, the utility of classification measurement models such as the DSM-IV is limited by their insensitivity to age and gender differences, the possibility of diagnostic overinclusion, or the possibility of missing subthreshold cases. Often family factors are only marginally considered and typically accounted for in an unsystematic or noninclusive manner. The empirical approach also tends to group large age spans together; to obscure differences in behavior because of the use of limited behavior descriptions and point scales; and to be insufficiently sensitive to emotional security, relationship quality, and adaptation to environmental functioning.

Because research methodology in developmental psychopathology posits examining the child from multiple domains and perspectives, assessments should include information from a variety of sources. These sources can include tools used in traditional assessments, such as questionnaires, interviews, observations (naturalistic or analog, structured or unstructured), standardized and normed test measures assessing aspects of cognitive functioning, academic achievement, personality, and social competence, along with physiological and biological measures. Although these tools when used in isolation have shortcomings, their use as a multimethod technique allows for a more informative assessment of the child and the processes that influence development to be obtained, including the delineation of the relative risk and protective factors at play. Development is thus conceptualized as an ongoing interaction between an active, changing person and an active, changing context.

Developmental psychopathology research by Cicchetti and others is concerned with positive and negative influences on development, including adaptation (resilience) and maladaptation (psychopathology) when faced with adversity. It also examines positive factors (protective factors) and positive outcomes (i.e., competence despite risk) that are seen as emerging from the transactions between children and their environment. Developmental psychopathology is concerned with mapping development over time, including the form, direction, and shape of pathways. To that end, methodology within developmental psychopathology uses repeated measures over time and assesses functioning through a multimethod approach. Research also draws from multiple domains of functioning (i.e., emotional, cognitive, and social), higher levels of functioning (i.e., patterns of attachment), specific

levels of responding in specific situations (i.e., reaction to separation), and information from other disciplines, (i.e., biology) for a more comprehensive understanding of development.

Conclusion

Human growth and development have been conceptualized and measured in a variety of ways. We have chosen to focus on physical, cognitive, social-emotional, and cultural growth in typical populations. We have also briefly considered attempts to assess and measure atypical growth and development. Each of these aspects of growth and development is measured in several ways, including norm-referenced tests, observations, narrative, and longitudinal methods. Despite the wide range of methods reviewed, it is worth remembering that often the most innovative thinkers in an area invent their own theories and methods about what characterizes human development and how to measure it.

Hypothesis Tests and Proofs

Lee Demetrius Walker

University of Kentucky, Lexington, Kentucky, USA

Glossary

alternative hypothesis The belief the investigator holds about a specified population if the null hypothesis is false.

degrees of freedom Generally, the number of observations minus the number of parameters to be estimated. In some estimation procedures, the degrees of freedom simply represent the parameters to be estimated.

efficient estimator A point estimate that has the lowest possible standard error.

maximum likelihood estimate The value of the parameter that is most consistent with the observed data.

null hypothesis The hypothesis to be tested and the nullification of which by statistical means is taken as evidence in support of the specified alternative hypothesis.

point estimate A simple statistic that predicts the value of the parameter of interest.

p-value The probability of obtaining a test statistic value as large as the one obtained, conditioned on the null hypothesis being true.

test statistic A statistic calculated from the sample data to test the null hypothesis.

type I error The error that occurs from rejecting the null hypothesis when the null hypothesis is true.

unbiased estimator A point estimate with a sampling distribution that is centered around the parameter.

Hypothesis tests and proofs are major aspects of social science research and are the means by which proposed relationships are tested. Hypotheses are developed from theoretical questions that drive research and relate to characteristics of a population. A significance test is

a procedure through which a hypothesis is statistically tested by comparing the data to values predicted by the hypothesis. In this article, elements of the significance test and application of the dominant formulation of the test are discussed. This is followed by a discussion of alternatives and enhancements to the hypothesis testing process in the social sciences.

Introduction

A hypothesis about an underlying population is a statement that may be true or false. Relationships in social science are generally probabilistic rather than deterministic, and this fact has major implications in the design of attempts to prove the existence of proposed relationships. Moreover, these relationships are usually asymmetric, with one variable having an influence on another, but not inversely. The testing of hypotheses can take several forms. For example, parametric tests require the population to follow a particular distribution (often the normal); nonparametric tests relax the normality assumption but require that the populations that are to be compared have similar distributional shapes. The dominant method for testing social science hypotheses is the null hypothesis significance test (NHST). This test allows the investigator to test the probability of a null or restricted hypothesis (usually specifying no relationship between the variables of a particular phenomenon) against a research or alternative hypothesis (generally the researcher's belief concerning the relationship of the variables of the phenomenon).

Elements of the Null Hypothesis Significance Test

Like all significance tests, the NHST has five elements: assumptions, hypotheses, test statistics, p -value, and conclusion.

Assumptions

Significance tests require certain assumptions for test validity. These include type and scale of data, the form of the population distribution, method of sampling, and sample size. Data may take quantitative or qualitative form and may spring from different research sources—reactive sources such as attitude surveys and focus group responses, or nonreactive sources such as governmental documents, historical records, newspaper files, voting statistics, or other stored data. Typical distributional forms include the normal, Student's t , gamma, binomial, and chi-squared. Additionally, assumptions must be made concerning the type of sampling that is required for the conclusions drawn from the sample to be applicable to the specified population. Many significance tests require a minimum sample size, and the validity of most tests improves as the sample size increases.

Hypotheses

The NHST examines two hypotheses about the value of a parameter: the null hypothesis and the alternative hypothesis. The null hypothesis (H_0) is the hypothesis to be tested and is usually a statement of a parameter value, say θ , that corresponds to a parameter value of no effect, say θ^* . In many social research applications, θ^* is zero. The alternative hypothesis, represented by H_a or H_1 and also referred to as the research hypothesis, may take the form $H_a: \theta \neq \theta^*$. The alternative hypothesis $\theta \neq \theta^*$ constitutes a two-sided test in the sense that the possibility that θ may be either larger or smaller than θ^* is considered. Though the two-sided test is employed most commonly, the investigator may choose to state the direction of the effect in the alternative hypothesis. This one-sided test would take one of the following forms: $H_a: \theta < \theta^*$; $H_a: \theta > \theta^*$. The investigator designs the research to determine the amount of evidence that exists to support the alternative hypothesis.

Test Statistics

Test statistics generally follow the normal, Student's t , F , or chi-squared distributions. The formation of the test statistic usually involves a point estimate of the parameter to which the hypotheses refer. Maximum likelihood estimators (MLEs) are favored in social research

because they are generally unbiased, efficient, and have approximately normal sampling distributions. Commonly used test statistics are the z -score, the t -statistic, the F -statistic, the chi-squared statistic, the likelihood ratio test statistic, and the Wald statistic, defined as follows:

1. The z -score for large sample means (\bar{Y}) and proportions ($\hat{\pi}$) is $z = (\bar{Y} - \mu_0) / \hat{\sigma}_{\bar{Y}}$, where \bar{Y} is the sample mean, μ_0 is the population mean, and $\hat{\sigma}_{\bar{Y}}$ is the sample standard deviation, or $z = (\hat{\pi} - \pi_0) / \hat{\sigma}_{\hat{\pi}}$, where $\hat{\pi}$ is the sample proportion, π_0 is the null hypothesis value of the proportion, and $\hat{\sigma}_{\hat{\pi}}$ is the standard deviation of the sample.
2. The t -statistic for small-sample means and proportions and individual coefficients in linear regression models is $t = (\bar{Y} - \mu_0) / \hat{\sigma}_{\bar{Y}}$, where \bar{Y} is the sample mean, μ_0 is the population mean, and $\hat{\sigma}_{\bar{Y}}$ is the sample standard deviation, or $t = b_i / \hat{\sigma}_{b_i}$, where b_i is the coefficient of the i th explanatory variable of a regression model and $\hat{\sigma}_{b_i}$ is the coefficient's standard error.
3. The F -statistic to test the significance of multiple regression models is $F = \text{model mean square} / \text{mean square error}$, or

$$\frac{R^2/k}{(1-R^2)/[n-(k+1)]},$$

where R^2 (the coefficient of multiple determination) = $\sum(Y - \bar{Y})^2 - \sum(Y - \hat{Y})^2 / \sum(Y - \bar{Y})^2$ (\bar{Y} is the sample mean and \hat{Y} is the predicted values), k is the number of explanatory variables, and n is the number of observations. The F -statistic can also be used to compare a complete model with k parameters to a reduced model with g parameters (nested models); i.e., $F = [(\text{sum of squared error}_{\text{reduced}} - \text{sum of squared error}_{\text{complete}}) / (k - g)] / \text{sum of squared error}_{\text{complete}} / [n - (k + 1)]$.

4. The chi-squared statistic (χ^2) to test independence of variables and goodness of fit for generalized linear models (GLMs) is $\chi^2 = \sum(f_o - f_e)^2 / f_e$, where f_o is the observed frequency and f_e is the expected frequency of independence.

5. The likelihood ratio test statistic ($-2 \log L$) to test nested GLM models is

$$-2 \log(l_0/l_1) = -2[\log(l_0) - \log(l_1)] = -2(L_0 - L_1),$$

where l_0 is the maximized value of the likelihood function for the simpler model and l_1 is the maximized likelihood function for the full model, and L_0 and L_1 represent the maximized log-likelihood functions and are the transformations of l_0 and l_1 . This transformation yields a chi-squared statistic with degrees of freedom (df) equal to the number of parameters in the null hypothesis.

6. The Wald statistic (z^2) to test the significance of parameters in GLM models is $z^2 = (\beta / ASE)^2$, where β

is the estimated coefficient and ASE is the asymptotic standard error estimate. The statistic is compared to the chi-squared distribution with degree of freedom = 1.

The generalized linear models generalize ordinary regression models by allowing the random component to have a distribution other than the normal and modeling some function of the mean. GLMs have three components: the random component identifies the response variable (Y) and assumes a probability distribution; the systematic component specifies the explanatory variables used as predictors; the link function is a function of the expected value of Y that is linearly predicted by the explanatory variables.

p -Value

The p -value provides a means to interpret the evidence provided by the test statistic on a probability scale. The p -value is the probability of obtaining a test statistic value as large as the one obtained, conditioned on the null hypothesis being true. The smaller the p -value the more strongly the data contradict the null hypothesis. Conversely, a moderate to large p -value indicates that the data are consistent with the null hypothesis. The p -value is the summary of the evidence in the data about the null hypothesis.

Conclusion

The NHST test is designed to minimize a Type I error, which is the error of rejecting the null hypothesis when the null hypothesis is true. To establish the minimization of a Type I error, the investigator sets the predetermined and small α level at which H_0 is rejected. The α level of 0.05 has become the conventional level of statistical significance in social research. The 0.05 level provides that only 5 times out of 100 the null hypothesis will be rejected when the null is true.

The investigator is interested in the range of values of the test statistic for which the null hypothesis will be rejected. Based on the predetermined α level, the distributional form, and the hypothesis to be tested (one sided or two sided), the critical region and corresponding critical value, T^* , are formed. The task is to determine what values of the test statistic, T , correspond to the cutoffs of the critical region. Figure 1 illustrates this process for the α level of 0.05 with a normal distribution and a two-sided hypothesis. Note that α is divided by 2, so that half of the 0.05 probability is in the left tail of the distribution and half of the probability is in the right tail of the distribution.

The decision to reject H_0 is made if $T < T_1$ or if $T > T_2$. Table I shows the possible conclusions, given the preceding conditions. Note that the investigator does not accept H_0 , but rather lacks the necessary evidence to reject H_0 .

Figure 1 Null hypothesis significance test. Critical values for a two-sided test: $T_1 = -1.96$, $T_2 = 1.96$, $\alpha = 0.05$.

Table I Possible Conclusions of the NHST with an α Level of 0.05^a

p -Value	Conclusion	
	H_0	H_a
$p \leq 0.05$	Reject	Accept
$p > 0.05$	Do not reject	Do not accept

^a NHST, Null hypothesis significance test.

A Multiple Regression Application of the NHST

The F -Test

To illustrate the NHST, we test whether a linear regression model consisting of income, education, and the interaction between income and education has a statistically significant effect on occupational prestige, and fit the model; $Y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + e$, where Y is the mean prestige; α is the Y intercept; β_1 , β_2 , and β_3 are the coefficients for explanatory variables x_1 (income), x_2 (education), and x_3 (the effect created by the interaction between income and education); and e is the $(n \times k)$ error matrix.

The null hypothesis takes the following form: $H_0: \beta_1 = \beta_2 = \beta_3 = 0$. This null hypothesis posits that neither income, nor education, nor the interaction between the two has an effect on prestige. The α level is set at 0.05. Alternatively, we argue that at least one of the explanatory components of the model does have an effect: At least one $\beta_i \neq 0$.

To test the null hypothesis, we investigate Duncan's Occupational Prestige Data, which contains 45 occupational

types as observations. Though the sample size is rather small to estimate four parameters, it is useful for illustrative purposes. The F -statistic is selected as the statistic to test the null hypothesis. Recall that $F = (R^2/k)/\{(1-R^2)/[n-(k+1)]\}$. We calculate the F -statistic using the regression results reported in Table II: $F = (0.8287/3)/\{(1-0.8287)/[45-(3+1)]\} = 66.13$. The F of 66.13 is compared to the predetermined critical value extracted from the F distribution, which can only assume nonnegative values and is somewhat skewed to the right. The shape of the F distribution is determined by two separate degrees of freedom measures. In the case of our example, $df_1 = 3$ and $df_2 = 41$. Figure 2 shows the distribution of the F -statistic given the two degrees of freedom, and an F^* that yields $\alpha = 0.05$.

Our test statistic value of 66.13 far exceeds an F^* of 2.935. Given this result, we reject the null hypothesis of no effect and accept the alternative that at least one β_i does not equal zero. This result also indicates that the prediction equation of income, education, and the interaction term produces a significantly better prediction of Y than does the mean of Y .

Figure 2 The F -test for the null hypothesis. Critical value of the F -statistic, $F^* = 2.935$; $\alpha = 0.05$, $df_1 = 3$, $df_2 = 41$.

The t -Test

An interaction term is included in the prediction equation, which posits the interaction between income and education as having an effect on prestige that is distinctive from income and education separately. To test the partial effect of the interaction term, the following null and alternative hypotheses are offered: for H_0 , $\beta_3 = 0$; for H_a , $\beta_3 \neq 0$, where β_3 is the coefficient of the interaction term x_3 (income \times education). The test statistic is $t = b_3/\hat{\sigma}_{b_3}$. From Table II, $t = -0.001237/0.003386 = -0.365$.

This value is compared to the t distribution and has $df = n - (k + 1)$, or 41. Like the standard normal distribution, the t distribution is bell-shaped and symmetric about zero. The spread of the t distribution depends on the degrees of freedom, and the probability of falling in the tails of the distribution is higher than that of the standard normal distribution. However, the larger the degrees of freedom, the more the t distribution resembles the standard normal distribution. For a t -statistic with $df = 41$, the results are practically equivalent to the standard normal distribution. For a two-sided test, the critical value of t^* for $\alpha/2 = 0.025$ is approximately -1.96 (see Fig. 1). Given that the value of the test statistic (-0.365) is less than the value of t^* , we fail to reject H_0 , that the coefficient of the interaction term is equal to zero. We can now employ the simpler model. The results of this type of test are generally referenced in footnotes or in a method appendix, because investigators are interested in presenting the most efficient model in the body of the paper.

Table II is illustrative of the manner in which many investigators report the results of the test of the partial effects of each component of the model. The asterisk (*) notation that accompanies the t -values for income and education is an indicator that the coefficients for income and education are significantly different from zero so as to exceed the predetermined α level to the point that they would exceed a predetermined α level of even 0.01. An alternative approach to the use of this notation to indicate significance is to report the

Table II Linear Regression of the Prestige Model^a

Model term	Coefficient	Estimated standard error	t -Value
Intercept	-8.250934	7.378546	-1.118
Income	0.655621	0.197148	3.326**
Education	0.606030	0.192363	3.150**
Income \times education	-0.001237	0.003386	-0.365

Multiple R -squared, 0.8287; F -statistic, 66.13 on 3 and 41 df; p -value, $9.286e-16$;
significant codes, 0 **** 0.001 *** 0.01 ** 0.05 * 0.1 ' ' 1.

^a Data from Duncan (1961). The Duncan data were extracted from the Companion to Applied Regression (CAR) Library in an **R** statistical-computing environment.

p -values (some advantages of this approach are specified in Section V, B).

The finding that results from the use of the t -test to test the significance of a single coefficient estimate is equivalent to the finding that would result from the use of the F -test to test complete versus reduced models with a single parameter difference. For example, comparing the complete model $Y = \alpha + \beta_1x_1 + \beta_2x_2 + \beta_3x_3 + e$ to the reduced model $Y = \alpha + \beta_1x_1 + \beta_2x_2 + e$ would result in the same p -value that the preceding t -test produced.

Controlling for Potentially Spurious Factors

Though parsimony (presenting the model with the fewest parameters) is an important consideration in the presentation of test results, it is equally important that the investigator addresses the possibility of competing explanations. The investigator may accomplish this by including the alternative proposed explanatory variables in the explanatory model. For example, another investigator has shown that father's educational level is a significant factor in an occupation's level of prestige. This result has been widely reported and has begun to gain support in the literature. To demonstrate that the relationship between father's educational level and occupational prestige is spurious, the investigator includes this variable in the full model. A spurious relationship is a relationship between two variables that disappears when it is controlled by a third variable. In this case, the third variable is education. Both the investigator's explanation and the competing explanation are now nested in the full model, and the F - or t -test can be employed to examine the competing explanations. In the case of binary or ordinal outcome variables, the likelihood ratio, chi-squared, or Wald test may be used for the same purpose.

Enhancements and Alternatives to the NHST

Though the NHST has attained a high level of acceptance in social research, it is, nevertheless, controversial

because of misunderstandings concerning the application and interpretation of the test by many investigators. Several alternatives have been proposed to enhance the hypothesis testing process.

Report the p -Value

Reporting the p -value is a more objective process that allows the reader to draw conclusions concerning the significance of the relationship, allows for the aggregation of evidence through meta-analyses, and is relatively consistent with conclusions drawn by using the α criterion.

Employ and Interpret Confidence Intervals around Point Estimates

Confidence intervals are attractive because they provide both an estimate for the effect size and an indication of the uncertainty concerning the accuracy of the estimate. Generally, the greater the level of confidence desired, the wider the confidence interval. That is to say, given the same model and data, achieving 99% confidence would require a wider interval than would achieving 95% confidence. A 95% confidence interval for the coefficient b_i is $b_i \pm (t_{0.025} \times \hat{\sigma}_{b_i})$, where b_i is the i th coefficient in a multiple linear regression model, t is taken from the t distribution tail probabilities, and, in this example, the subscript of 0.025 ($0.05/2$) yields a t -value of 1.96, and $\hat{\sigma}_{b_i}$ is the standard error for b_i .

Table III shows the 95 and 99% confidence intervals for the coefficient estimates of the preceding model. The fact that the confidence intervals for coefficients for income and education are bound above zero indicates that there is strong evidence that the coefficients for both of these explanatory variables are not equal to zero and are positively associated with prestige.

Use Bayesian Analysis

In Bayesian analysis, inferences about unknown parameters are summarized in probability statements of the posterior distribution, which is a product of the likelihood function and some prior belief about the distribution. Contra the frequentist approach to statistical inference, the Bayesian approach allows the investigator to determine the probability of the null hypothesis, or a range of

Table III Linear Regression of the Prestige Model with 95 and 99% CIs

<i>Model term</i>	<i>Coefficients</i>	<i>Estimated standard error</i>	<i>t-Value</i>	<i>95% confidence interval</i>	<i>99% confidence interval</i>
Intercept	-8.250934	7.3785	-1.118	[-22.713, 6.211]	[-27.288, 10.786]
Income	0.655621	0.1971	3.326	[0.269, 1.042]	[0.147, 1.164]
Education	0.606030	0.1924	3.150	[0.229, 0.983]	[0.110, 1.102]
Income \times Education	-0.001237	0.0034	-0.365	[-0.008, 0.005]	[-0.010, 0.007]

values within which the true value lies, with a pre-determined level of probability. Using a 95% Bayesian probability interval, the investigator can declare that there is a 95% probability that the interval contains the unknown true value.

Impact/Outcome Evaluation

Frederick M. Hess

American Enterprise Institute, Washington, DC, USA

Amy L. Klekotka

University of Virginia, Charlottesville, Virginia, USA

Glossary

adaptive behaviors Behaviors that are required by different major life activity areas such as home and community living, school or work, and health and wellness.

benefit-costs The extent to which the program's benefits outweigh the costs.

effectiveness The extent to which a program meets its slated goals and objectives.

habilitation The acquisition of abilities not possessed previously.

impact The extent to which the program makes a difference compared to either having no program or having an alternative program.

objective Observable and measurable data.

outcome/impact evaluation A type of program evaluation that uses valued and objective person-referenced outcomes to analyze a program's effectiveness, impact, or benefit-costs. For instance, an impact evaluation studies whether a counseling program has in fact reduced such factors as recommitment, recidivism, and the crime rate.

outcomes Changes in adaptive behaviors and role status that are logical consequences of the services.

person-referenced outcomes Outcomes related to an individual's adaptive behaviors and role status.

process evaluation A type of program evaluation that analyzes simply whether a program has carried out a stated goal or objective. For instance, a process evaluation studies whether a program has provided counseling to the intended number of clients.

program evaluation A process that leads to judgments about the effectiveness, impact, or benefit-costs of a program.

programs A set of operations, actions, or activities designed to produce certain desired outcomes.

rehabilitation The reacquisition of lost abilities.

role status A set of valued activities that are considered normative for a specific age group. Examples include

school, independent living, employment, and recreation/leisure pursuits.

An impact or outcome-based evaluation addresses the essential question of whether education and social programs are delivering the desired results in terms of person-referenced outcomes. Outcome (impact) evaluation is a type of program evaluation that uses valued and objective person-referenced outcomes to analyze a program's effectiveness, impact, or benefit-costs; this is different from process evaluation, which emphasizes simply whether a program has carried out a stated goal or objective. This discussion focuses on effectiveness and impact in impact evaluations.

The Difference between Outcomes and Impacts

It is common to use the words outcome and impact interchangeably, and therefore the terms outcome evaluation and impact evaluation are often considered to be interchangeable. Technically, there is a difference between outcomes and impacts; however, in common parlance, evaluators typically treat them as meaning roughly the same. Strictly speaking, impacts occur on program staff and funders, and possibly some other stakeholders, all of whom are upstream of the outcomes. In this entry, outcome is used to refer to any results or consequences of an intervention, the evaluation model is

referred to as outcome evaluation, and impact analysis is considered to be a component of that model.

Impact analysis should be done only after a program has attained a level of stability—we cannot look at the effects of a program before we are certain that the program has been implemented as intended. Attempting to assess the impact of a program that has yet to be put into place is fruitless. In practice, an impact analysis should be preceded by an implementation evaluation designed to determine that the intended program elements are in place. In addition, demonstrating that changes in behavior occur as a result of a program is not always easy because behaviors are likely to naturally change over time. Also, determining which changes occur as a result of natural forces such as experience or maturation and which occur as a result of the interventions provided by a program is difficult.

Uses of Outcome Evaluations

Program evaluations with an outcome or impact focus are especially important for nonprofits, educational institutions, and social programs. These organizations typically design intervention programs that have a particular population with particular needs in mind. Therefore, these organizations have a vested interest in seeing whether or not the programs are meeting the needs of the population. Funding groups are also typically interested in outcome evaluations. These groups hold a vested interest ensuring that their financial and human resources are being allocated to a program that solves social and/or educational problems. An outcome-based evaluation focuses on the notion of efficient allocation of resources—whether an organization's or program's activities are bringing about the desired outcomes. Outcome-based evaluations can be thought of as an accountability measure in that these evaluations seek to prove that programs are not to simply engaging in activities that seem reasonable at the time. Service has traditionally been measured in terms of what is provided (counseling, therapy, guidance, and the like), and “good” service has been viewed as that which is provided by a qualified person. However, service needs to be viewed not only in terms of process, but also in terms of outcomes. Outcomes can be considered as benefits to clients gained through participation in the program. These are usually described in terms of enhanced learning (knowledge, attitudes, or skills) or conditions (increased literacy, self-reliance, or reduced negative behaviors). Outcomes are sometimes confused with program outputs or units of service, which include the number of clients that went through a program. Outcomes are the effects that programs have on clients, whereas outputs are simply the number of services provided to clients.

Outcome-based evaluation is especially important in light of trends currently sweeping educational and social programs. These trends include a quality revolution, consumer empowerment, increased focus on accountability, the emerging paradigm of practical evaluation, and an emphasis on enhanced functioning. The quality revolution focuses on such issues as quality enhancement, teacher quality, school quality, quality-of-life issues, and quality assurance. These emphasize that quality is essential to both the processes of service delivery and the outcomes resulting from those services. The consumer movement is also gaining in power and popularity. Educational and social programs are considering the needs of consumers as a critical concern. For example, this phenomenon can be seen in the issue of school choice. Proponents of school choice emphasize that parents and children are consumers of education and thus design programs and schools tailored to the needs of those consumers. Outcome-based evaluation can become a critical part of the decision-making processes for consumers in terms of where they live or work, what school they send their children to, or what services they use. Accountability data is in demand by the government, funders, program managers, policy makers, and consumers. Accountability is currently defined in terms of outcomes and organizational effectiveness and efficiency. Most states employ an accountability system that requires public reports of school effectiveness. Outcome-based evaluation is consistent with the increasing need for accountability because it provides a value-added system of outcome data.

The field of program evaluation is also changing toward a more practical approach to evaluation. The classic experimental paradigm was very popular in the program evaluations of the 1960s and 1970s because of federal requirements to assess the efficacy of federally funded educational and social service organizations. This model is less practical when it is applied to social or education programs. Educators, social workers, and other providers of social services can rarely meet the required experimental conditions and assumptions. In addition, it is politically undesirable to withhold a potentially beneficial education or social program from human subjects.

The purposes of outcome assessments are to give direction to policy makers, accountability to constituents, and feedback for improving the program and the services provided. The questions to be addressed by an outcome evaluation should originate from the stakeholders: the governing committees, the policy makers, the staff of the program, and the constituents. The reason for this is so that the focus of the evaluation is meaningful to those who have the greatest interest in seeing it be successful. The stakeholders should also have a high level of commitment to use the results of the assessments for the development of policy, accountability, program evaluation, and program improvement. An evaluation

whose results are not used in a productive manner or as a means of improvement is a waste of time and money.

Outcomes Are Connected Logically to the Program

Connecting outcomes to the program seems like a simple criterion for outcome evaluations, but it is often overlooked. This criterion requires that the analyzed outcomes logically be the product of the services received through the program and not an unintended effect of externalities. The outcomes should first be identified as being sensitive to change and intervention; otherwise an intervention provided by a program would have no effect. The outcomes should then be attributed to the intervention in such a way that it is obvious that a link exists between the services provided and the outcomes observed.

Outcome-Based Evaluation Model

A common model for outcome-based evaluations has four components. The first stipulates that the mission statement and goals of the agency or program provider should shape the program's efforts. The second is that the interventions or services provided should mirror the goals and mission of the agency or program provider. The third is that outcomes should be value- and person-referenced (related to behaviors and role status or knowledge that can be changed as a result of interventions). The fourth component is that the stakeholders in the program should have a strong voice in the design and management of the program. This can be done through providing formative rather than summative feedback to the stakeholders. Formative feedback allows for the systematic evaluation and improvement of services, as well as identifying focus points for program change.

Recognizing Outcomes and Linkages

The linkage between processes and outcomes is a fundamental issue in many program evaluations. The purpose of an outcome evaluation should be to help define program processes, program outcomes, and the linkages between the two. Identifying and conceptualizing program outcomes and impacts are both inductive and logical processes. Inductively, the evaluator looks for changes in participants, expressions of change, program ideology about outcomes, and ways that service providers make distinctions between those who are receiving the desired outcome and those who are not. In programs that are

designed for individual progress or change, statements regarding change from program participants and staff may be global in nature. Such participant outcomes as personal growth, increased awareness, and insight into self are difficult to standardize and quantify, resulting in a situation in which qualitative analysis may be more beneficial and appropriate. The evaluator's job then becomes to describe what exactly happens to those in the program and what they have to say about what happens to them. Once data on both the processes of the program and the outcomes of the participants are available, it must be organized logically so that the processes and outcomes can be linked. A way to do this is to first classify outcomes (i.e., changes in knowledge, attitudes, feelings, behaviors, and skills). It is then possible to organize the data in a way that describes the content and focuses of the program. This enables both stakeholders and those outside the program to know which kinds of changes (outcomes) are occurring. The changes can then, through participant data, be related to specific program processes.

Using a process/outcomes matrix is helpful in organizing these data. In such a matrix, major program processes or implementation components are listed along the left-hand side and types or levels of outcomes are listed across the top. The combination of any process (identified by the mission of the program) with any outcome (identified through participant data from interviews or observations) produces a cell in the matrix. The process/outcome matrix becomes a way to organize, consider, and present the qualitative connections between the dimensions of the program and the outcomes of the program.

Evaluation Designs

The focus of the outcome evaluation is on determining whether the intervention has made a difference for the target groups or individuals. There are several ways to do this and these approaches constitute the evaluation designs. The designs may vary, but the essential question is the extent to which they produce results that allow us to connect the implementation of program elements to the outcomes. This effort to illuminate the causal link between the two is key to outcome evaluations. The most commonly used models are the pretest-posttest design, control/comparison group design, and regression design. Each model must establish a standard against which program results are compared.

Pretest-Posttest Design

The pretest-posttest design is the most common method of assessment that looks at only one group. A group of participants is given the intervention, which can also be considered the treatment, thus creating a treatment

group. Data are collected from the group both before and after the treatment. In this model, the expectation is that without the treatment, no changes would occur. Data are collected before treatment to establish a baseline for the individuals in terms of the behavior or skill being intervened on; data are collected after the treatment to look for differences, whether they be positive or negative. The differences that are observed are attributed to the intervention. This design, which uses only one group, is relatively easy and inexpensive to administer; a drawback is that it may not be possible to definitively attribute changes in outcomes to the treatment because extraneous variables are not accounted for.

Control/Comparison Group Design

The expectation in this design is that without the intervention, characteristics of the participants would be very similar to a group of people not in the program. The first step in this design is to identify and select an equivalent or similar setting or group of people. This group does not receive the treatment and thus forms a control group that the treatment group is compared against. The knowledge, behavior, or attitudes of the control group are measured over the same interval of time as those of the participants, or treatment group.

One of the best ways to ensure that the participant and comparison groups are comparable is to employ random assignment. This procedure ensures that each member of each group has an equal chance of being assigned to either of the groups. Random assignment addresses the possibility that the treatment group is different from the comparison group in a manner that affects program outcomes.

Control group designs determine the effects of a treatment in a more rigorous manner than do pretest-posttest designs and are commonly used in experimental design and pharmaceutical studies. However, control group designs are difficult to employ in educational settings because denying a potentially more effective treatment to one group is frowned upon. Moreover, treatment and comparison students may interact, thereby contaminating the groups by potentially sharing aspects of the treatment. The process can be adjusted so that classes or school buildings are randomly assigned to treatment or control status; this would solve the contamination problem because the entire population of the room or school would be in the same group, thus eliminating interaction effects.

An evaluator might also compare the observed results to those that would be anticipated in a hypothetical comparison group formed on the basis of his or her prior knowledge. Such knowledge might be rooted in average outcomes from other closely related programs, preenrollment status, archival data, and current data that can be used as benchmarks for comparison. By relying on

a general knowledge of preenrollment status, the evaluator may estimate what would have happened to participants had they not participated in the program. This design obviously presents some inexact estimation, and thus it is much less precise in terms of certainty, comparability, and generalizability.

Regression Model

This model uses statistical analysis to predict what things would have been like without the program. Unlike other designs, a regression design takes into account relevant factors both inside and outside the program. Regression analysis provides advantages over the simple comparison of mean values. In the two previous designs, data are produced at two points—either the same group twice or two groups once each. In order to observe change, the averages (means) from the groups are compared against one another. Regression analyses allow for more powerful tests of the program's potential effects because they statistically control for other extraneous variables. In addition, regression analyses include these variables in the model, allowing for the direct observation of the individual net effects on the outcome variable.

Basic Evaluation Procedures

Regardless of the design of a particular evaluation, some fundamental procedures should generally be followed:

1. Identify the major outcomes to study or examine. This may require reviewing the mission of the program and asking what the intended impacts are for program participants. It is important to look at the activities of the program and the rationale for doing each activity; the rationale for each activity results in an outcome. It is important to avoid the justification of ineffective activities and to focus on examining how well the activities are working. In addition, it is necessary to carefully state the hypothesized effects. In the project/program-planning stage, the developers should carefully state the expectations of the program when it has been implemented correctly. In some programs, the effects may be expected to over an extended period of time. The foci of social and educational programs often target complex problems that are not conducive to short-term solutions. The effects of social and educational programs may also be expected to happen in stages—one stated effect is expected to create another.

2. Prioritize the outcomes. This is especially important if time is an issue because stakeholders may then want to target selected outcomes for the evaluation to concentrate on rather than trying to evaluate a multitude of outcomes. Also, be sure to identify possible unintended effects. Most

programs have possible associated risks that must also be identified in the planning stage. The evaluation can then assess whether the unintended effects occurred.

3. Define the measurement criteria. For each outcome, specify what observable measures or indicators will suggest that the outcome is being achieved with the clients. This is often the most challenging and confusing step of evaluations. The researcher must transfer his or her thinking from rather intangible concepts to specific activities. In this step, it is often useful to have a secondary evaluator to serve as a devil's advocate. The secondary evaluator questions the assumption that an outcome has been reached simply because certain associated indicators are present. Although it may be difficult to define the indicators in social and/or educational programs, they must be clear enough so that evaluators can obtain consistent and reliable data. Terms should be clarified so that evaluators understand exactly what is to be measured and how it is to be measured.

4. Determine the appropriate time periods. Information about the results is important to stakeholders, the people with investments in the program. The stakeholders may need or want information immediately, and this may not always fit with the necessary timelines for data collection. Thus, in order to most effectively work with the stakeholders, evaluators must often compromise the ideal time periods. This step addresses issues such as how far back in time baseline data should be collected and how long the program should operate to give it a fair opportunity to show results.

5. Monitor program implementation. Program monitoring should occur in a systematic way so as to aid program personnel in correcting and overcoming problems, to effect management improvements that may reduce future implementation failures, and to interpret program results correctly. Some evaluators consider this step to be the most important in ensuring that the program is implemented as it was originally planned. As noted earlier, implementation evaluations may also be conducted as separate evaluations, but in the event that separate evaluations are not possible, implementation monitoring is helpful.

6. Decide how data can be efficiently and realistically gathered. Consider program documentation, observations of program personnel, clients in the program, questionnaires and interviews about clients' perceived benefits from the program, documentation of the program failures and successes. If an evaluation is to include reporting on personal information about clients participating in the program, the clients' consent to do so must be gained beforehand. Clients have the right to refuse to participate. Collect data systematically. The data collected on program implementation, hypothesized effects, and unintended effects must be as accurate as possible. If more than one evaluator collects data, each must follow the

same rules and use the same definitions. If data are collected over a long period, the same rules and definitions must be used throughout to ensure consistency.

7. Analyze the data. Data analysis should produce a description of the program as it was implemented.

Common Statistical Analyses for Outcome Evaluations

In program evaluations, it is often more useful in practical terms to describe events accurately than it is to test specific hypotheses. First, hypothesis testing is often not practical in social and educational program evaluations due to the constraints on experimental design. Second, stakeholders often do not have the prior knowledge necessary to understand the level of data that will emerge from such studies—thereby making descriptive information more appropriate. Along these lines, an evaluator may simply want to describe the characteristics of the people served by the program, to summarize the services or interventions provided by the program, or to summarize the status of program participants on a range of outcome variables. The two best methods for looking at this type of data are matrices and descriptive statistics. The data can easily be put into a matrix so that it is readily described and exhibited, and these matrices coordinate well with descriptive statistics, especially such calculations as the mean or percentages.

Descriptive statistics can provide clear insight into important characteristics of the program's clientele, the interventions needed by the clientele, the interventions being provided, and the effects of the interventions. Such data allow aspects of the program to be quantified, and questions that will be answered by later stages of the evaluation to be refined. Describing the data at intervals of the evaluation allows the program to be monitored, the evaluation foci to be refined, and any further necessary interventions to be revealed.

Reality Check: Obstacles to Reporting Evaluation Results

Two major problems frequently emerge when evaluators seek to report results from outcome-based evaluation: (1) the equivocal nature of the results and (2) a skeptical audience. Findings are generally equivocal for a number of reasons. First, it is frequently not known how specific interventions produce specific outcomes. Numerous internal and external factors, often called side effects, can have significant influence on the results of a program. Each of these factors must be controlled for experimentally

in order to be able to attribute the outcomes to the interventions with certainty. An evaluator is often left uncertain about the degree to which a particular program can be held to have caused observed changes. Second, the results may not be clear or consistent. They may even contradict one another—some results may point in direction, some in quite another. This presents a challenge to the evaluator to explain this contradiction. Third, the data collection method may be inconsistent with the type of analysis performed. For example, if an evaluator collects data that deals with a program's effectiveness, these data should not be used for making cost-benefit statements.

An evaluator may also encounter a skeptical audience. Evaluators must present evidence to an audience that may be resistant to change or criticism. People generally know what they want to believe and are hard to convince that this is incorrect. People also find change difficult and, if the evaluation points to change(s) being needed, this may be met with resistance. The program's stakeholders may often hold differing views as to what the central purpose of the program is and therefore often do not agree about what the purpose of the evaluation should be. Thus, reporting the results of an outcome evaluation may not be easy. Given the need to negotiate these sensitive issues, it is vital that evaluators communicate their results well.

Establishing Credibility

In seeking to establish credibility, evaluators ought to strive to demonstrate competence and to report results in a straightforward fashion. This is more readily accomplished when an evaluator understands the program and its context, works with the stakeholders of the program, and is competent and honest. Before any evaluation is done, the evaluator must become familiar with the program by spending time in the program itself. The evaluator should also familiarize him- or herself with the history of the program, the program's organization, the culture of the program, the services provided by the program, and the community context of the program. The basis of the evaluation—the approach, the questions, and the activities—comes from knowing the context of the program. Because program stakeholders are likely to

have varied opinions regarding the goals they hold for the program, working with them is key. In order to be competent, the evaluators must understand the basic requirements of an outcome evaluation. They must be able to analyze the data correctly, meeting the requirements of any statistical analyses performed. Evaluators must also be able to explain to lay people the differences between statistical and practical significance with regard to any statistics found or run. Stakeholders may not understand the concept of statistical significance and how it applies to the results presented to them. Evaluators must be honest in terms of what the evaluation can deliver. It is important not to over-promise. Evaluators should be thorough in their descriptions of the questions asked, the measurement of the outcomes, and the legitimate uses of the data.

Glossary

database An electronic means for storing, sorting, cataloging, retrieving, and accessing information.

electronic commerce (e-commerce) The exchange of goods or services at cost to the user via electronic means. Typically, it involves the use of the World Wide Web and related technologies.

electronic government (e-government) The provision of information and services by a government to other government agencies, businesses, and citizens via the Internet. It can span local, state or provincial, national, and supranational levels.

information Anything that informs or produces a difference in knowledge or understanding. Information can be found in many forms and is an essential part of virtually every contemporary activity, event, and interaction.

information access The ability to obtain the information being sought.

information behavior A range of acts that includes seeking, avoiding, sharing, censoring, using, or suppressing available information.

information management The entire range of technical, operational, and social functions of a system handling information, affecting the creation, organization, storage, and disposition of information; the access to that information; the behaviors of users of the information; and the information policy environment in which it exists.

information policy Rules and guidelines, such as laws and regulations, created by government agencies and

institutions to steer the creation, management, access, and use of information.

measurement A process by which a value is attached to an observable phenomenon or relationship.

The social measurement of information management is the procedure of employing research strategies to attach a value to an observable phenomenon or relationship involving the management of information in an individual, organizational, or social setting. It encompasses a range of strategies and methods that can be used to describe and assess the social impacts related to the management of information. Studies of information management most often focus on the way information is accessed, the behaviors of individuals as they interact with information, and policy influences on information management. Measurement approaches in these areas of information management are in a process of evolution and refinement.

Introduction

Social measures currently used in information management primarily originate in or are derived from other academic disciplines, because information management is an area of study that is still evolving and expanding. As quickly as information technology changes, so does the

way information is relayed, stored, and processed to adjust to incorporate newer, more effective, and more efficient management techniques. For example, governments around the globe are adapting government agency structures to incorporate database and computer technologies in their daily information transfers. Moreover, there is considerable discussion as to the appropriateness of quantitative, qualitative, mixed methods, action research, and other approaches to social science measurement in general. There are several valid ways to examine these issues. As such, the definitions and measurements used herein have been selected as prime examples of the multidisciplinary and evolving nature of this field of inquiry.

The issues related to the social measurement of information management can be examined as they are used in the study of information behavior, information access, and information policy. These three broad areas of research account for many of the areas in which information management can be studied and provide for the discussion of a wide range of different social measurements. To understand how social measures can be applied in the management of information, the meanings of information are first examined. Concepts of information management are then reviewed.

What Is Information?

Information is anything that informs or produces a difference in knowledge or understanding. In its many forms, information is omnipresent in modern society, having a wide array of uses and meanings, with a breadth of purposes and manifestations. The term “information” can indicate a process (such as a message passing from sender to receiver), an item of knowledge (such as a piece of news), or a thing (such as a document). Information can also be the content of a message, anything that is communicated, or data that have a specific purpose. Information can be found in data, text, objects, and events, in both physical and electronic forms. As a result of the multiplicity of its meanings and roles, information is an essential part of virtually every contemporary activity, event, and interaction.

As a result of significant advances in information technologies in the past two decades, information has become a part of practically every interaction in society. This means that the various roles that information plays can be examined using social measures. One of the most important contexts in which information can be measured is the management of information.

What Is Information Management?

Information management is the entire range of technical, operational, and social functions of a system that is used

to handle information. Individuals, social networks of individuals, organizations, businesses, and governments all engage in some form of information management. They organize the information they use to communicate, to record history, and to share, store, and create meaning from information. Information management affects the organization of information, the access to information, and the ways in which users can interact with the information. Information management further includes policies that affect the availability and uses of information.

Information management is usually influenced by a strategy or framework that guides the planning, application, and uses of that information. A university, for example, needs a framework for their information systems to accommodate instantaneous changes in student enrollment, across-the-board changes in tuition fees and balances, occasional changes in faculty data, and so forth. Information management strategies influence the relationships between information, technology, and the larger social or organizational information, and have an impact on the functions of information and information systems. Some agencies and businesses do nothing but manage information.

The social measurement of information management is becoming extremely important in this information age, because all organizations employ information in some manner, using and providing some amount of information as a central function of the operation of the organization at some level. Many businesses have embraced electronic commerce (e-commerce) and many governments around the world are providing information and services through electronic government (e-government) web sites. Within these business and government organizations, information has technical, operational, and social roles. Most organizations use information technologies and information systems to provide or deliver information to service populations, such as patrons, customers, or citizens. The increasing usage of information by a diverse range of organizations heightens the importance of measuring information management, as the way in which an organization manages its information affects the organization and the organization's service population.

Social Measurement and the Information Management Process

The general process of the management of information provides numerous opportunities for study. Generally, social measures are intended to translate observable relationships, organizations, characteristics, and events into classifications or data that can be employed to discuss, analyze, and represent the nature of the observed phenomena. Social measurements of information management can be applied inductively or deductively in the research process. They can be used in a range of ways

in research, from exploring new aspects of phenomena to evaluating a complex information system. These measures, ideally, allow for describing phenomena and relationships that would otherwise remain hidden.

The process of information management can generally be envisioned as offering several distinct ways to apply social measures:

1. The information can be analyzed for the types of information involved, the purposes of the information, the intended audiences for the information, and the presentation of the information. For example, a department store may perform customer focus groups to elicit feedback on the store's marketing effectiveness. By ranking or even assigning numerical values to the participant responses to focused questioning, the store can determine where and how the information they are presenting is reaching its intended audience and how the information appears to the intended customer group.

2. The life cycle of the information can be researched. Information can be created, collated, processed, disseminated, deleted, and archived. Each of these and many other steps in the information life cycle present opportunities to apply social measurements. For example, a bank will have policies as to how customer information is processed, who can access that information, where it is sent, and how long it will be kept. These policies could then be measured in terms of security and privacy.

3. The decisions made regarding information can be studied. From the original idea to create or collect information to the use of the information by an individual, each decision made to create, retrieve, access, use, and apply the information can be examined with social measurements. For example, the decision-making process can be studied as an individual searches for information on a certain web site. Information seeking-behaviors can be assessed using information search process (ISP) measurement, and these findings can be used to determine how to improve information management on the web site.

4. The impacts of the information on society can also be examined. Issues that can be studied with social measures include how the information is used, who has access to it, how it affects particular populations, and how it shapes social behaviors. The library community, for example, can survey library users and nonusers about their information needs in order to determine how the library affects the community it serves. This data can be combined with other community statistics to create a fuller picture of how the information available at the library influences users in that community.

Though there are likely other opportunities to apply social measurements to the process of information management in specific circumstances, the preceding criteria introduce the breadth of possible applications of social measurements.

Approaches to the Social Measurement of Information Management

Diverse sets of measures have been employed in the study of information management. Many of these measures have been used more as abstract methodologies than as applied measurements. Information management research is influenced by theories and methodologies developed in other social and human sciences, including information studies, communications, sociology, psychology, information technology, management of information systems, business and administration, and education research. Researchers in these diverse fields often employ a range of social measures for various types of research about issues of information management. As a result, many different social measurements are used in the study of information management; a comprehensive review of the social measures that are applied to the management of information would be extensive and is well beyond the scope of the discussion here.

The social measurement of information management can be done with quantitative, qualitative, or action research, or even mixed methods, using many different types of data collection instruments to describe information measurement in individual, organizational, or social settings. A selection of the most common methods, measures, theories, and techniques that can be used in the social measurement of information management is included in [Table I](#).

Given the range of possibilities that could be discussed in terms of the social measurement of information management, the focus here is only on a selection of relevant

Table I Social Measurement Instruments for the Study of Information Management

Analysis of administrative records	Media richness theory
Behavioral intention toward technology usage	Models of question negotiation
Bibliometrics	Narrative research
Case studies	Perceived usefulness
Cognitive authority	Personality tests
Conjoint analysis	Phenomenology
Demand simulation	Policy analysis
Diffusion of innovation	Question answering
Ethnographies	Social network theory
Focus groups	Speech act theory
Genre theory	Surveys
Grounded theory research	Task-system fit
Information search process	Technology acceptance model
Measurement of user information satisfaction	Unobtrusive observation
	Usability assessment
	User modeling

studies and measures. These have been chosen to represent well-respected methodologies in information behavior, information access, and information policy. Of the three, information behavior has been the most heavily studied and has created more generalizable approaches to social measurement. The other two areas are just as valuable as areas of research, but there simply has been less scholarship to date.

Information Behavior

Information behavior is an individual's action (or inaction) when faced with an information need. The range of information behaviors includes deciding that information is needed, searching for information when desired information is not present, sharing or suppressing information once discovered, avoiding information, storing information, and myriad other possible behaviors. Information behaviors affect, and ultimately shape, how individuals manage information. As a result, studying and measuring information behaviors help provide an understanding of how information can be managed to facilitate its use.

Some examples of the use of social measurement to study information behavior include studies that use social network theory (SNT), ethnographic, sense-making, and ISP methodologies to analyze observed behavioral phenomena. SNT is a way to account for the social connections that an individual employs to reach valued information. Researchers study social positioning by studying the relationship between the strength of social connections and the quality and quantity of information that an individual receives. Ethnographic methods used by some researchers measure information behavior to examine how individuals behave in a natural setting with everyday information. Sense-making research focuses on how individuals approach the world with underlying assumptions that affect how they use information to make sense of the world. Sense-making methodologies provide a detailed examination of an information-seeking event in order to determine whether the information need has been met. The information search process methodology is another prominent social measurement in information management behavior. The ISP is a six-stage model for studying how meaning is sought in the information-seeking process from the point of view of the user.

Information Access

Information access is the ability to obtain the information that an individual is seeking. The social measurement of information access can reveal ways in which information can be managed so as to provide greater awareness of available information, to improve access to the information, and to assure that the information can be understood

by and be of benefit to those who seek it. Information access can be affected by awareness of the existence of information, the availability of the technology necessary to reach that information, the knowledge to use any necessary technology properly, the ability to locate the desired information, and many other factors. The technical, social, and economic factors that inhibit information access are commonly identified as "barriers," indicating a gap in the abilities of certain groups of individuals to access information in both a print and a digital environment. Specific populations are particularly prone to barriers to information access, and each of these populations and barriers can be examined using social measurements.

Research using social measurement to examine information access often has been related to access to the Internet. These studies have used a range of survey approaches, focus groups, and web site analyses to evaluate levels of information access, for a range of populations, to electronic information and services such as e-commerce and e-government. Examples of research using these approaches include surveys of access to e-government by demographic populations, research by the U.S. Department of Commerce into levels of Internet access in relation to economic factors, and studies of student access to the Internet.

Information Policy

Information policy is the set of guidelines, regulations, and laws that determines how information can be stored, provided, and used. Policy research is, by its nature, complex, multidimensional, and can be examined using a range of theoretical frameworks. Governments, primarily at the national and state levels, pass laws and issue regulations that govern the dissemination and use of information by individuals, private entities, and government organizations. Information policies affect access, use, dissemination, transfer, sharing, storage, transmission, privacy, security, and display of information. These laws and regulations legislate many of the roles of information in a society, but they are also shaped by the social roles of information. For example, in the United States, the First Amendment guarantee of freedom of speech has created a social expectation that information will usually be available, which influences how the government can regulate or direct the flow of information.

Differences in philosophy regarding information policy have led to considerable discrepancies in the ways in which separate nations handle the management of information. The social measurement of information policy can demonstrate how policies impact organizations that manage information and individuals seeking access to the information. Information policy is studied

through several types of social measurements, including social interventions, surveys, policy analysis, and case studies.

Specific examples of social measurements of information policy include descriptive modeling of the policy environment, side-by-side analysis, review and analysis of legal and policy instruments, and evaluation of outcomes measures. Examples of these measurement techniques can be found in the literature; some authors have described how such techniques can be used in association with a range of frameworks for studying the policy process, including the “stages heuristic,” “institutional rational choice,” and a number of other approaches.

This area of information management has been the subject of limited study to date. Some work has been done to bridge issues of information policy with issues of information access and information behavior, such as examination of information poverty in the electronic environment from the interconnected perspectives of information policy, access, and behavior. Further work that investigates policy in relation to access and behavior may help to expand the use of social measurements in information policy.

The Future of Social Measurement in Information Management

As previously noted, social measurement of information management is still evolving and draws on techniques and frameworks from a host of social and behavioral science fields. There is limited agreement on key definitions of terms as fundamental as “information” and “information management,” resulting in some disagreements as to how measurement does or should take place. Currently, the measurement approaches are disparate and lack a cohesive or organized relationship. A number of key measurement issues related to information management have yet to be adequately addressed:

- What specific variables best describe the information management process? How are these variables operationalized?
- Does information management, as a process, vary from a print to a digital environment? From an individual to organizational context? If yes, how?
- What social activities or impacts related to information management are most important for measurement?
- How can different epistemological paradigms (e.g., positivism, constructivism, and ethnographic approaches) be best used in social measurement of information management?

These issues only begin to suggest the complexity of work that needs to be addressed in this area. The social measurement approaches identified and proposed in the literature thus far offer only a preliminary understanding of the validity and reliability of these measures and of the situations or contexts in which one versus another measure might be more or less appropriate. Social measurements also need to be studied and applied much more extensively in relation to information access and information policy. Further, there is still limited understanding of how social measurement of information management can “improve” information management in different individual and organizational contexts. In short, there remains much work and research to be done in the development of social measurement of information management.

Conclusion

Social measurement concepts relative to information behavior, information access, and information policy provide a foundation for further research in information management. The array of social measurements discussed herein offer quantitative, qualitative, action research, and mixed-method approaches to the study of information management. The far-reaching nature of information management allows for the use of such a diversity of social measurements. As information technology continues to evolve, the research in this field will parallel these developments, continuing to refine the social measurement of information management.

Innovative Computerized Test Items

Fritz Drasgow

University of Illinois, Urbana–Champaign, Illinois, USA

Glossary

computer adaptive test A computer-administered test in which items are selected from a large item pool so that they are appropriate for each examinee; specifically, a more difficult item is selected following a correct response and an easier item is selected following an incorrect response.

conventional test A test format in which all examinees are administered the same items in the same order.

disattenuated correlation The correlation between two variables that would be obtained if the two variables could be measured without error; classical test theory provides a simple formula for computing this quantity.

dimensions of innovation The fundamental ways in which assessment can vary; specifically, alternatives to paper-and-pencil conventional tests using multiple-choice formats with number-right scoring.

item response theory A measurement theory that relates the probability of a correct or positive response to the underlying trait assessed by a test.

latent trait The underlying skill or ability assessed by a test.

Innovative computerized test items refer to item types that creatively use the computer's capabilities to improve measurement and assessment. For example, multimedia stimuli may be presented, dynamic branching may be used so that the test responds to the examinee, and examinees may construct responses using tools such as spreadsheets or computer-assisted design tools.

Introduction

The traditional multiple-choice test, administered via paper and pencil, provides a highly constrained

assessment environment. All examinees receive the same items, they select the best answer from a short list of options written by the test developer, and their scores are usually based on the number of items they answer correctly. Although it is possible to include color pictures, sound clips presented by tape recorder, or video clips from tape or videodisc, the inclusion of such rich stimuli is rare. Consequently, traditional tests seem most suitable for assessing the breadth and depth of an individual's accumulation of information and facts that can be expressed via written communication.

Many skills and proficiencies are not easily assessed by paper-and-pencil multiple-choice items. Consider, for example, musical aptitude, the diagnostic skills of a physician, or the design ability of an architect. Musical aptitude cannot be assessed without the inclusion of sound; the assessment of medical diagnostic skills requires a dynamic environment in which tests can be ordered, some conditions can be ruled out on the basis of the initial results, and then further tests and treatments can be prescribed; and evaluating architectural ability requires an open-ended response format in which individuals can create their own unique designs.

Innovative computerized item formats have been introduced over the past two decades to improve the assessment of skills and abilities not easily measured by paper-and-pencil multiple-choice tests. Computerization allows dynamic interactions between the test and the examinee; multimedia capabilities includes high-resolution color displays, digital sound, and full-motion video; and sophisticated algorithms can be used to score open-ended responses recorded by the computer. This increased flexibility in assessment methodology has led to much

innovation and genuine improvement in evaluating critical skills and abilities.

Some History

Test developers and psychometricians recognized the potential benefits of computerized test administration long ago, in an era when computers were quite primitive. Bartram and Bayliss, for example, provided a review of efforts dating to the late 1960s that utilized teletype terminals connected to mainframe computers. This work, largely in the area of clinical psychology, was devoted to automating test delivery by simply using the computer to deliver conventional tests and assessments. Memory on mainframe computers was limited to a few hundred kilobytes, the mouse had not yet been invented, and widespread use of graphical user interfaces lay well in the future.

In the late 1970s, the United States military testing program began a program of research designed to develop and then implement computer adaptive tests (CATs). Such tests not only administer test items via computer, but also use the computer's computational capabilities to determine which item in a large item pool is most informative about an examinee's ability given his or her pattern of responses to already administered items. The first item administered is of intermediate difficulty; if an examinee answers correctly, the computer branches to a more difficult item, whereas the computer branches to an easier item following an incorrect answer. Item response theory (IRT) is used as the basis for ability estimation and branching algorithms. Although computer systems had improved from those in the 1960s, McBride, and Wolfe and co-workers, recounted difficulties encountered due to the limitations of computers in the late 1970s and early 1980s.

It was not until the mid-1990s that personal computers had finally become adequate for innovative item types to proliferate. Graphical user interfaces had finally become pervasive, sound cards and speakers were standard, memory had become relatively inexpensive, video adaptor cards could display full-motion video, and computation power was adequate to implement complex algorithms. Thus, the hardware and operating systems had at last evolved to a point where test developers could innovate without extraordinary efforts.

Dimensions of Innovation

Parshall and co-workers described five dimensions of innovation that can be used to characterize many novel computerized item types. The first two are closely related: item format and the examinee's response action. Item format refers to the distinction between selected response items, with multiple-choice items as a

prominent example, and various alternatives. For example, constructed response items, such as essays or architectural designs, require examinees to create a response. Other response formats blur the distinction between selected and constructed responses; for example, examinees may rearrange or organize components via the computer's drag-and-drop functionality to reflect a logical ordering or relationship. Response action describes how examinees make their response. The response action for a traditional multiple-choice test consists of using a No. 2 lead pencil to fill in a bubble on an optical scan sheet. Analogous response actions for computer-administered multiple-choice items include clicking on a bubble with a mouse or speaking aloud to a computer with speech recognition capabilities. Other response actions include drag-and-drop operations, entering text or constructing equations, and using a joystick to track a moving object.

Parshall *et al.*'s third dimension is media inclusion, which refers to the use of nontext material. Examples include Ackerman *et al.*'s high-resolution color images on a test of dermatological skin disorders, Vispoel's sound clips on a computerized test of musical aptitude, and Olson-Buchanan *et al.*'s full-motion video to assess workplace conflict-resolution skills. Note that the capability to include such diverse materials greatly increases the range of knowledge and skills that can be assessed.

Degree of interactivity is Parshall *et al.*'s fourth dimension of innovation. The computer can be used as an electronic page turner to administer a fixed set of multiple-choice items to each examinee in the same order; here the degree of interactivity would be nil. CATs, on the other hand, select items from a large item pool so that their difficulty level matches the ability of each individual examinee, thus illustrating the dynamic capability of computer-administered tests. In addition to this dynamic branching capability (based on the computer "interacting" with the examinee's responses), computerized assessments also allow interactivity between the examinee and the item. Such assessments can have the flexibility seen in video games and allow a wide variety of examinee interactions with the stimulus materials.

The fifth dimension of innovation is the scoring method, which is closely tied to item format and response action. There is relatively little opportunity for innovation with selected response items where examinees click a bubble to indicate their choice; answers are typically scored as correct or incorrect. In contrast, perhaps the greatest challenge for test developers utilizing constructed response items is computerized scoring (note that it is always possible to use human graders, but this is slow, inefficient, and expensive). Scoring algorithms for essays, architectural designs, and mathematical formulas entered by examinees represent

some of the most interesting and sophisticated work by psychometricians in the area of innovative item types.

Desiderata

There is little value in innovation for the sake of innovation. Instead, it is important to ask "What is the value added by the innovation?" To address this question, in 1999 Bennett *et al.* examined whether their innovative item type broadened the construct measured by traditional items. Specifically, they constructed tests consisting of 20 items of the new type, estimated reliability, and then computed the disattenuated correlations of the test forms consisting of new items with the old test. Their disattenuated correlations were in the 0.70s, indicating a moderate but not complete overlap of the latent trait measured by the new items with the latent trait assessed by the old test. Thus, adding the new item type to the test has the potential to increase the substantive richness of the assessment by broadening the set of skills that are assessed.

A second consideration is authenticity: to what extent does the test assess the skills required of the candidates? For example, the purpose of licensing exams is to protect the public by ensuring that only individuals who can work competently in their profession receive passing scores. Unfortunately, there is often a substantial gap between proficiency in answering multiple-choice questions about some content area and skill in the practice of the corresponding profession. Consider the difference between answering multiple-choice questions about the physiology of the heart and cardiac system versus performing open-heart surgery. Although this example is obviously an exaggeration, the gap between the knowledge and skills assessed by multiple-choice items and the knowledge and skills essential for competent practice in a profession provides strong motivation for innovative computerized item types. Of course, adding innovation item types to a multiple-choice licensing exam broadens the skills assessed and improves the substantive richness of the exam.

Thus, a goal of computerization is high-fidelity emulation of critical real-world skills and practice. By using graphics, sound, and full-motion video, many real-world activities can be realistically simulated by the computer to provide highly authentic assessments. Performance on a realistic emulation of a real-world activity is then assumed to provide a valid indication of an individual's level of performance on the activity itself and related tasks. Beyond obvious face validity and apparent content validity, empirical demonstrations that such assessments add value beyond traditional multiple-choice tests is very important. Collecting evidence of improved construct validity for these assessments constitutes an important area for future research concerning innovative item types.

Innovation to Improve Existing Tests

It is possible to view innovations as falling into three categories. First, new item types that improve the assessment of some ability or skill can be created. Here the assessment of some well-known construct is enriched by broadening the set of skills that are evaluated; Bennett *et al.*'s research provides a good example. The second category includes assessments designed to improve the authenticity of the assessment. Licensing exams that use computers to create high-fidelity simulations of professional activities, such as the medical and the architectural licensing exams discussed below, fall into this category. Assessments of constructs not easily measured by conventional tests constitute the third category. Examples include tests of musical aptitude and interpersonal skills.

To improve assessment of familiar constructs, a wide variety of innovative item types have been developed. Zenisky and Sireci provide an extensive summary of such item types. They give examples that illustrate drag-and-drop, drag-and-connect, moving objects to create a tree structure, inserting text, editing text, highlighting text, and several other response actions. In this section, a few examples will be given to illustrate how such alternative response actions can be used to improve measurement.

In 2000, Bennett and co-workers noted that traditional mathematical reasoning items are "tightly structured and contain all the information needed to reach a single best answer," which is given as one of the multiple-choice options. To broaden the mathematical reasoning construct, they proposed using an item type that they called mathematical expression. Here a mathematical question is posed and the examinee's task is to write an equation that gives the answer. For example, an item might ask "Suppose a raft drifts M miles down a river in K hours. How far would it drift in 2 hours?" Examinees use a simple equation editor to enter their answers. The challenge for this item type is scoring: many mathematically equivalent expressions can be entered (e.g., $2 \times M/K$, $1/K \times 2 \times M$, and $2M/K$). Bennett *et al.* used symbolic computation principles to reduce answers to a single canonical form that could be compared to the correct answer. In an evaluation of the scoring algorithm, they compared the computer grading to human grading and found an accuracy rate of 99.62% (and most of the discrepancies were actually errors in the examinees' use of subscripts that human graders scored leniently but the computer algorithm scored as incorrect).

Another example concerns the assessment of writing skills. The most direct approach is to have examinees write essays, but human grading is time-consuming and expensive (computerized grading is an area of active research).

Davey *et al.* note that two multiple-choice approaches to assessing writing skills are common. The cloze item type presents examinees with a short piece of text that includes a blank; examinees then select the missing textual element from the multiple-choice options provided. The second item type also presents a short piece of text, but here some part is underlined. Examinees are instructed to select the multiple-choice option that provides the best replacement for the underlined text. Note that both of these approaches highlight the selected response nature of the test in that the item focuses examinees' attention on a specific portion of a sentence.

In contrast, Davey *et al.* present longer essays with no blanks or underlined portions; some portions consist of exemplary prose and others contain errors. Examinees move the cursor to a part of a sentence they wish to edit and press the enter key. Multiple-choice options are then presented for revising that portion of the sentence (one option is to not change the text). Thus, examinees can change grammatical prose to ungrammatical, ungrammatical prose to an alternative ungrammatical form, and ungrammatical text to grammatical. This assessment format appears to constitute an improvement over the two multiple-choice alternatives in that examinees must decide what portions of the essay need revision rather than having the item format focus their attention on what is to be edited.

Of course, having examinees write one or more essays is the most direct means of assessing writing skills. Unfortunately, essay grading is plagued by low interrater agreement and high cost. Computerized grading has been an area of active research and newly developed scoring algorithms show considerable promise.

Improving Authenticity

In this section, three licensing exams that use innovative computer formats to improve authenticity are described. In each case, it would have been much easier for the test developer to construct an exam consisting entirely of multiple-choice items. Instead, these assessments required test developers to reconceptualize the assessment process, to decide what should be measured, and to invent a new approach to testing. The difficulties and challenges of this process were described for a variety of testing programs in a book edited by Drasgow and Olson-Buchanan.

The experiences of the American Institute of Certified Public Accountants (AICPA) provide a good illustration of why licensing exams are moving away from exclusive use of multiple-choice questions. Senior partners in accounting firms expressed concerns to the AICPA that newly hired accountants who had passed the Uniform Certified Public Accountant Examination lacked skills required to perform their jobs. For example, when clients

meet with accountants, they do not ask multiple-choice questions, but rather describe complicated dilemmas. The accountant, in turn, may need to conduct research, evaluate several options via spreadsheet analyses, and finally make a recommendation and provide supporting evidence. Multiple-choice questions are poorly suited to assess the higher order skills needed by practicing public accountants.

Uniform Certified Public Accountant Exam

In April 2004, the Uniform Certified Public Accountant exam began to incorporate computer-administered simulations in addition to multiple-choice questions. Each simulation describes a problem that might be encountered by an entry-level CPA. The simulation has a series of tabs across the top of the screen. Clicking the Directions tab causes the directions for the simulation to be displayed, the Situation tab contains details about the simulation, and additional tabs pose questions and guide the examinee through the simulation. Examinees will be assessed on the workaday tasks performed by entry-level accountants: entering values correctly into spreadsheets, determining gains and losses, evaluating risk, and justifying conclusions.

The Research tab is particularly interesting; clicking it produces resources such as a financial calculator, a spreadsheet, and a searchable version of a document containing authoritative accounting standards issued by the appropriate professional association. Examinees can be asked to copy and paste accounting standards that justify their decisions in the simulation; this is an activity commonly performed by practicing accountants.

The AICPA simulations have the "look and feel" of actual client encounters and therefore have considerable face validity. However, do they assess skills beyond those already tested via multiple-choice questions? An important area for future research will be an examination of the extent to which the simulations improve the assessment of candidates' readiness for jobs as CPAs.

Architect Registration Exam

Architectural site-design proficiency is a skill that appears poorly suited to assessment via selected response items: it is easy to recognize Frank Lloyd Wright's Fallingwater as an inspired design, but its creation required genius. Consequently, the Architect Registration Exam (ARE) has long incorporated constructed response items as part of the paper-and-pencil examination. The solutions were subsequently scored holistically by human graders.

A research team from the Educational Testing Service and the Chauncey Group International worked with the

National Council of Architectural Registration Boards to convert the constructed response portions of the ARE to a computerized format scored via algorithm. Part of this effort required the development of tutorial materials and a user interface that enabled all examinees—both computer-naïve individuals and computer-sophisticates—to easily create their designs. Bejar and Braun summarize evidence showing that examinees are able to construct all design elements (i.e., the user interface does not impose restrictions on examinees' imaginations) within the exam's time limits.

Interestingly, the research team did not attempt to develop scoring algorithms to emulate human graders. Bennett and Bejar argue that human graders should not be viewed as the ultimate criterion for evaluating computerized scoring because humans are unreliable and may be insensitive to important features of responses. Instead, Bejar and Braun note that the ARE computerized scoring algorithms were developed to be reproducible (not only should the same answer receive the same score when rescored, but the same scoring criteria should be consistently applied across answers), granular (the features of an answer are examined in a detailed way, rather than holistically), and hence more objective. Interestingly, these requirements had important implications for the development of design tasks: they had to be constructed in a way that allowed the scoring algorithm to be consistently applied. Consequently, it was necessary to construct design tasks according to a detailed set of specifications, which imposed a rigor and discipline on item writing.

Rigor in item development was implemented by careful specification of a few basic design tasks, called vignette types by the ARE research team. For each vignette type, many "isomorphs" (i.e., instantiations of the item type) that can be scored according to one algorithm were created. Moreover, these isomorphs are treated as psychometrically equivalent; examinees' scores are not adjusted for differences in difficulty across isomorphs of a given vignette type. Bejar and Braun describe a careful program of research studying characteristics of vignette types that may cause isomorphs to differ in difficulty and the learning process that enabled the development of isomorphs that are virtually identical in their psychometric properties.

National Board of Medical Examiners Case Simulations

In 1999, the National Board of Medical Examiners (NBME) began using computerized case simulations as part of the medical licensing exam. Each simulation begins with the computer providing a description of the patient's presenting symptoms. The user interface then displays an order sheet familiar to physicians. The candidate

physician can use it to request the patient's history, order a physical exam, order one or more tests, provide a treatment, or request a consultation; the case simulation software is able to accept orders for thousands of tests and treatments. The information given to the candidate physician following a request for a physical exam, test, or treatment is based on the simulated patient's condition.

In real life, each activity of a physician takes time to complete. The case simulation emulates this process by providing a clock on the computer screen. If the candidate physician orders a test that takes 90 min to complete, the information provided by the test is given when the candidate physician moves the clock ahead by 90 min. Simultaneously, the patient's condition progresses as if 90 min had passed.

Clyman *et al.* note that the NBME case simulation is designed to assess a candidate physician's patient care strategy in a realistic context. Multiple-choice questions artificially segregate components of patient care strategy. In contrast, a case simulation does not provide cues, but instead unfolds over time as does the actual care of a patient. Clyman *et al.* (1999, p. 31) note: "The complex interplay of clinical information about the patient with time and physician action cannot be accurately and comprehensively represented and evaluated by the separation of patient care into many individual parts." Indeed, Clyman *et al.* report that the disattenuated correlation between scores on the case simulations and scores on the multiple-choice portion of the NBME exam is approximately 0.5.

Assessing Constructs not Easily Measured by Conventional Tests

This section reviews assessments of two constructs that are difficult to assess via traditional paper-and-pencil methods. The computer's multimedia capabilities, in addition to its dynamic capabilities, suggest that innovative assessments of many other important human attributes will be developed in the years to come.

Musical Aptitude

Conventional assessments of musical aptitude have the test administrator use a tape recorder to play short audio clips. There are many problems with this approach, including poor-quality sound from old audio tapes, unfair disadvantage caused by sitting far from the tape recorder or another examinee coughing or sneezing as a sound clip is played, and pacing of the exam set by the test administrator rather than the examinee. Computerization solves these problems: audio clips recorded digitally do not degrade over time, each examinee wears headphones so that

seating is irrelevant and the effects of coughing and other distracting sounds are minimized, and the computer can proceed to the next item when the examinee is ready.

In programmatic research, Walter Vispoel has pioneered the development of computerized adaptive assessments of musical aptitude. Vispoel reviews earlier approaches to the assessment of musical aptitude and then summarizes his work. Interestingly, he notes that earlier researchers had disputed whether items should be nonmusical (so that they would be culture fair) or musical (so that they would resemble previously encountered melodies). Vispoel constructed test forms with both types of items, which he administered to a sample of college students. In a confirmatory factor analysis, a single overall musical aptitude factor fit the data well, with additional factors not improving fit. Thus, any dispute between musical and nonmusical items is pointless because both item types assess the same underlying musical ability.

Other versions of Vispoel's musical aptitude test have tested tonal memory. The computer plays a melody consisting of four to nine notes. The computer then plays the same melody with perhaps a single note changed. The computer display shows a digit for each note, as well as "0 = no change"; the examinee's task is to click on the digit corresponding to the note that was altered or click on "no change" if there was no change. Using the three-parameter logistic IRT model as the basis for the CAT, Vispoel has found that adaptive measurement provides precise assessment of musical aptitude with many fewer items than conventional tests.

Assessing Interpersonal Skills

Psychologists have been interested in assessing social and interpersonal skills since E. L. Thorndike's 1920 article. However, reviews of attempts to assess interpersonal abilities have concluded that such measures either are unreliable or measure traditional cognitive ability or personality. Attempts to assess interpersonal skills via textual material may be doomed to failure because such a format elicits intellectual processing. Chan and Schmitt, for example, found that a paper-and-pencil test of work habits and interpersonal skills had a correlation of 0.45 with reading comprehension, but a parallel assessment based on video clips had a correlation of only 0.05.

Olson-Buchanan *et al.* developed a computer-administered test of conflict resolution skills in the workplace. The assessment presents video clips depicting common workplace problems such as an employee informing her supervisor that another employee is taking credit for her work, an employee complaining to his supervisor that a co-worker is absent so often that their work group's productivity is affected, an employee telling her supervisor that she has been sexually harassed, and so forth. For

each scene, a first video clip depicts the conflict progressing to a critical juncture. Then, the video ends and a multiple-choice question asks the examinee what he or she would do if he or she were the supervisor. After the examinee selects a response, a second video clip presents a follow-up scene showing a likely outcome of the examinee's choice. Again, the video progresses to a critical point, the video ends and a multiple-choice question is presented. After this question is answered, the computer presents an entirely new scene.

In a sample of 347 examinees from six organizations, scores on the conflict resolution assessment showed a correlation of 0.26 with on-the-job performance ratings of the examinees by their supervisors. Correlations of the assessment with verbal and quantitative abilities were near zero. Other research has found relatively small correlations with measures of personality. In sum, this video assessment demonstrates criterion-related validity but is apparently not redundant with cognitive ability or personality.

Future Directions

For more than a third of a century, researchers have sought to improve assessment by computerization. However, for most of this time the researchers' ideas exceeded the capabilities of existing computers. It was not until the mid to late 1990s that graphical user interfaces on powerful personal computers with multimedia functionality became commonplace. Extraordinary efforts are no longer necessary to develop innovative computerized assessments; instead, off-the-shelf hardware and software provide the capabilities to devise a wide variety of assessments.

It is important to recognize that traditional psychometric concerns about reliability and validity pertain to these new assessments. Test developers should examine the psychometric properties of the new item types: item-total correlations, reliability, dimensionality, convergent and discriminant validity, and so forth. Bennett *et al.*'s research examining the value added by their new item type provides a good example of the research that is needed.

In addition to psychometric research, a better understanding of a content domain may be needed for the development of assessments using innovative item types. For example, the Educational Testing Service (ETS) introduced the computer-based Test of English as a Foreign Language (TOEFL) in 1998. Similar to Vispoel's work on musical aptitude, computer-administered audio clips can obviously improve the assessment of English language comprehension. But ETS was dissatisfied with simply utilizing audio clips as a new item type; the TOEFL 2000 project was initiated to develop a conceptual

framework for communicative competence, develop test specifications based on the new conceptual framework, and conduct research to test the framework and validate the new item types. Thus, a broad research and development program will be conducted to support this computer-based innovation in assessment.

Some major trends in computerized assessment are obvious. Licensing and credential exams, for example, are evolving in ways that make their assessments more similar to on-the-job practices. It is unlikely that traditional multiple-choice questions will be eliminated, but they will be supplemented by innovative item types that provide high-fidelity emulations of important professional skills. More generally, assessment media are changing to better match the skills and abilities assessed. Audio clips are used for musical aptitude assessment, video clips depicting interpersonal interactions are used to assess social skills, and computer-assisted design tools are used to assess architectural design skills. Matching the assessment media to the relevant skill clearly improves face validity and content validity; evaluations of criterion-related validity and construct validity are needed.

It is likely that the use of innovative assessment will continue to grow. Exams will emphasize the assessment of skills—such as a physician's patient management skills—in addition to measuring the breadth and depth of knowledge. The assessment's administrative medium will be selected to be most appropriate for the trait assessed, rather than the "one-size-fits-all" approach of traditional paper-and-pencil testing. The use of constructed response formats will increase, albeit slowly, because the development of valid scoring algorithms for such items is hard work. Finally, dynamic assessment methods, in which the computer responds to the examinee's actions as in the NBME case simulation, seem likely to proliferate.

University of Amsterdam, Amsterdam, The Netherlands

Willem Jan Willemse

University of Amsterdam, Amsterdam, The Netherlands

Glossary

actuarial valuation A valuation based on a combination of discounting and probabilities.

actuary An insurance mathematician.

antiselection A situation in which individuals with greater than average risk are able to purchase a policy at a standard average premium rate.

discounted value A valuation solely based on discounting cash flows.

equivalence, actuarial Payments having the same actuarial value.

equivalence, interest Payments having the same discounted value.

insurance policy A contract that offers protection (against economic losses) with respect to the time of death of the insured.

insured An individual covered by an insurance policy.

insurer A company offering insurance protection.

mortality table A table showing the rate of death at each age in terms of numbers of death or number of survivors; the basic instrument to determine death and survival probabilities for individuals belonging to a certain group of insured.

net premium The rate that an insured is charged (net of expenses).

premium reserve The amount retained to meet the difference between the actuarial value of future benefits and the actuarial value of future premiums.

risk classification The formulation of different premiums for the same insurance coverage, based on group characteristics.

underwriting The determination of the insurability of the applicant for an insurance policy.

Actuarial notation is explained and an example of a general mortality table is provided. Rates of mortality q , and how they are estimated, are discussed; an introduction to compound interest and discount calculations is followed by explanations of premiums, premium reserves, standard actuarial methods, risk classification, and some related subjects. In addressing the subject of mortality tables, the question is considered as to which mortality table has to be used for several types of insurance policies. Some aspects of the rich history of insurance are considered in combination with the development of actuarial science.

Introduction

Why Are Mortality Tables Needed in the Insurance Industry?

Mortality tables, also called life tables, are used by the insurance industry to calculate premiums and reserves for insurances and annuities. The tables are used to determine the death and survival probabilities of the insured. Other elements in the premium and reserve calculation are interest and expenses. A primary aspect of life insurance and annuities is the often rather long duration of the issued policies. An actuary (insurance mathematician) uses mortality tables and interest (and expense) assumptions to calculate actuarial values of payments that are contingent on death or survival of the insured. Actuarial values are based on a combination of discounting and probabilities.

This article gives some insight into the use and significance of mortality tables in the life insurance industry.

Why Are There So Many Different Mortality Tables in Use in the Insurance Industry?

Mortality tables differ per country, per insurance company, and within insurance companies. For different insurance products, different tables are used; tables are differentiated per subclass of risk, based on classification factors involving sex, smoking habits, etc. Also, tables are periodically updated as new data become available.

What Are the Major Problems of an Insurance Company?

Insurance companies must address major problems concerning the mortality tables:

- How to get suitable basic data?
- Should raw data be used, or should analytical mortality functions be used to construct mortality tables?
- How to take account of the long duration of the life insurance policies in premium and reserve calculations with regard to future mortality trends?
- Which actuarial (mathematical) method should be used to calculate premiums and reserves?
- How to assign probabilities to an individual policy, given one or different sets of mortality tables (this also has to do with medical selection and restriction by law)?
- Is there antiselection of the insured in case of life insurance, and if this is the case, how does the insurer have to deal with this problem?

Another important problem of insurance companies, though outside the scope of this article, concerns investments (the reserves of an insurance company have to be balanced by suitable assets). A connected problem is how to value the reserves and the assets; this is the problem of the valuation of the expected cash flows (and connected financial risks) of the insurance portfolio and the investment portfolio. Other problems have to do with expenses of the insurance company and how those expenses have to be related to the policies. This is a complex issue, thus in the following discussions, only net premiums are considered.

Definition of Actuarial and Probabilistic Symbols

The notation used by the International Association of Actuaries is presented in Table I; additional symbols are given in Table II. Each actuarial symbol consists of a core symbol—in general, a single letter for an interest or discount function, a probability function, an insurance or annuity function, etc. The core, or principal, symbol is often combined with auxiliary symbols, mainly subscripts

Table I International Actuarial Notation

<i>Symbol</i>	<i>Definition</i>
i	Effective annual rate of interest
v	Present value of the amount 1, due at the end of the year
$\ddot{a}_{\overline{n} }$	Present value of an annuity of 1/year
$\ddot{a}_{x:\overline{n} }$	Actuarial present value of a life annuity of 1/year
A_x	Actuarial present value of a term assurance
$A_{x:\overline{n} }$	Actuarial present value of an endowment assurance
l	Expected number, or number of survivors at a given age
d	Expected number, or number of persons dying in a given time period
ω	Limiting age of a mortality table
p	Probability of surviving for a given time period
q	Probability of dying within a given time period
\hat{q}	Estimated value of q
P	Net level premium
V	Premium reserve

Table II Other Actuarial Symbols

<i>Symbol</i>	<i>Definition</i>
D	Actual number of deaths
E	Number of entries
$K(x)$	Random variable for the future lifetime of an insured aged x ; it can only take integer values
L	Actual size of group of insured
O	Number of transitions other than death from group L
$\Pr[K(x) = k]$	Probability that an insured aged x dies between age $x + k$ and age $x + k + 1$
$q_x(y)$	Mortality rate at age x depending on (future) calendar year y
r_x	Reduction factor
y	Calendar year

(lower left or lower right) or superscripts (upper left or upper right). The definitions of symbols used here are given in Tables I and II; a complete list of actuarial functions can be found in a 1949 publication of the Comité Permanente. For easy reading and interpretation herein, the actuarial formulas for premiums and reserves, are written using the notation of standard probability theory.

Mortality Tables

A mortality table, also called life table, is a table showing the 1-year rates of death at each age and the number of survivors. Certain tables also show the number of deaths

occurring between two ages, and the average remaining lifetime. There are cohort-based tables and period-based tables. The cohort-based table describes the mortality experience from birth to death of a specific cohort (group) of persons, all of whom were born about the same time. This cohort has to be followed until every member dies; so it takes a rather long time to complete such a table. Besides, an insurance company needs more recent mortality experience; this can be acquired from a period-based table based on recent period. For a period-based table, age-specific mortality rates of a population for a given period of time are used to construct a life table from a hypothetical cohort of lives at age 0 (see Table III, which contains the data for a Dutch life table for the period 1995–2000).

For a certain mortality table, d_x denotes the number of deaths between age x and age $x + 1$. The number of survivors for the same table is denoted by the symbol l_x , hence for each x ,

$$d_x = l_x - l_{x+1}. \quad (1)$$

For human lives, there is a certain limiting age ω such that $l_x > 0$ for $x < \omega$ and $l_x = 0$ for $x \geq \omega$; ω is, for instance, 115 for a table for females. The number of lives at age 0 has a value that can be arbitrarily chosen (say, $l_0 = 10,000,000$); l_0 is called the radix of the table. Assume for the moment that the 1-year death rates q_x are known for $x = 0, 1, \dots, \omega - 1$, $q_{\omega-1} = 1$; then

$$l_{x+1} = (1 - q_x)l_x, \quad x = 0, 1, \dots, \omega - 1. \quad (2)$$

An abridged table of numbers of survivors l_x and death rates q_x can be found in Table III. The k -year probability to live for a person of age x , using the notation ${}_k p_x$, is

$${}_k p_x = l_{x+k}/l_x. \quad (3)$$

Table III Dutch Life Table for 1995–2000

x	l_x	q_x	x	l_x	q_x
0	10,000,000	0.0058395	50	9,498,570	0.0039600
1	9,941,605	0.0004996	55	9,268,954	0.0065635
2	9,936,638	0.0003804	60	8,897,261	0.0111826
3	9,932,858	0.0002480	65	8,276,947	0.0199477
4	9,930,395	0.0002111	70	7,299,388	0.0333654
5	9,928,299	0.0001898	75	5,904,065	0.0559742
10	9,920,504	0.0001347	80	4,131,376	0.0919937
15	9,911,844	0.0003079	85	2,285,035	0.1447875
20	9,888,451	0.0006636	90	881,226	0.2204651
25	9,854,693	0.0006914	95	203,800	0.3128630
30	9,820,644	0.0007232	100	22,068	0.4159440

40	9,727,241	0.0014687	110	37	0.5439559
45	9,640,014	0.0024149	115	0	—

Using the data from Table III, ${}_1 p_{30} = 0.9992768$ and ${}_{35} p_{30} = 0.8428110$.

The probability that an insured of age x dies between age $x + k$ and age $x + k + 1$, $k = 0, 1, \dots$, is

$$\Pr[K(x) = k] = {}_k p_x q_{x+k} = (l_{x+k} - l_{x+k+1})/l_x. \quad (4)$$

In Eq. (4), $K(x)$ is the random variable for the (curtate) future lifetime of x ; of course, for each x ,

$$\sum_{k=0}^{\omega-x} \Pr[K(x) = k] = \sum_{k=0}^{\omega-x} {}_k p_x q_{x+k} = (l_x - l_{\omega})/l_x = 1, \quad (5)$$

and for $n = 0, 1, \dots$,

$$\Pr[K(x) \geq n] = {}_n p_x. \quad (6)$$

Using the data from Table III, ${}_{35} p_{30} q_{65} = 0.01681214$.

In the random variable model, l_{x+k} is the expected number of survivors at age $x + k$ (in the deterministic model, l_{x+k} denotes the number of survivors at that age). In the following discussions, the only notation needed is $\Pr[K(x) \geq k]$, the probability that an insured x dies between age $x + k$ and age $x + k + 1$, and the notation $\Pr[K(x) \geq n] = {}_n p_x$, the probability that x is still alive at time n .

Estimation of Rates of Death

In the previous section, Eq. (2) showed how the expected number of survivors l_{x+k} can be determined recursively on the basis of given rates q . The rates q have to be estimated on the basis of actual mortality data of (part of) a country or a portfolio of an insurance company. For a closed group, the actuarial estimator \hat{q}_x is defined for each integer x by

$$\hat{q}_x = \frac{D_x}{L_x}, \quad (7)$$

where L_x is the number of persons alive at integer age x , and D_x is the number of deceased from the group L_x between age x and $x + 1$. For an open group,

$$\hat{q}_x = \frac{D_x}{L_x - 1/2(O_x - E_x)}, \quad (8)$$

where O_x denotes the number of transitions from group L_x other than by death; E_x is the number of entries into group L_x . In Eq. (8), it is assumed that the number of entries (E_x) and the number of exits (L_x) are approximately uniformly distributed over $[x, x + 1]$.

The \hat{q}_x values as defined in Eqs. (7) and (8), or in other formulas, are by definition based on historical data for each separate risk group (e.g., “male smoker,” “female nonsmoker”). Normally, the \hat{q} values are rather crude data that are graduated by analytical formulas and the least-squares method. More advanced methods combine a measure of goodness of fit of the graduation and

a measure of smoothness (Whittaker–Henderson graduation). It is also possible, and in some countries becoming more popular, to estimate the force of mortality $\mu_x = \ln(1 - q_x)$. If the \hat{q} values are known for a large number of observation periods and if certain trends are observed, they can be used for extrapolation purposes to obtain q values that are suitable for forecasting purposes. This is especially important for life annuities if the \hat{q} values are decreasing for all or most values of x over the last observation periods. The extrapolated death rates are used to determine a mortality table that is suitable for life annuities. The dramatic effect of mortality downward trends on the technical equilibrium of life annuity portfolios and pension plans requires more emphasis on the problem of extrapolating mortality rates. The notation $q_x(y)$ is used to stress that the mortality rate at age x depends on the future calendar year y . An example is the exponential formula, which is widely used in actuarial practice in some countries to forecast mortality rates via extrapolation of observed rates:

$$q_x(y) = q_x(y')[\lambda_x + (1 - \lambda_x)(r_x)^{y-y'}], \quad (8a)$$

where y' denotes the current year and $r_x < 1$ is the reduction factor at age x . A formula like this can be found in the Continuous Mortality Investigation Reports of the Institute and Faculty of Actuaries. For insurance policies with a positive death risk, such as term insurance, the use of an older table does not lead to financial problems for the insurer (see the section on Which Mortality Table to use in Actuarial Practice?).

Accumulation and Discounting

The calculation of actuarial values requires not only a mortality table, but also some theory of compound interest and discounting. A capital 1 at time 0 is accumulated by the effective annual interest i ; this means that its value at time 1 is equal to

$$1 + i \quad (9)$$

and at integer time k , because the interest is compounded,

$$(1 + i)^k. \quad (10)$$

The 1-year discount factor v is defined by

$$v = \frac{1}{(1 + i)}. \quad (11)$$

This means that the k -year discount factor of an amount 1 is

$$v^k = \frac{1}{(1 + i)^k}. \quad (12)$$

This means that a single payment of 1 at time k has a value v^k at time 0.

A so-called annuity due with a payment 1 at time k , for $k = 0, 1, \dots, n - 1$, valued at time 0 and denoted by $\ddot{a}_{\overline{n}|}$, is defined by

$$\ddot{a}_{\overline{n}|} = \sum_{k=0}^{n-1} v^k. \quad (13)$$

This is equivalent under compound interest with a payment of its accumulated value $\ddot{a}_{\overline{n}|}(1 + i)^n$ at time n .

Calculation of Actuarial Premiums and Reserves

The mathematical formulas that are used in actuarial theory and in actuarial practice to calculate individual premiums and reserves are based on the so-called individual equivalence principle. This equivalence principle is in fact an expected value principle based on the assumption that the expected value of the future premiums to be received equals the expected value of the future benefits to be paid out. Although the insurers adopt the equivalence principle in premium calculations, a (positive) expected profit arises from appropriate assumptions concerning both the interest and the mortality table, which must be on the “safe side” with respect to a realistic scenario interest rate and mortality. Expenses are not incorporated into the model for premiums and reserves here. Instead, in this section, we depart from the probability functions that were introduced in the section on Mortality Tables and the discount functions that were introduced in the section on Accumulation and Discounting. As before, a discrete time model is used.

For a whole-life insurance policy, the single premium issued on a life x with insured amount 1, payable at the end of the year of death, by the equivalence principle notation A_x , is

$$A_x = \sum_{k=0}^{\omega-x} v^{k+1} \Pr(K(x) = k). \quad (14)$$

On the right-hand side of Eq. (14), each probability of dying in a certain year is multiplied by the corresponding discount factor. Single premiums are also called actuarial values.

The next policy to consider is an endowment policy; this policy pays the insured amount following the death of the insured or on survival of the insured to the end of the term of the policy. For an endowment policy with duration n and sum assured 1, and payments at the end of the year of death, the single premium is

$$A_{x:\overline{n}|} = \sum_{k=0}^{n-1} v^{k+1} \Pr(K(x) = k) + v^n \Pr(K(x) \geq n). \quad (15)$$

The policy in Eq. (15) is the sum of an n -year term insurance and a pure endowment that pays amount 1 at time n if the insured is still alive at time n .

As a final example of a single premium, consider a life annuity that pays an annual benefit while the insured survives. The annuity of 1 is due at the beginning of each year, issued on a life x , with duration n and notation $\ddot{a}_{x:\overline{n}|}$:

$$\ddot{a}_{x:\overline{n}|} = \sum_{k=0}^{n-1} \ddot{a}_{\overline{k+1}|} \Pr(K(x) = k) = \sum_{k=0}^{n-1} v^k \Pr(K(x) \geq k). \quad (16)$$

In Eq. (16), two alternative definitions are given for the actuarial value of the annuity. In the first expression, an amount $\ddot{a}_{\overline{k+1}|}$ is paid if the insured dies in year $k+1$; this is a payment valued at time 0, and is equivalent to a payment of $(1+i)^{k+1} \ddot{a}_{\overline{k+1}|}$ at time $k+1$. The second summation pays an amount of 1 if the insured is alive at time k . The proof of the equality of both summations follows easily using the definition given by Eq. (13).

The net level periodical premium P for the endowment policy described earlier can be found using the actuarial equivalence principle

$$P\ddot{a}_{x:\overline{n}|} = A_{x:\overline{n}|}, \quad (17)$$

or

$$P = \frac{A_{x:\overline{n}|}}{\ddot{a}_{x:\overline{n}|}}. \quad (18)$$

The net level premium is also equal to the ratio of two single premiums for more general single life cases because premiums are based on the equivalence principle.

Implicitly, it is assumed in the equivalence principle that large numbers of similar or identical policies are issued, to reduce the probability of ruin of the insurance company. In fact, the large group has to be homogeneous, and the policies stochastically independent and identical. This is a necessary requirement of the mathematical law of large numbers. A practical law of large numbers has to imitate the mathematical law as far as possible. A first practical requirement is that heterogeneity of the groups of life insurance policies is reduced as much as possible.

An insurer needs reserves to meet its future obligations. Consider two such reserves formulas (net premium reserves) at integer time m , using notation ${}_mV$. For the whole-life policy of Eq. (14),

$${}_mV = A_{x+m}, \quad (19)$$

and for the endowment policy [Eq. (15)] bought by periodical premium P of Eq. (18),

$${}_mV = A_{x+m:\overline{n-m}|} - P\ddot{a}_{x+m:\overline{n-m}|}. \quad (20)$$

In Eq. (20), the term $A_{x+m:\overline{n-m}|}$ is the actuarial value at time m of the future payments of the insurer, whereas $P\ddot{a}_{x+m:\overline{n-m}|}$ is the actuarial value of the net premiums to be received from time m by the insurer.

In the discussions here, the premiums and reserves are based on the same mortality table and the same discount function, which is of course not necessary. By external developments, insurers probably will be obliged to value within a few years, in external reports, the insurance obligations (and the assets) and, as much as possible, actual values (market values). The drawback of such valuation methods is that the annual financial results of insurance companies will vary much more. There also may be differences in the approach made by American and European companies.

Risk Classification, Underwriting

The mortality table defined in the section on Mortality Tables and the estimated rates \hat{q} in the section on Estimation of Rates of Death say little about the probability that a specific insured person will die at a given age. The rates q in the mortality table and the estimated rates \hat{q} are in fact “average” rates for groups that have some previously determined risk characteristics in common.

Life insurances and annuities are traditionally classified according to sex, age, and health. More recently, smoking habits have also been introduced in some countries as a risk factor. Risk classification can be seen as a process by which different premiums are charged by the insurer for the same insurance coverage for insureds belonging to different risk groups. In each risk classification system, it is assumed that the policies can be easily divided into homogeneous risk classes at the time of policy issue. The probabilities of the insured to die will in general depend on many factors, including biological, genetic, life style, social, and geographical factors. Risk classification systems can become more refined if more data are available. The classification system should be as good as the insurance market allows. If competitors do not use smoking as a risk factor, the insurance company can charge a premium based on an “average” mortality table, not taking smoking explicitly into account. An important instrument for an insurance company to obtain (to a certain extent), homogeneity, is in actual practice obtained by classifying the insured in certain risk groups. Risk classification is based on actual risk factors such as age and sex, (rates of dying and survival, etc., and in this special case the mortality table is directly coupled to the risk classification.

The fact, however, remains that each risk group in life insurance will in practice be heterogeneous to some extent, and premiums, according to the equivalence principle, are in fact calculated with reference to some heterogeneous group. As seen in the probabilistic model in the section on Mortality Tables and the premium rating and reserving formulas of the previous section, there is no explicit heterogeneity in the model. This means that homogeneity is a basic assumption in the individual rating system of life insurance mathematics, and the equivalence principle of the previous section. The entire underwriting procedure, which also uses application forms and medical exams, functions to determine if an applicant is insurable at standard rates, substandard rates, etc. The insurer also has to be aware in the underwriting procedure of adverse selection by the applicant, meaning that an applicant tries to select against the risk classification system used by the insurer. For example, a smoker may want to buy insurance from an insurance company that uses only age and sex as risk factors and charges a premium based on these two factors alone.

Which Mortality Table to Use in Actuarial Practice?

The estimated death rates defined in the section on Estimation of the Rates of Death are based on past observations; this means that a mortality table based on such death rates reflects only a certain past period. Future death experience will of course differ from the past due to sociological and medical developments. This means that the insurer, in some way, has to take into account expectations of the future death experience, and higher premiums or higher premium reserves may be necessary. For life insurances, the insurer may use a recent or even older table if mortality is expected to be lower in the future (and competition allows this). Use of an older table leads to higher and thus more conservative premiums. For life annuities, which require taking into account the possibility that the insured live longer than expected, other adjustments are necessary to obtain higher premiums and reserves. A frequently used method in practice is based on extrapolation of probabilities into the future of a series of observed \hat{q}_x values for each x . Extrapolation of probabilities leads to smaller death rates, hence higher survival probabilities. If there is only a limited number of observations or if it can be assumed that the observations do not represent expected future probabilities, then the actuary will usually choose a safe mortality table, which will result in more or less conservative premiums.

Historical Aspects of Insurance, Actuarial Science, and Probability Theory

Nowadays, the determination of insurance premiums and reserves has a sound theoretical basis in actuarial science. However, at the end of the 17th century and the beginning of the 18th century, when the first insurance companies were formed, the relationships between probabilities, statistical data, and life insurance as described by the preceding sections were by no means clear. There was not even a clear distinction between insurance and gambling in terms of taking risks. Insurance was seen as a gamble and the idea of a mathematical approach seemed a strange one. The main reason for the development and growth of the first insurance companies in the 17th century was not the development of a scientific basis of insurance, but the combination of profitable insurance practice and the legal notion of risk as a genuine uncertainty, as opposed to quantifiable uncertainty. The application of probability theory and statistics for problems in insurance and annuities was neglected in the early days of the life industry.

Two important developments provided the possibility of sound theoretical basis. With the growing influence of a middle class, the purpose of life insurance changed from risk taking to aversion of risk, hence a type of insurance had to be created that benefited the family of the deceased. Next there was the emphasis for this new type of insurance based on predictability and not on the contingency of mortality. In fact, a new value system was created, which led to the application of probability theory and statistical data to insurance problems. This theoretical basis resulted in the separation of insurance and gambling, and in the second decade of the 19th century, this separation was almost complete. From that time, faith in statistical regularities and trust in insurance companies were symbiotic. The existence of statistical regularities was proved by the financial success of insurance companies, and the companies saw every new-found regularity as a new foundation of their practice.

In 1762, the Equitable insurance company, based on these new thoughts, was established. The Equitable used an interest rate of 3% (the market rate was at that time 6%) and a mortality table with high death rates (London Table), and only healthy persons were insured. These prudent assumptions and rates led to a very profitable Equitable in the years to come. In 1775, calculations of the Equitable showed that 60% of the assets could be considered as surplus. Recently, the Equitable faced major financial problems because the tariff guarantees of some of their policies were not financially covered by appropriate insurances. This made actuaries more aware of the financial risks involving insurance contracts.

Intangible Assets: Concepts and Measurements

Baruch Lev

New York University, New York, New York, USA

Glossary

comprehensive valuation of intangibles A methodology for estimating the total value of enterprise intangibles, based on their contribution to profitability.

intangible assets Sources of future benefits that lack a physical embodiment.

intellectual property Intangible assets legally protected by patents, trademarks, or copyrights.

organizational capital Business designs, processes, and employee incentive-compensation systems that create economic value.

partial excludability The inability of owners of intangibles to capture fully the benefits of these assets.

resource allocation The division of national or corporate funds among investments, tangible and intangible.

Intangible assets capture center stage among national and corporate productive investments. The measurement and valuation of these assets—derived from their costs and benefits—are challenging yet crucial to resource allocation decisions made by corporate executives, capital market investors, and public policymakers.

Introduction

The annual investment of the U.S. corporate sector in intangible assets during 2000 amounted to 1 trillion dollars—so estimated Leonard Nakamura, a senior economist with the Philadelphia Federal Reserve. To put this staggering amount in perspective, the same-year investment of the U.S. manufacturing sector in physical assets (primarily property, plant, and equipment) was about \$1.1 trillion. Thus, corporate investment in intangibles

almost matched the investment in tangible assets, and given the substantially higher rate of growth of the former, relative to the latter, the rate of investment in intangibles will soon surpass that of physical investments.

Viewed from another perspective, in October 2003, the market value (stock prices times number of shares outstanding) of U.S. publicly traded companies was five times larger than their balance sheet value, which reflects primarily the net worth of physical and financial (stocks, bonds) assets. Thus, about three-quarters of the value of public companies, as perceived by investors, reflects non-physical and nonfinancial assets. Much of this huge value constitutes intangible assets, which are absent from corporate balance sheets. Even if capital markets will slide, it would take a monumental collapse to erase a 5:1 gap between market and balance sheet equity values.

What are those intangible assets, sometimes called intellectual capital or knowledge assets, whose size surpasses the traditional physical assets of business enterprises? This question is addressed in the next two sections, and the reasons for the ascendance of intangibles to the top of corporate investments are presented in the following section. The widespread concerns of corporate managers, investors, and policy makers about the management, valuation, and reporting of intangibles are discussed in the next section, and the measurement and valuation methodologies aimed at alleviating these concerns are articulated in the final section. The aim here is to familiarize the reader with one of the major economic developments of the late 20th and early 21st centuries: intangible assets.

What Are Intangible Assets?

An intangible asset, like any other asset (a machine or a rental property), is a source of future benefits, but in

contrast with tangible assets, intangibles lack a physical embodiment. Pfizer's patents on the best-selling drug Celebrex (relief for arthritis) and the Coca Cola' brand name are examples of highly valuable intangible assets that enable their owners to generate substantial revenues and profits over extended periods. (Financial assets, such as stocks and bonds, also lack a physical embodiment, but they are not intangible assets, because they essentially represent claims on corporate assets, both tangible and intangible.) The wide scope of intangibles can be grasped by their categorization as products/services, customer relations, human resources, and organizational capital.

Products/Services

A large and constantly growing share of the gross national product of developed economies is in intangible form; this includes software products, financial and health services, and leisure and entertainment, to name a few intangible products. Furthermore, for many tangible products, such as drugs, computers, or machine tools, the physical component is overshadowed by the intangible ingredient—knowledge—embedded in them. Intangible and intangible-intensive products and services generally emanate from the discovery (research and development) and learning processes of companies. In many cases, the property rights of owners over these assets are secured by patents and trademarks, conferring on owners of such intellectual property a temporary monopoly. This patent-driven monopoly is strongly challenged these days by developing countries and many nongovernmental organizations, claiming, for example, that it puts essential drugs (e.g., for AIDS and malaria) out of reach of poor patients and hinders the technological progress of developing nations (which cannot afford to pay for expensive technology). Nevertheless, the mainstream view, supported by economic theory, is that strictly enforced patent and copyright laws are essential to provide incentives for the heavy investment in research and development, required for sustained innovation and consequent economic growth. Indeed, practically all developed countries and an increasing number of developing ones have and enforce intellectual property laws.

Customer Relations

When the loyalty of customers to a product (e.g., Bayer aspirin) or a company enables a business enterprise to charge higher prices than its competitors charge or to secure a large market share (e.g., the investment bank Goldman Sachs), customer-related intangibles are present. Such intangibles are generally known as brand names, and are secured and enhanced by unique and continuously improved products/services (Microsoft operating

systems), coupled with extensive promotion, advertising campaigns, and cultivation of customers (McDonald's, or Disney). The world's 10 most valuable brands according to a *Business Week* ranking (August 5, 2002) are as follows: Coca-Cola (brand value of \$70 billion), Microsoft, IBM, General Electric, Intel, Nokia, Disney, McDonald's, Marlboro (cigarettes), and Mercedes (\$21 billion).

Human Resources

Unique human resource policies and practices, such as employee incentive and compensation systems, or on-the-job training programs, which consistently enhance labor productivity and reduce employee turnover, create intangible assets. An example of a human resource practice generating substantial benefits is provided by Edward Lazear, a Stanford economist, who has studied the consequences of the transition from a flat hourly rate to a piece-rate compensation of employees in the Safelite Glass Corp., the nation's largest installer of automobile glass. The findings were surprising: a 41% employee productivity jump, enabled in part by a 61% drop in paid sick hours. Such profit-generating human resource practices are, in fact, intangible assets.

Organizational Capital

Intangible assets increasingly come in the form of unique corporate organizational designs and business processes that allow companies to outperform competitors in generating revenues or by economizing on production costs. Dell's built-to-order computers (customers design the configuration of the products they order), Wal-Mart's supply chains (essentially shifting their inventory management to suppliers), and Citibank's online (Internet-based) banking activities are examples of organizationally related intangibles that have created sustained and considerable value for their owners. Unique information processes, such as those of the Italian apparel manufacturer Benetton, relaying real-time information about product colors from stores to production facilities, provide another example of the intangible—organizational capital.

What Is Unique about Intangibles?

Intangibles differ from physical and financial (stocks, bonds) assets in two important aspects that have considerable implications for the management, valuation, and the financial reporting of intangibles.

Partial Excludability

Although the owner of a commercial building or a bond can enjoy to the fullest the benefits of these assets (is able to exclude fully nonowners from sharing in the benefits), the owners of patents, brands, or unique business processes, and the employers of trained personnel, can at best secure some of the benefits of these intangibles for a limited duration (partial excludability). Patents expire after 20 years, but in many cases are infringed upon by competitors long before expiration; there are thousands of patent and trademark infringement lawsuits filed every year. Brand values are fickle, given severe competition in most economic sectors and frequent changes in customers' tastes, as demonstrated by erstwhile leading brands, such as Xerox, Polaroid, or the airlines Pan Am and TWA, which are now financially struggling or bankrupt. Trained employees often shift employers, taking with them the investment in human capital made by employers. In short, the property rights over intangibles are not as tightly defined and secured as are those over physical and financial assets, challenging owners of intangibles to capture large and sustained shares of the benefits.

The difficulties of fully capturing the value of intangibles increase the riskiness of owning these assets (value dissipation) and complicate their valuation by investors, because valuation generally requires a reliable estimate of future cash flows to owners. As for corporate financial reporting to investors, accountants often claim that the absence of complete control over the benefits of intangibles disqualifies these assets from recognition as such in corporate balance sheets.

Nonmarketability

Although many physical and most financial assets are traded in competitive markets (stock exchanges, used car dealerships), intangibles are by and large not traded in active and transparent markets (i.e., those in which prices and volumes of trade are observable). To be sure, there are frequent transactions in some intangibles, particularly the licensing and sale of patents and occasionally of trademarks, but these transactions are not transparent—details of the deals are generally not publicly disclosed. The major reasons for the “nontradability” of intangibles are the incomplete property rights, mentioned previously, and serious information asymmetries, i.e., differences in knowledge about intangible assets between buyer and seller. Thus, for example, developers of drugs or software know about these intangibles and their profit potential much more than do outsiders, and it is difficult to convey to the fullest such information in a credible way. Trade in assets when owners possess a significant information advantage over potential buyers is often limited or nonexistent.

The nontradability of intangibles causes serious valuation problems for investors and managers, because valuation techniques are often based on “comparables,” which are observed values (prices) of similar assets traded in transparent markets. Nontradability also increases the risk of owning intangibles, given the difficulties or impossibility of selling them before or after completion of development (no exit strategy). For many accountants, the absence of markets disqualifies intangibles from being considered as assets in corporate balance sheets. Intangibles thus differ inherently from physical and financial assets, and the management, valuation, and financial reporting of intangible assets are challenging. Of particular concern in the early 21st century is the vulnerability of intangibles, as expressed by Federal Reserve chairman Alan Greenspan, in testimony (February 27, 2002) to the House of Representatives: “As the recent events surrounding Enron have highlighted, a firm is inherently fragile if its value added emanates more from conceptual [intangible] as distinct from physical assets. A physical asset, whether an office building or an automotive assembly plant, has the capability of producing goods even if the reputation of the managers of such facilities falls under a cloud. The rapidity of Enron's decline is an effective illustration of the vulnerability of a firm whose market value largely rests on capitalized reputation.”

Whence the Ascendancy of Intangibles?

If intangibles are so risky, their benefits so difficult to secure, and their liquidity (tradability) low, how did they ascend in the last quarter of the 20th century to become the most valuable corporate assets? What is the upside (benefit) of intangibles? The answer lies in the confluence of two major international economic developments: the ever-increasing intensity of business competition and the commoditization of physical assets. Regarding competition, the globalization of trade and the far-reaching deregulation of vital economic sectors, such as transportation, financial services, and telecommunications, have intensified significantly the competitive environment in which business enterprises operate throughout the world. This severe competitive environment makes innovation—the continuous introduction of new products/services, and of cost efficiency mechanisms—literally a matter of life or death for business enterprises. Computer and semiconductor companies, drug manufacturers, health care providers, and television networks that fail to generate new products continuously and to cut costs soon fall hopelessly behind competitors. Chemical and oil companies that do not constantly economize on costs will fall by the wayside, and retailers that do

not improve on inventory management and delivery channels to customers will end up in Chapter 11 (bankruptcy).

How is the necessary level of innovation achieved? Primarily by intangible investments: research and development aimed at generating new products and cutting costs, collaboration with other companies and universities to share technology and minimize risk, training employees to better serve customers, enhancing brand and trademark values to secure competitive positions, and developing unique business processes to streamline operations. Thus, as the competitive pressures intensify, companies respond with enhanced innovation, brought about primarily by intangible investments.

The second economic development to escalate the importance of intangibles is the commoditization (equal access to competitors) of physical assets. These assets, such as machine tools, car-producing robots, or computer-aided design systems, initially conferred significant competitive advantages to their early owners. Nowadays, however, most physical assets are commodities, available to all competitors. For example, all pharmaceutical companies, from the giants Merck and Pfizer to the smaller biotech companies, use state-of-the-art laboratory equipment and computer systems in drug development; General Motors, Ford, and Toyota avail themselves of the most advanced car design and manufacturing systems; and Citibank, Bank of America, and even smaller banks can afford the most advanced computer systems. When competitors have equal access to physical assets, such assets obviously cannot generate abnormally high profits and create sustained values.

In contrast, permanent profits and shareholder value are created by intangible assets, which by their nature are unique to the enterprise: patents, brands, in-house employee-training systems, or cost-cutting business processes. This unique ability of intangibles to enable companies to withstand competitive pressures and prevail is responsible for their remarkable ascendance to the role of premier corporate and national assets. In a sense, intangibles are high-risk/high-reward assets.

So, What Is the Problem?

Having noted that intangibles are fast growing and crucial to the survivorship and growth of business enterprises and national economies, why should there be concern about them? What is the problem with intangibles? In a word—measurement. The adage stating that “what’s not measured is not managed” is true for individuals (personal investments are carefully managed by most people, whereas their human capital, which is difficult to measure, rarely is), for business enterprises, and at the national level (national debt, easy to measure, is effectively managed, whereas the hard-to-measure environmental impact of

public policies is often ignored). The specific attributes of intangibles—partial excludability, high risk, and nontradability—render the measurement and valuation of intangibles a daunting task. Consider the value of a newly registered patent: like that of any other asset, the value depends on the future cash flows to be generated by it. But given the generally high technological uncertainty prevailing in most industries (competitors developing similar products), cash flows from patents are hard to predict, and consequently patent valuations are often of questionable reliability. For example, studies have shown that about 90% of registered patents turn out to be worthless, namely, their benefits do not cover costs. Even more challenging, how can a value be placed on an employee-training program, given the usually high labor turnover? And, how to value a brand that is constantly threatened by competitors’ products? In general, the softer the intangible, such as social capital (value of relationships) or environmentally-friendly policies, the harder its valuation. The absence of transparent markets for intangibles, in which similar transactions and prices can be observed, deprives managers and investors of value gauges for intangibles.

The measurement and valuation challenges raised by intangible assets are of major concern to corporate executives, capital market investors, and public policymakers. The fundamental decision of executives is how best to allocate corporate resources (funds): How much should be invested in new production facilities, international market penetration, technology acquisition, research and development, and labor force development? Such “resource allocation” decisions are generally based on a comparison of investment costs with prospective benefits, i.e., a return on investment computation. But the benefits of intangibles (e.g., cash flows from a drug under development, or future benefits from an employee-training program) are difficult to assess, complicating the decision of how much to invest in intangibles. Investors, too, encounter serious measurement problems in assessing the value of intangible-intensive enterprises. How, for example, can the value of a biotech company with a large investment in early-stage research and development that has uncertain prospects be ascertained? Indeed, empirical evidence indicates that investors systematically misprice the securities of research-and-development-intensive companies.

Accountants, the prime providers of measures and values, essentially have given up on intangibles. Practically all investments in intangibles such as research and development, brand enhancement, employee training, and systems development are expensed in corporate financial reports; such investments are not considered assets that promise future benefits. Physical and financial investments, in contrast, are considered enterprise assets. The large gap—5 : 1 in late 2003—between market values

of public companies and their balance sheet values is a reflection of the absence of intangibles from corporate balance sheets, due to the accounting treatment of intangibles as expenses. A ray of hope exists: accounting regulatory bodies, such as the U.S. Financial Accounting Standards Board, are currently considering ways of communicating some information on intangibles to capital markets. Difficulties in measuring intangible investments also beset policymakers in charge of fiscal policies and the measurement of national accounts (e.g., gross national product). Education and research and development, for example, are subsidized by governments throughout developed countries, but how can policymakers assess the adequacies of such intangible investments (too much, too little?) without reliable measures of their benefits (national resource allocation)? These intangibles-related measurement and valuation challenges, which surely cause misallocation of private and public resources, lead to the need to discuss measurement and valuation approaches.

The Measurement and Valuation of Intangibles

It is important to distinguish at the outset between input (cost) and output (benefits) measures of intangibles. Given an effective accounting system, there are no special problems related to the measurement of the costs of most intangible investments. The investments in research and development and software development programs are routinely tracked by business enterprises, as are the expenditures on brand maintenance (advertising, product promotion) and the design of business processes, such as Internet-based supply chains and distribution channels. More challenging is the determination of the cost of employee training. A large part of this activity involves on-the-job training, such as the mentoring of junior employees by veterans, which is not systematically accounted for by most corporations. By and large, though, input measures of intangibles are available, or they could be obtained by corporate executives. However, although available to managers, these investments, with the exception of research and development, are not disclosed to outsiders (investors, policymakers) in corporate financial reports.

The measurement and valuation of the benefits of intangibles is more challenging. Consider, for example, the valuation of Microsoft's respected brand name. The consistently high profits and large market share of Microsoft are jointly determined by a superior technology (research and development), highly trained employees, and an effective sales and promotion effort. But how can Microsoft's total output (revenues, profits) be allocated among the various intangibles (research and development, human

capital, brands) responsible for it, to determine, for example, the brand value and to decide whether to invest more or less in brand enhancement? Stated differently, how can Microsoft's brand be valued and managed independently (stand-alone basis) of its research and development and physical assets? This joint nature of most intangibles is a major challenge to the valuation of individual assets. In fact, most intangibles are not stand-alone assets with unique benefit streams, like a commercial real estate property; rather, they generate benefits collectively with other assets. Pfizer's top-rated scientists, along with its effective sales force and reputation for reliable drugs, are jointly responsible for the success of this company. Given such "jointness," the allocation of Pfizer's revenues to the contributing resources—research and development, sales force, and reputation (brand)—which is required for the valuation of these intangibles and for resource allocation decisions, is a daunting task. Three approaches (benefit allocation, stand-alone valuation, and comprehensive valuation of enterprise intangibles), circumventing some of the difficulties, are often used to measure and assess the desirability of investment in intangibles.

Benefit Allocation

Under certain circumstances, reasonable assumptions can be made that allow the allocation of benefits to individual intangibles, and thereby facilitate their valuation. For example, consider the estimated productivity (return on investment) of research and development and brands for a major chemical company. Return-on-investment measurement requires an evaluation of benefits against costs. The chemical company's annual costs of research and development and expenditures on brand enhancement (advertising, promotion) are routinely recorded by the accounting system. But how could the combined benefits of research and development, brands, and physical facilities—represented by the company's revenues and cash flows—be attributed to the individual intangibles to assess their productivity and value to the organization? Based on consultation with experts, the company's revenues and consequent cash flows (after first deducting a reasonable return on physical assets) can be allocated between research and development and brands according to the following criterion: a brand is manifested by an ability to charge a premium price to customers, namely, a price consistently higher than that of a close competitor. Accordingly, the portion of the company's revenues resulting from the price differential with competitors can be attributed to brands, with the remaining revenues assigned to research and development. This revenue allocation allows estimating the productivity (return on a dollar investment) of research and development and brands individually, based on their costs and benefits. Similar allocation procedures may be used to value

other intangibles in different circumstances, for the purpose of resource allocation or valuations in licensing and mergers and acquisitions cases.

Stand-Alone Valuation

Some intangible assets, particularly those with legally protected ownership (intellectual property), generate unique streams of benefits. Such intangibles can be valued on a stand-alone basis by computing the present value of the expected benefit stream. For example, the patent and technology portfolio of IBM is reported to have generated \$500 million in licensing revenues in 2001 (*The Wall Street Journal*, February 19, 2002, page A3). It is relatively straightforward to estimate the present value of the forecasted stream of licensing revenues, which yields an estimated value of IBM's licensed intellectual property. A similar approach can be used to assess values of patents, trademarks, and copyrights, as long as reliable forecasts of cash flows from these assets can be made.

A Comprehensive Valuation of Enterprise Intangibles

The problem of jointness of intangibles is mitigated when the objective is to place a combined value on all of the company's intangibles, rather than on individual assets. In many real-world situations, such a comprehensive valuation of intangibles is all that is needed. Investors, for example, are primarily interested in the total value of a company's intangibles, which is missing from its balance sheet. Similarly, in cases of mergers and acquisitions, a comprehensive valuation of the acquired company's intangibles is needed to consummate deals. There is a methodology for such a comprehensive valuation of intangibles. The basic premise (elaborated in Gu and Lev, 2002) is that of an economic production function, whereby the earnings of an enterprise are related to the assets that generate those earnings. Three clusters of corporate or divisional assets are formed: physical, financial (stocks, bonds), and intangible. The initial valuation stage involves an estimate of "normalized earnings," that is, typical annual earnings that can be expected from the enterprise, accounting for both historical and future earnings, and abstracting from nonrecurring, abnormal items (e.g., a loss from a strike, or a gain from selling a subsidiary). The three classes of assets generate these normalized earnings. Accordingly, to isolate the earnings generated by intangibles, the contribution of physical and financial assets is subtracted from normalized earnings, leaving as a residual the "intangibles-driven earnings." An asset's contribution to earnings is based on its value and the return on the asset. The values of physical and financial assets can be obtained, with some adjustments,

from published balance sheets; the estimated returns on physical assets (contribution to earnings) are assessed from industry-wide data. The subtraction from normalized earnings of the contributions of physical and financial assets leaves as a residual the earnings contributed by the intangibles: these are the intangibles-driven earnings. The final stage of the comprehensive valuation of intangibles involves computation of the discounted (present) value of the expected stream of intangibles-driven earnings.

Table I demonstrates the outcome of this valuation methodology. It presents the estimated intangibles-driven earnings for the year 2000, along with the estimated total value of intangibles (intangible capital) for the 25 companies with the largest intangible capital in the widely watched Fortune 500 ranking. General Electric, with an estimated \$254 billion value of intangible assets captures top rank, followed closely by Pfizer and Microsoft. Walt Disney closes the list with \$47 billion of value from intangibles. It is important to note that high values of intangibles are not restricted to high-technology

Table I Comprehensive Value of Intangibles of the Top 25 Companies^a

Rank	Company	Intangible capital ^b	Intangibles-driven earnings ^b
1	General Electric	254,381	12,435
2	Pfizer	219,202	7686
3	Microsoft	204,515	8735
4	Philip Morris	188,538	10,226
5	Exxon Mobil	176,409	10,050
6	Intel	173,964	7339
7	SBC Communications	155,402	7897
8	IBM	148,679	7534
9	Verizon Communications	141,471	7494
10	Merck	139,494	7497
11	Wal-Mart Stores	99,973	5018
12	Johnson & Johnson	94,769	4976
13	Bristol Myers Squibb	85,837	4709
14	Coca-Cola	73,976	3906
15	Dell Computer	72,985	2499
16	Bellsouth	71,269	4004
17	Procter & Gamble	66,609	3931
18	Ford Motor	59,311	4310
19	Honeywell International	52,798	2533
20	Boeing	51,179	2427
21	PepsiCo	50,614	2607
22	United Parcel Service	48,508	2470
23	Home Depot	48,389	1952
24	Hewlett-Packard	48,226	2500
25	Walt Disney	46,960	2307

or science-based companies. In fact, as made clear by the table, approximately half of the top 25 companies are “old economy”: Philip Morris, Exxon Mobil, Wal-Mart, Coca-Cola, Procter & Gamble, Ford, etc. The conclusion is that valuable, productive intangibles are the unique characteristic of innovative, well-run, and successful enterprises, rather than of companies operating in specific industries.

Summary

Intangible assets reached prominence in the business world in the late 20th century and will surely persist to capture center stage in the future. Intangibles are inherently different from physical and financial assets. These differences are responsible for the unique potential of intangibles to generate vast economic value and growth, at both the corporate and national levels, as well as for the serious difficulties in managing, measuring, and reporting the values of intangibles. Various methods are available to overcome the valuations challenges, but efforts to improve the measurement and reporting of intangibles should continue.

Intelligence Testing

Wilma C. M. Resing

Leiden University, Leiden, The Netherlands

Glossary

academic intelligence The intellectual thinking and problem-solving processes with which academic tasks or academic problems that have a fixed and closed structure are concerned.

culture-fair test Tests with a content related to the knowledge and experience of a wide variety of cultures, avoiding specific cultural-linguistic contexts.

deviation IQ The deviation of an individual's test score from the mean test score achieved by a representative peer group.

Flynn effect The generational raising of IQ scores within populations.

intelligence quotient (ratio IQ) Mental age divided by chronological age multiplied by 100.

mental age The level of correctly solved intelligence test items belonging to a certain age group.

test A systematic measuring procedure, consisting of tasks that are presented in a standardized manner so that the answers can be processed objectively and so that the outcome enables the tester to estimate the (measured) capacity of the examinee or to predict performances in the future.

Interest in intelligence and intelligence testing dates from the start of the twentieth century, but even today a large number of different definitions and theories exist on this subject. In this entry, intelligence is restricted to academic intelligence and, therefore, the emphasis lies on thinking processes and on solving (new) problems. It is important to notice that human intelligence is not static but has a dynamic, developing character. After first sketching the history of the field, the question of whether intelligence has one general dimension or a larger number of independent dimensions is addressed briefly. Modern intelligence theories propose models with a hierarchical structure. Examples of group and individual intelligence tests are described, including the modern way

of calculating IQ, deviation IQ. The entry ends by emphasizing several important topics in intelligence testing: whether culturefree tests exist, whether intellectual performance increased or decreased during life span, and whether mean IQ scores rise over generations. Finally, a sketch is given of the characteristics and the applicability of good intelligence tests.

Defining Intelligence

Ever since the start of the twentieth century, we have witnessed a huge increase in intelligence research and intelligence testing. This enduring interest in the subject of intelligence is based on the desire to measure and describe all kinds of human abilities and led to the first test diagnostics being developed.

Academic Intelligence

The concept of intelligence goes back to the Latin verb *intellegerere*, meaning the acquirement, processing and storage of information. From this point of view, intelligence is restricted to the cognitive, mental abilities of the human being. Two thousand years later it still seems wise to reserve the term intelligence for what in the scientific literature is frequently called academic intelligence. This is defined as intellectual performance, within a closed system, on academic tasks or on academic problems that have fixed goals, a fixed structure, and known elements, and is distinguished from social, everyday, successful, or practical intelligence. We use the term intelligence here to mean academic intelligence.

Intelligence A, B, and C

If we want to understand and comprehend discussions about intelligence and intelligence testing, it is good to

keep in mind the three-way split in intelligence—A, B, and C—made by Vernon in 1967. Intelligence A is the genetically determined disposition or potential to act intelligently that cannot be influenced by culture, environmental stimulation, education, or learning experiences. It is a postulate; it cannot be observed nor measured. Intelligence B is the result of the interaction between this genetic disposition (A), environmental influences, and learning experience. It is culturally bound and can be observed and estimated. It is the visible intelligence, the cognitive abilities that a person has at a particular moment in time that are the result of earlier learning experiences. It changes during an individual's life span. Intelligence C is what intelligence tests—created to estimate intelligence B as well as possible—measure. Intelligence C is the measured intelligence of a person, in terms of the intelligence quotient (IQ); it is restricted to the specific test that is used.

Demarcating Intelligence

Based on the literature, academic intelligence can best be seen as a conglomerate of mental abilities, processes, and aptitudes, such as abstract, logical, and consistent reasoning; detecting relations; (complex) problem solving; detecting rules in seemingly unordered materials; solving new tasks by using existing knowledge; adapting to new situations flexibly; and being able to learn without direct and complete instruction. From this perspective, the accent in intelligence definition(s) lies on thinking processes and on solving (new) problems.

According to Sternberg's 1997 definition, "Intelligence comprises the mental abilities necessary for adaptation to, as well as shaping and selection of any environmental context. According to this definition, intelligence is not just reactive to the environment but also active in forming it. It offers people an opportunity to respond flexibly to challenging situations. Because the landscape of an environmental context changes over time, adequate adaptation, shaping, and selection involve a process of lifelong learning, one that starts in infancy and continues throughout the life span." It is important to notice that intelligence is not static; it has a dynamic character: Humans are always developing themselves, expanding their intellectual expertise.

Intelligence: A Historical Perspective

For almost 100 years, there have been two different research perspectives within the field of intelligence: the psychometric perspective and the experimental cognitive perspective. Within the psychometric tradition, research

focuses on the nature and causes of individual differences in intelligent human behavior, particularly in cognitive problem-solving tasks, and on the structure of intelligence. Within the experimental tradition, research focuses more on regularities in both general and specific cognitive processes in problem-solving behavior and in how people perform cognitive tasks in general, how they deal with task demands, and how they use different forms of knowledge and memory. In short, the focus is on shared mechanisms and processes that are the core parts of intelligence.

Pioneers within the Experimental Tradition and Pioneers in Test Development

Experimental studies on intelligence started in France around 1850 with Broca's famous studies on craniometry, relating cranial volume with intelligence. However, after several years of study this relationship was found to be nonexistent. Around the same time, Sir Francis Galton performed the same type of experiments in England. He became strongly influenced by Darwin's theory of evolution and developed a model of the relationship between heredity and intelligence. Galton was the first to try to measure this kind of psychological and physiological relations in the laboratory. He developed experimental tests, such as reaction-time measurement and other sensory tasks, by which, according to him, researchers could differentiate between highly gifted and less gifted individuals. In addition, he collected physiological measures, for instance heart rate and skin conductance. He considered all these variables to be good measures of mental speed, his equivalent of intelligence.

The first pioneers in test development were medical scientists. Esquirol, a Frenchman, was one of the first. In 1838, he developed a test for measuring language disorders in patients with severe mental disorders. Sequin, a second French medical doctor, tested and trained his mentally retarded patients in mental institutions in both France and the United States. These training periods were intended to raise human intelligence. Both scientists practiced early forms of psychodiagnostics with very simple tests. These tests were mainly used as selection instruments for groups of individuals with and without intellectual disorders.

Alfred Binet (1857–1911): Father of the Intelligence Quotient Test

In 1905, Binet and Simon developed the first true intelligence test. According to Binet, mental tests had to include a complex compilation of corresponding mental facets such as attention, comprehension, memory, and

verbal and abstract reasoning, which could not be considered separate parts and could not be measured separately. He therefore decided to measure intelligence as one complex conglomeration of interwoven mental facets. Binet examined, for each half-year age cohort, which cognitive tasks had strong correlations with school performance. Based on these data, he then composed a series of test items for each age group, such as naming objects, memory of number series, searching for rhyming words, logical reasoning, and concept defining. All these test components had to be tested in a fixed sequence, making it possible to estimate the mental level of a child. Using this first mental scale, researchers and psychologists in the field were, for the first time, able to compare the mental level of a child with that of its peer group.

The intelligence scale became very popular in the United States thanks to a translation by Goddard in 1908 and further adaptations. He considered intelligence to be a hereditary trait of the human being that could be operationalized in terms of mental age, the age of the group of children whose mean test performance equaled that of the examinee, and later as IQ, which was defined as the child's mental age (MA) divided by the child's chronological age (CA), multiplied by 100.

$$IQ = (MA/CA) \times 100$$

When the scores of a 6-year-old child on an intelligence test equal those of an average 8-year-old child, the mental age (MA) of the child is 8 years and its chronological age (CA) is 6 years. Therefore, this child's $IQ = 8/6 \times 100 = 133$.

The First Group Intelligence Tests

Individually administered tests have an important function in clinical psychodiagnostics, when learning disabilities or social-emotional problems are involved. However, for routine use in school and personnel selection or in industrial and military selection, group tests for measuring intelligence often are more practical and time saving. Group tests were first developed during World War I, when it became necessary to screen and classify recruits for the army on the basis of their general intelligence level as quickly as possible. The groups of recruits were very heterogeneous; some of them could not speak English and could not read at all. Therefore, it was important both to test the general intelligence level of large groups of people at the same time effectively and to bear in mind the large individual ethnic, cultural, and linguistic differences. Two tests were constructed: the Army Alpha, a group test for people who could read and comprehend English and who were able to write down their answers to the test items on paper; and the Army Beta,

a nonverbally instructed multiple-choice test in which the examinee had to cross out the right pictures and symbols.

Intelligence Structure

One or More Intelligence Dimensions

The development of psychometric theories on the structure of intelligence ran parallel with the construction of the first instruments. From 1920 onward, answers were sought indirectly to the question "What is intelligence?" by examining whether intelligence has a complex undivided general nature or takes the form of a combined series of separate unique factors, such as abstract reasoning, memory, and vocabulary. Around 1930, Spearman interpreted his test results with newly developed psychometric techniques such as correlational and factor analysis. According to him, a wide variance in intellectual performance on different tasks could be accounted for by one general underlying factor called *g* (for general intelligence). This factor was supplemented by specific, different *s* (for specific intelligence) factors. It soon became evident that Spearman's view was too simple. Several intelligence models added extra factors, mostly intermediary group factors, and some theorists stated that there were several primary factors instead of one general factor. Toward the end of the 1930s, Thurstone reported seven primary intelligence factors; in 1959, Guilford described 120 different intelligence factors in his famous structure-of-intellect model.

However, it became clear that the different cognitive components representing different aspects of intelligence had predominantly positive intercorrelations. To make this conclusion visible, several hierarchical intelligence models were developed in which, in addition to a general intelligence factor as opposed to specific intelligence factors, one or more intermediate levels with group intelligence factors could be discerned. In 1960, Vernon developed a model with a general factor at the first level, intermediate group factors (verbal-educational vs. practical-mechanical-spatial) at the second level, a number of smaller group factors at the third level, and very specific factors at the fourth level. At the same time, Cattell postulated two kinds of intelligence in his model: fluid and crystallized intelligence. In 1993, Carroll confirmed a hierarchical theory of higher-order abilities and combined this with Cattell's fluid-crystallized dimension. In addition to a general intelligence factor, he described at a lower level of analysis fluid intelligence, crystallized intelligence, and a general memory ability. At the same level in this model, he added broad visual and auditory perception, broad retrieval abilities, and broad cognitive speediness. It is this hierarchical intelligence structure and the interconnectedness between

most cognitive components that legitimizes the use of one single intelligence score in combination with individually based intelligence profiles.

Information-Processing Theories

More recently, research on the cognitive processes or components of intellectual functioning has been performed from an information-processing perspective. Examples are Sternberg's triarchic theory of intelligence and the PASS (planning, attention, simultaneous and successive processing) model of Das, Naglieri, and Kirby, both developed in the mid-1980s. The PASS model of intelligence is based on Luria's neuropsychological theory of the functioning of the human brain, in which three parts of the brain are described: the brain stem and the limbic system, responsible for attention and arousal processes; the visual, auditory, and general sensory parts of the cerebellum, responsible for simultaneous and successive reasoning processes; and the prefrontal parts of the brain, responsible for the planning and regulation of cognitive processes and activities. In 1985, Sternberg, in his triarchic intelligence model, described various components necessary in intellectual problem solving: performance components, meta components, and knowledge-acquisition components. Later he added the importance of intellectual styles and mental self-government to his model of intelligence.

Current Measures of Intelligence

What is a test? An intelligence test can be defined as a systematic measuring procedure, consisting of a number of carefully selected tasks that are presented in a standardized manner to the examinee in such a way that the answers or solutions can be processed objectively. The last part of this definition allows the psychodiagnostician to interpret and to describe the measured capability of the examined individual, for instance to describe his or her intelligence or to make predictions about his or her school success.

The Intelligence Quotient

When intelligence test development first started, the intelligence of an individual mostly was described in terms of the mental age or the IQ. The use of this measure allows both the delay and the advantage in mental development to be estimated. The ratio IQ seemed to be a good measure for estimating the intellectual level of young children. For older children and adults, this measure of intelligence appeared less suitable. First, the idea behind Binet's test was that mental development is directly related to age and that progression in mental development automatically

leads to better test scores. Of course, mental development is related to age, but the progress in mental development will not be the same each year we become older. Apparently, there is no linear progression in development. Second, a 2-year difference between mental age and chronological age at the age of 5 years is not comparable with a 2-year difference at the age of 9 years. This incongruity is even greater after the chronological age of 15–17 years. At this adolescent age level, we hardly see differences in the mean raw scores of the various age groups.

Therefore, the ratio IQ coefficient appears to be a poor measure of intelligence. For this reason, modern tests all have deviation IQs. By using deviation-IQ scores, it is possible to calculate how much an individual's test score deviates from the mean test score achieved by a representative peer group of this individual. The calculation of the deviation IQ goes as follows: (1) large representative norm groups of people of various ages are tested, (2) the mean raw test scores and standard deviations are calculated, and (3) it is assumed that intelligence test scores for each age group have normal distributions. For the calculation of deviation IQs per age group, the raw test scores are transformed into norm scores. Almost all intelligence test constructors follow the rule that the mean raw test scores for each age group are transformed into the deviation IQ of 100, with a standard deviation of 15. Therefore, 68.3% of all IQ scores lie within the 85–115 IQ score range and more than 95% of all IQ scores lie within the 70–130 IQ score range, as Fig. 1 shows.

By using the deviation IQ, the test scores of each examinee can be compared with those of his or her peer group. Instead of the original comparison of the mental age with the chronological age, with deviation IQs the scores of each individual can be related to the norm tables of his or her age group. Scores on different tests easily can be compared with one another because almost all the different instruments have norm scores with equal means and standard deviations.

Intelligence Tests: Some Examples

Although all general intelligence tests aim to measure one and the same concept, their formats are not the same. The commonest way of classifying intelligence tests is in terms of individual and group tests. Individual intelligence tests are to be administered to only one person at a time, whereas group intelligence tests can be administered to whole groups of individuals at the same time. In general, an examiner uses an individual test from a different perspective or for a different goal than a group test. Individual IQ tests can, for example, be used to test more clinical hypotheses, whereas group tests can be used for selection for university or for the prediction of school or job

Figure 1 The normal curve with the deviation-IQ scores. (A) Percentages within segments of the normal curve. (B) Standard deviations. (C) Percentile scores. (D) T-scores. (E) Deviation-IQ scores ($m = 100$, $SD = 15$). (F) Stanines.

success. Group intelligence tests are more often used for screening, followed by an individual test that can be used to confirm a particular low or high score level.

Individually Administered Tests

Stanford-Binet Intelligence Scales The first individually administered test in the United States was the Standard-Binet Intelligence Scale for children and adolescents. This Stanford-Binet Scale is constructed as an age scale; the items of the scale are grouped into age levels. Items, such as “compares 2 lines” (age 4), “repeats a sentence of 10 syllables” (age 5), and “compares 2 objects from memory” (age 8), are included in the tests when the percentages of correct answers are lower for each successive age level.

Terman tried to include a broad sample of intellectual tasks that were less dependent on specific school learning than the original Binet Scales. He turned the original idea of mental age into the ratio IQ concept: IQ was defined as $MA/CA \times 100$.

In 1937, 1960, and 1972, the Stanford Binet Scale was revised twice, with new floor and ceiling items. In 1960, the deviation IQ was introduced. The fourth edition of the Stanford-Binet Intelligence Scale (SB-IV; 1986, Riverside Publishing Company) was based for the first time on a theoretical and more complex, hierarchical three-level factorial intelligence model, with general intelligence (g level) at the highest level, three broad factors (crystallized intelligence, fluid-analytic intelligence, and short-term memory) at the intermediate level, and three factors (verbal reasoning, quantitative reasoning and abstract/visual

abilities) at the lowest level. Carroll’s intelligence theory clearly underlies this model. Various empirical studies with SB-IV data, however, have not supported a clear distinction between fluid and crystallized intelligence. The SB-IV is intended to measure intelligence in a broad age range, from 2 years old to adulthood. The test has been constructed using modern test theory (including Rasch scaling). Item-bias analysis for ethnic groups has been performed, making the test as bias-free as possible. This edition no longer focuses only on the general intelligence of children and on detecting mental retardation or giftedness, but also on diagnosing learning disabilities. The reliability of the composite scores is good.

Wechsler’s Intelligence Scales In 1939, Wechsler argued that a new instrument with separate subtests—unlike the complex age scales of the Binet scales—could be used to reveal specific disorders in adults by analyzing the individual test profile of the client. Although Wechsler thought that intelligence could only be measured by a complex combination of cognitive tasks, he constructed a test with which both the global intelligence (IQ) of a person could be estimated and a more diagnostic profile analysis could be performed. He published his first Wechsler scale, the Wechsler-Bellevue Scale Form I for adults, in 1939, followed by a revised Form II in 1947. Wechsler noted that the intelligence tests available at that time had been constructed primarily for younger children and that adult examinees found the adapted versions too childish.

Various revisions of the instrument led in 1997 to the Wechsler Adult Intelligence Scale III (WAIS-III;

Psychological Corporation). Like the earlier versions, the WAIS-III has two broad intelligence factors, with subtests loading on a verbal and a performance scale. Verbal subtests are, for example, the detection of Similarities, answering Information questions, and Vocabulary. Performance subtests are, for example, Object Assembly and Block Design tasks. The previously developed WAIS-R had 11 subtests; three new ones are included in the WAIS-III. Therefore, it is possible to provide good estimates for not only the traditional full-scale IQ and the verbal and performance IQs but also for four smaller intelligence factors, described as verbal comprehension, working memory, perceptual organization, and processing speed. The test has been developed for the adult age range from 16 to 90 years. Various clinical groups were tested in addition to a stratified norm group. Reliability coefficients for the full-scale IQ, verbal and performance scales, and the smaller intelligence factors are high.

In 1949, Wechsler published a child and adolescent version of the test, the Wechsler Intelligence Scale for Children (WISC). Revisions were published in 1974 (WISC-R) and 1991 (WISC-III). The WISC-III, constructed for children from 6 to 17 years, has the same format as the adult Wechsler tests with the content adapted to the younger age group. A verbal, performance, and full-scale IQ and four smaller factors scores can be administered: verbal comprehension, freedom from distractibility, perceptual organization, and processing speed. Reliability coefficients for the performance and verbal IQ, the full-scale IQ, and the smaller factors are good. The four factors have been identified in several empirical studies. The WISC-III has been adapted and translated for use in more than 22 different countries. The four smaller factors cannot be identified in the data sets of all countries.

In 1967, Wechsler published a test for young children ages 4– $6\frac{1}{2}$ years, the Wechsler Preschool and Primary Scale of Intelligence (WPPSI), followed in 1989 by the WPPSI-R, the revised version for a broader group of children, ages 3–7 years. The reliability coefficients of the scales are high. Strong evidence for a two-factor structure can be found in the manual. The main criticisms of the WPPSI-R are that the test is too difficult for young intellectually at-risk children.

Kaufman's Intelligence Batteries In 1983, the Kaufman Assessment Battery for Children (K-ABC; American Guidance Service), an intelligence tests for children ages 2.5–12.5 years, was constructed from a theoretical perspective in which Cattell's distinction between fluid and crystallized intelligence was combined with the Luria's neuropsychological ideas about the importance of simultaneous versus sequential mental processing. Test scores on four intellectual domains can be administered: sequential processing, simultaneous processing,

mental processing (which is the first two domains combined), and achievement. The scales have high reliability coefficients. Separate percentile norms have been presented for different ethnic and socioeconomic groups.

Kaufman constructed two other intelligence tests: the Kaufman Adolescent and Adult Intelligence Test (KAIT; 1993) and the Kaufman Brief Intelligence Test (K-BIT; 1990). The KAIT was designed for the age range 11–85 years. The test has a good reliability. Validity coefficients with WISC-R and WAIS-R can be interpreted as high. The K-BIT was designed as a screening instrument to get a quick estimation of the intelligence level of an examinee. The structure of the test differs from KAIT or K-ABC, consisting of only two subtests: a vocabulary test and a nonverbal subtest for inductive reasoning (matrices). The K-BIT is designed for the age range 4–90 years and takes only 15–20 minutes.

Das-Naglieri Cognitive Assessment System A new instrument for measuring IQ is the Das-Naglieri Cognitive Assessment System (CAS; 1997, Riverside Publishing). Like, for example, the Woodcock-Johnson tests of cognitive ability (Riverside Publishing), the CAS is based on a cognitive theory linked with parts of Luria's neuropsychological theory, the PASS theory (planning, attention, simultaneous, and successive). Reliabilities and standardization can be interpreted as good.

Group Intelligence Tests

The first group intelligence tests, the Army Alpha and the Army Beta, were constructed for a quick screening of large groups of potentially interesting recruits for the army. At first, the tests were not available to other psychologists. But the idea of mass testing became more and more popular for aims other than military selection. Group tests often differ from individual tests in their content and format. Today, most group tests have multiple-choice formats. They also often have time limits. Examinees have to start and stop at a certain time and have to wait for an order to turn the page; and instruction for each test part takes place for the whole group at once. By using group tests, large numbers of examinees can be tested simultaneously. Personal circumstances that may influence the test scores will not be easily noticed under these conditions. Therefore, the scores on group tests should be considered with extra caution; very low scores should be given extra attention, and these examinees should be given some parallel form of the same test on another day. Multilevel batteries, adaptive testing, and computer-based testing and/or administration could be useful in overcoming the negative aspects of group testing.

Cognitive Abilities Test The Cognitive Abilities Test (CogAT; Riverside Publishing) is a multilevel test

assessing children's reasoning and problem solving using both verbal and nonverbal subtests. With multi-level batteries, the examinee does not have to solve a restricted range of test items that are probably good for his age and ability level but can be tested at a level that is the most suitable for him or her. The test is constructed so that most examinees are tested with items with intermediate difficulty levels. Successive batteries overlap one another and the scores on one of the batteries can be compared with various types of norms. The CogAT has levels 1 and 2 for grades K–3 and levels A–H for grades 3–12. At each level, the scores on three subbatteries (verbal, nonverbal, and quantitative) can be administered and converted to various types of norms.

SAT and Otis Many group intelligence tests have been developed to measure aptitude for scholastic work or are intended to measure a combination of intellectual ability and scholastic aptitude. The Otis-Lennon School Ability Test (OSALT; Harcourt Brace, 7th edition) has been constructed to measure verbal comprehension and verbal, figural, quantitative, and pictorial reasoning in children and adolescents in the school-age range K–12.

The Scholastic Assessment Test (SAT) consists of two parts: a reasoning part (verbal and mathematical reasoning) and a subject part (English, history, social studies, mathematics, science, and languages). The test was constructed for college-admission purposes. The reasoning part of the test has good predictive qualities, not only for performance in the first few months of college but also for later performances and examinations.

Nonverbal and Culture-Free Tests

Individual tests (and some group tests as well) that are constructed from the perspective that intelligence must be measured as a conglomerate of scores on a number of different cognitive tasks generally consist of a combination of tasks that depend heavily on language. But word use, relations between words, and verbal instructions are not very suitable for groups of people who do not speak the language very well. Therefore, some tests have been constructed that do not, or hardly, use verbal language or symbols. Most of these tests measure reasoning processes with pictures, geometrical forms, numbers, or symbols instead of verbal materials. The examiner shows how to solve the examples by gestures and pointing. Perhaps the most widely used nonverbal test, often described as culture-free, is the Progressive Matrices test (PM) constructed by Raven in 1958. The PM was designed primarily as an estimator of general intelligence,

more specifically of inductive reasoning. The items are presented as matrices, arranged into three rows and three columns, resulting in nine pictures of symbols changing from left to right and from top to bottom. However, the ninth picture is missing and has to be found from several alternatives by reasoning. The test can be administered in groups or individually. The instructions are very simple (e.g., pointing to the right alternative and then to the blank space on the page of the instruction items).

Tests such as Raven's PM were constructed for their potential applicability across cultures. Many studies have been performed trying to establish the hypothesis that nonverbal tests such as the PM are culture-free, meaning that samples of people from different cultures or immigrant groups will perform equally on these tests. However, it has become evident that culture-free tests do not exist.

Studies with intelligence tests so far have shown that culture, as well as other aspects of the environment, influence the test scores to some extent. Consequently, culture-fair tests rather than culture-free tests are being constructed. In designing such tests, the researcher chooses only those items related to the knowledge and experience of a wide variety of cultures. Specific cultural-linguistic contexts are avoided. Items should not be biased toward one or more specific groups of individuals (defined by sex, cultural group, etc.). An example of a culture-fair intelligence test is the Naglieri Nonverbal Ability Test (NNAT; Psychological Corporation), a nonverbal reasoning test with several reasoning components, such as serial reasoning, matrices, and visual spatialization. The test is appropriate for children and adolescents K–12. Item-bias techniques to ensure that tests are unbiased against certain groups are quite normal these days when the construction of new tests and test versions takes place.

The Nature–Nurture Issue

Is intellectual ability innate, having hereditary components only (nature), or can it be influenced by environmental factors, such as nutrition and education (nurture)? For a long time in research on intelligence, proponents of heredity and proponents of environment have debated this question; this battle is known as the nature-nurture controversy. Although most researchers in the field of human intelligence now believe that both factors—innate ability and environmental influences—play important roles in intellectual development, the discussion on the interaction between both aspects still has a central place in testing. The conclusion seems justified that the hereditary component accounts for approximately 50–60% of the variance in intelligence test scores. Given the human genetic foundation, clear restraints are imposed on the maximum level of intelligence of an individual. At the same

time, however, intellectual differences among individuals cannot be explained entirely by nature. The 40–50% of the variance in intelligence test scores not attributable to heredity must be attributed to environment, both group environmental influences (e.g., those shared by the family: family characteristics, socioeconomic conditions, parenting styles) and individual, unique environmental influences. Note also that the high percentage of genetic influence does not imply that intelligence test scores have a fixed level for an individual. Changes in the environment, for instance level of schooling, diseases, or nutritional deficiency, certainly will influence the level of the IQ.

Therefore, both environmental influences and the interaction between genetic predisposition and the environment play an important role in IQ. Hence, it is necessary to keep at the back of our mind the distinction between intelligence as a predisposition (i.e., intellectual potential) and actual intelligence (i.e., level of intelligence). Although nature restricts the maximum level of intellectual potential, it is unlikely that anybody will make optimal use of this potential. Goal-directed training programs can therefore make it possible (through nurture) to bring the intelligence scores of individuals closer to their intellectual potential.

Stability and Change over Time

Throughout an individual's lifetime, performance on measures of intelligence increases and decreases. A rapid increase in mastery is seen on cognitive tasks in infants and young children and a less rapid increase is seen in older children, with the slope of the increase in mastery becoming less steep during adolescence. Longitudinal studies with normal samples show that intelligence scores measured before 3 years of age have only limited predictive value for later measured intelligence. Between the ages of 3 and 7, the predictive value becomes much better, and from the age of 8 years on it reaches stability. For each age group, intelligence tests have more difficult items and more complex problems to solve, but large individual differences among children of the same age remain. From the age of approximately 18 years, it is no longer necessary to use more difficult items; cognitive development has been stabilized. Important research questions are: Does the intellectual level remain stabilized after adolescence? And if not, when do cognitive abilities start to decrease? Based on cross-sectional research, Wechsler reported a rapid increase in ability, followed by a very gradual decrease from the age of 20. More recently, in 1996, Schaie presented the results of his Seattle Longitudinal Study. He found no uniform patterns of change in intelligence when looking at the whole spectrum of intellectual abilities. Reasoning ability remains at

a very high level as people get older. The vocabulary decreases somewhat after the age of 60 and word fluency decreases after the age of 50. After the age of 80, there is some decrease in perceptual speed and numerical abilities. Schaie stressed individual differences.

Another important question raised in relation to the stability of intelligence over time is whether there are generational differences in intelligence. That is, is the mean intelligence level of a population raising in time? Indeed, mean scores on intelligence tests do increase over time. This effect is called the Flynn effect, after James Flynn who reported it in several studies since the mid-1990s. He collected intelligence test data sets in more than 20 countries and detected a general effect: The mean IQ scores of the populations rose approximately 10 points over a period of 30 years (i.e., one generation). The full reason for this improvement remains unclear. Factors such as better and longer education, better economic circumstances, better information technology, a more complex environment that permits the use of a larger part of the cognitive potential, and better food conditions are all only partial explanations of the reported increase in IQ scores.

What Is a Good Intelligence Test?

How can good tests be characterized? First, good tests are standardized. In a good test, an estimation of a person's intellectual level is always based on a comparison with the standardized norm tables of comparison groups, mostly peers. If a test is good, score fluctuations cannot be attributed to differences in the instructions, in the behavior of the examiner, or in the situation. Every examinee has to have an equal and optimal opportunity to perform as well as possible on the test. Test standardization therefore means that the test material, the test instruction, and the test manual unequivocally prescribe what the examinee has to do to receive and to interpret the test results. Second, the administration of a good test should result in an objective description of the examinee. Two different examiners should arrive at the same results and interpretation. The test scores must be as independent as possible of observations or subjective interpretations. Computerized testing and a good standardized test manual both diminish possible subjective influences. Third, a test should be reliable, meaning that test scores must be influenced as little as possible by the situation or incidental circumstances. Of course, this reliability is partly related to the conditions of standardization and objectivity. But a test score can be influenced by other things as well, for example, illness or emotional upset, the examinee's motivation and work attitude, boring test items, or a boring test room. By using a reliable test, an examiner can be more confident that the test scores estimate the true IQ scores

of the examinee. Fourth, a good test is valid. The test should indeed measure the theoretical concept on which it is based. In addition to validity, a test should predict future test scores, for instance school success or job performance in the future. And finally, a good test has good standardized norms and is standardized on large, stratified norm groups. Current intelligence tests should have deviation IQs; it must be possible to compare the test scores of each examinee with the mean test scores of his or her peer group.

Applications of Intelligence Tests

One reason for using intelligence tests lies in the predictive qualities of these tests. The test scores are closely linked with the prediction of future success in school and with future job performance. A second reason is that, in principle, these tests provide an opportunity to describe the cognitive (dys)functioning of the examinee. These tests could thus be used to go one step beyond merely predicting school success by detecting weak cognitive areas. They could thus offer direct advice to teachers and encourage the rearrangement of educational settings. However, the standard intelligence test is not the most suitable instrument for this purpose. For this reason, new test forms such as learning potential tests and other dynamic and adaptive forms of testing, including computerized testing, have been developed. In addition to the static test situation of the traditional intelligence test, with a learning potential test the examinee is tested more than once and is given help or individualized hints. This means that the examiner can look more specifically into the problem-solving process of the examinee and can describe in more detail what is happening during testing, which can add valuable diagnostic information for the

interpretation of the test scores itself and can add more information about the examinee's ability to learn and on-going developing intellectual expertise. Thus, the predictive validity of both static intelligence tests and dynamic learning potential tests guarantee the value of intelligence testing in modern society.

Inter-Rater Reliability

Robert F. DeVellis

University of North Carolina, Chapel Hill, North Carolina, USA

Glossary

alpha coefficient A statistic representing internal consistency among items in a set.

intra-class correlation coefficient A class of statistics representing the proportion of true score variance to total variance, expressed as a ratio of variances ascribable to specific sources.

kappa coefficient A statistic representing the chance-corrected extent of agreement between observers.

product-moment correlation coefficient A widely used statistic (often simply called the correlation coefficient) representing the amount of association between continuous variables.

reliability The proportion of variance in a measure that can be ascribed to a true score.

true score The hypothetical error-free component of an obtained score, reflecting the actual state of the variable measured.

Inter-rater reliability is the extent to which assessments of a phenomenon by two or more observers are influenced by some aspect of the phenomenon being observed rather than by some aspect of the observers. Typically, it concerns the degree of consistency or agreement that exists across multiple observers or raters of some phenomenon. Larger discrepancies across observers are interpreted as representing more error in the observers' collective ratings. Several alternative computational approaches have been developed for quantifying inter-rater reliability.

Classical Test Theory and Reliability

According to classical test theory, a score obtained in the process of measurement is influenced by two

things: (1) the true score of the object, person, event, or other phenomenon being measured and (2) error (i.e., everything other than the true score of the phenomenon of interest). Reliability, in general, is a proportion corresponding to a ratio between two quantities. The first quantity (denominator) represents the sum total of all influences on the obtained score. The other quantity (numerator) represents the subportion of that total that can be ascribed to the phenomenon of interest, often called the true score. The reliability coefficient is the ratio of variability ascribable to the true score relative to the total variability of the obtained score. Inter-rater reliability is merely a special case of this more general definition. The distinguishing assumption is that the primary source of error is due to the observers, or raters as they are often called.

Multiple Raters

If two or more raters are accurately observing the exact same thing, their reports of what they see should be identical. To the extent that they differ, it is assumed that characteristics of the raters (i.e., biases) are responsible. Such characteristics, of course, are sources of error and consequently the resultant ratings are inaccurate to some degree. It follows from this reasoning that the degree of discrepancy among raters represents the extent of unreliability that the set of observations possesses or, conversely, that the lack of variation from rater to rater represents the extent of reliability. Quantifying discrepancies among raters thus becomes an important part of assessing inter-rater reliability.

A hypothetical example may help to clarify these concepts. Assume that a researcher is content analyzing transcripts collected in the course of a research project. The researcher's aim is to categorize free-form narrative from the transcripts into quantifiable data that can be analyzed

using standard inferential statistical procedures. The process may begin by defining units of information, that is, chunks of text corresponding to the unit of analysis chosen on conceptual grounds. Having chosen a unit of analysis, the investigator typically will want to evaluate some quantitative aspect of the units. Therefore, a classification system must be developed that defines the criteria to be used to classify units of speech.

Both the unitization and classification processes require a degree of judgment. For example, if the investigator is interested in coding "affective responses," he or she must determine what text segments (i.e., units) to evaluate for affective content and when a given text segment is an expression of emotion. The judgments involved in both unitization and classification create opportunities for systematic bias.

Still another way of viewing this situation is with respect to sources of variation in the data. Presumably, the investigator wants the data to manifest variation attributable to some aspect of (1) the individuals studied, (2) the situations to which they were exposed, or (3) some combination of these. If, however, in the process of transforming the data from raw to quantifiable form, a personal bias or point of view is superimposed, then characteristics of the coder are an additional source of variation in the data.

One means of addressing the impact that data rating has is to use multiple raters. To the extent that multiple raters are able to produce comparable data (i.e., similar characterizations of affective vs. nonaffective verbalizations within identical transcripts), the likelihood that the ratings are substantially influenced by idiosyncratic perceptions has been attenuated. Consequently, it is customary for research of the type described to employ multiple raters. The idea is that, if independent raters can reach the same conclusions from the same data source, then those conclusions must reflect some aspect of the data examined (which are identical) rather than something about the raters (who are different).

Assessing Inter-Rater Agreement

Consider a simple, if not very realistic, example. Assume that an investigator has a theory that action-oriented people will be more aggressive practitioners of health-promotion behaviors. That is, the theory speculates that action-oriented people will exercise more, seek appropriate professional care, regulate their diets, and generally choose health-benefiting as opposed to health-compromising activities. To test this theory, the investigator reasons that the number of verbs used in individuals' speech should serve as an index of how action-oriented they are. This imaginary theory specifies that people whose speech is more heavily laced with verbs will enjoy

Table I Cross-Tabulation of Classifications of Transcript Words

<i>Rater #2 \ Rater #1</i>	<i>Verbs</i>	<i>Nouns</i>	<i>Adjectives</i>	<i>Total</i>
<i>Verbs</i>	10	2	9	21
<i>Nouns</i>	6	43	0	49
<i>Adjectives</i>	5	5	20	30
<i>Total</i>	21	50	29	100

an improved health status. So, the task of the investigator is to determine which individuals use more verbs in their speech and, subsequently, to compare verb frequency to various health-status measures. Because certain words can have a verb and a nonverb form (for example, "score" can be either a noun or verb), the investigator feels that there is possibly room for error in the coding of the data and decides to have two independent raters determine how many verbs exist in each transcript. That is, the investigator will determine how reliably a verb score can be assigned to each subject's transcript by comparing the scores given by two raters for each transcript.

Let us assume that the two raters evaluate the same transcript and that their results are cross tabulated as shown in Table I. Having tabulated the data for agreement between two raters, we now must determine to what extent the conclusions of the two are comparable.

Percentage Agreement

One of the simplest ways of judging reliability is percentage agreement (i.e., the percentage of cases that raters classify similarly). There are at least two ways to do this, and the difference between them is important. The simplest method is to take a simple count of the number of instances of a category that each rater reports. Assume, as in Table I, that each of two raters found 21 instances of verbs among 100 possibilities. Because they agree on the number of instances, 21 in 100, it might appear that they completely agree on the verb score and that the inter-rater reliability is 1.0. This conclusion may be unwarranted, however, because it does not determine whether the 21 events rater #1 judged to be verbs were the same events that rater #2 assigned to that category. The raters have agreed on the rate of occurrence (i.e., 21%) of the category, "verbs" but not necessarily on specific examples of its occurrence. Rater #1 might have rated the first 21 of 100 words of a transcript as verbs, whereas rater #2 might have described the last 21 words as verbs. In such a case, the raters would not have agreed on the categorization of any of the specific words on the transcript. Rather than simply tallying the number of words each rater assigned to a category, the researcher could determine how the raters evaluated the *same* words. The cross-tabulation shown in Table I accomplishes this by

indicating how many words rater #1 classified as verbs, for example, and how many of those same words rater #2 classified similarly. The number of word-by-word agreements for the several categories appear along the main diagonal of the table. This is a more specific indicator of percentage agreement as a measure of inter-rater reliability. In this case, the overall percentage agreement is 73% and, for verbs, it is $10/21 = 47.6\%$.

Chi-Square

Another method for describing the pattern of ratings is to perform a chi-square test on the data in the 3×3 table. The null hypothesis for such a test is that the patterns of ratings for the two raters are random. That is, if the ratings are unreliable (i.e., not influenced by the nature of the words, but only by the proclivities of the raters) the number of verbs identified for a given subject by rater #1 should be independent of the number of verbs seen by rater #2. The chi-square test can be applied to the obtained data to determine whether the pattern of ratings fits the null hypothesis or whether there is some degree of association such that the raters agree with one another more than chance would predict.

The computation of chi-square requires that we compute expected rates of agreement, as shown in Table II. Chi-square (χ^2) can be computed from this table by summing across the cells the squared difference between expected and observed frequencies divided by the expected frequency:

$$\begin{aligned}\chi^2 &= \sum [(O - E)^2 / E] = (10 - 4.41)^2 / 4.41 \\ &\quad + (2 - 10.50)^2 / 10.50 + (9 - 6.09)^2 / 6.09 \\ &\quad + (6 - 10.29)^2 / 10.29 + (43 - 24.50)^2 / 24.50 \\ &\quad + (0 - 14.21)^2 / 14.21 + (5 - 6.30)^2 / 6.30 \\ &\quad + (5 - 15.00)^2 / 15.00 + (20 - 8.70)^2 / 8.70 \\ &= 66.94\end{aligned}$$

The degrees of freedom (df) for this table is $(3 - 1) \times (3 - 1) = 4$, and thus the chi-square statistic is significant beyond $p < 0.0000000000000001$. This analysis indicates that the distribution of verbs versus nouns versus

adjectives is not independent across raters. Even with a highly significant chi-square, however, we cannot be certain that the rates agree on the number of verbs. All we know is that the overall pattern is nonrandom.

A more appropriate test might collapse categories into “verbs” versus “nonverbs” (i.e., adjectives and nouns combined). This is shown in Table III. Note that the overall percentage agreement has now climbed to 78% because instances in which one rater judged a word to be a noun and the other judged it to be an adjective are now counted as agreements (i.e., “nonverb” matched with “nonverb”). For this table, $\chi^2 = 11.35$ with 1 df. This is significant with $p < 0.001$. Therefore, we can conclude that the pattern of rating words as verbs or nonverbs is not independent across the two raters.

Based on the value of χ^2 alone (or its associated probability), however, we *cannot* conclude that an adequate level of agreement exists between the two raters. Chi-square is a measure of association (i.e., nonrandomness), not agreement. An association might exist that is *not* a reflection of agreement. For example, two sets of ratings may be negatively associated; that is, the assignment of an event to one category by rater #1 may tend to co-occur with the rater #2’s assigning the same event to the other category, or one type of disagreement may occur far more often than expected while another type occurs less often. Even though the ratings in such a case would not agree very well, the pattern is indicative of an association and the chi-square would probably be high.

Chi-square looks for departures from zero relationship. It does not care about the direction of association. In addition, it does not care if the amount of agreement is actually quite small as long as it is statistically improbable. A chi-square corresponding to a low degree of agreement might be significantly different from a totally random pattern and, thus, the chi-square statistic would be significant. It does not follow, however, that the level of agreement is substantial. Chi-square can thus be misleading when the extent of agreement is the concern.

Kappa

Cohen’s kappa (κ) statistic is a chance-corrected method for assessing agreement (rather than association) among

Table II Cross-Tabulation of Classifications of Transcript Words with Expected Frequencies^a

Rater #2 \ Rater #1	Verbs	Nouns	Adjectives	Total
Verbs	10 (4.41)	2 (10.50)	9 (6.09)	21
Nouns	6 (10.29)	43 (24.50)	0 (14.21)	49
Adjectives	5 (6.30)	5 (15.00)	20 (8.70)	30
Total	21	50	29	100

^a Expected frequencies are in parentheses.

Table III Cross-Tabulation of Classifications of Transcript Words, Collapsing Nonverb Categories^a

Rater #2 \ Rater #1	Verbs	Nonverbs	Total
Verbs	10 (4.41)	11 (16.59)	21
Nonverbs	11 (16.59)	68 (62.41)	79
Total	21	79	100

^a Expected frequencies are in parentheses.

raters. Kappa is defined as follows:

$$\kappa = (f_O - f_E)/(N - f_E)$$

where f_O is the number of observed agreements between raters, f_E is the number of agreements expected by chance, and N is the total number of observations. In essence, kappa answers the following question: What proportion of values not expected to be agreements (by chance) actually *are* agreements?

We can examine the data from Table III using kappa (recall that $N = 100$):

$$f_O = 10 + 68 = 78$$

$$f_E = 4.41 + 62.41 = 66.82$$

$$\kappa = (78 - 66.82)/(100 - 66.82) = 0.34$$

This ratio can be considered conceptually. The numerator is the amount of observed agreement minus the amount expected by chance. The denominator is the total number of observations minus the number of agreements expected by chance—in a sense, this denominator is the number of cases in which the rate of occurrence for the two response classes (verb vs. nonverb) does not guarantee agreement, i.e., the number not determinable merely from the marginal probabilities of the two response classes. It also is equal to the sum of the expected frequencies of the two nonagreement cells (i.e., $16.59 + 16.59$). Thus, kappa is equal to the proportion of “observations free to vary” that yields an agreement between raters. Stated in terms of Table III, it is the number of agreements, beyond chance, relative to the number of expected misses. Thus:

$$\kappa = \frac{\text{Actual agreements beyond chance}}{\text{Potential agreements beyond chance}}$$

A $\kappa = 0.34$ is regarded as modest agreement.

As another example of how chi-square and kappa compare, consider the distribution of agreements shown in Table IV. Here $\chi^2 = 6.25$ ($p < 0.02$), whereas $\kappa = 0.20$. Thus, although chi-square is significant, the value of kappa suggests little agreement.

Although kappa is probably the most frequently used measure of agreement, it has come under criticism. One of these criticisms is that kappa is a measure of *exact* agreement and treats approximate agreements in the

same way as extreme disagreements. But with some types of data, a “near miss” may be better than a “far miss.” Although this is usually not the case when the categories being rated are truly nominal (as in our example of verbs vs. nonverbs), for ordinal categories the idea of a “near miss” makes more sense. Note also that, for a given number of observations, the more categories there are, the smaller kappa is likely to be. Even with our simple percentage agreement, we have seen that collapsing adjectives and nouns into a single category increases the “hit rate.” *Weighted kappas* are one way around the “near miss” problem. Essentially, the weighting system can differentiate between relatively proximal and relatively distal ordinal categories. Disagreements that entail different raters choosing nonidentical but proximal categories contribute more positively to the measure of agreement than due disagreements involving highly dissimilar classifications by the raters.

Product-Moment and Other Correlation Coefficients

In some cases involving ratings of continuous variables, it may be appropriate to evaluate inter-rater agreement by means of the everyday Pearson product-moment correlation coefficient. This is the case when the investigator is interested in to what extent raters agreed in their placement of specific stimuli within their total distributions of all the stimuli being rated. In other words, this method applies when the investigator want to know whether raters agreed on the percentile scores given to the stimuli being rated, but the actual ratings are given in some absolute rather than relative metric. Imagine, for example, that two raters agreed that a certain phrase represented an average degree of emotionality compared to all the phrases in a transcript. If rater #1 considered the whole transcript to be somewhat more emotionally laden than rater #2 did, rater #1 might consistently assign higher scores than rater #2. So, a phrase that both raters considered to be precisely at the midpoint of all phrases with respect to emotionality would receive different numerical scores. Agreement in the literal sense would be zero. But the score discrepancy would result not from a fundamental difference in perceptions but merely in calibration. In such a case, a correlation coefficient, which is blind to units of measurement and is based on similarities of location along a continuum, might actually be preferred as an indicator of inter-rater reliability over a method such as kappa.

The product-moment correlation assumes that the variables (ratings in this case) are measured on a continuous scale. Often, although we may think of the phenomenon being evaluated as inherently continuous, its measurement is not. Rating, in fact, implies assignment to discrete categories. In such circumstances, the tetrachoric

Table IV Hypothetical Data Illustrating Modest but Statistically Significant Association

Rater #2 \ Rater #1	A	B	Total
A	45 (40)	5 (10)	50
B	35 (40)	15 (10)	50
Total	80	20	100

(binary case) or polychoric (multiple ordered category case) correlation coefficient can be used as an indicator of inter-rater reliability in a manner analogous to the use of the product-moment correlation with continuous data. Tetrachoric and polychoric correlations are means of estimating what the correlation would have been had the variables been measured continuously. As with the product-moment correlation, the tetrachoric or polychoric correlation between the raters provides a window into the relationship of ratings to true scores and, thus, can serve as an indicator of reliability. A full examination of these methods is beyond the scope of this entry.

Coefficient Alpha

Cronbach's coefficient alpha is used primarily as a means of describing the reliability of multiitem scales. Alpha can also be applied to raters in a manner analogous to its use with items. Using alpha in this way allows us to determine inter-rater agreement when the ratings entail noncategorical data (for example, the degree of emotionality, on a scale of 1 to 10, in various units of text). Scale items and raters both are, in essence, indicators of information about a phenomenon of interest. The information that the items or raters provide is divisible into a portion that is about the phenomenon common to all the indicators and another portion that is due to the idiosyncratic features of each specific data source, be it item or rater. The final score on an item assessing emotionality, for example, will be an amalgam of a respondent's true level of emotionality plus error arising from unintended characteristics of the item, such as confusing language. Similarly, a rater's judgment of the emotionality of a text passage is an amalgam of the actual emotional content of the text plus rater characteristics that affect judgments.

For multiitem scales, alpha can be computed from the correlations among the items. Inter-rater reliability can be computed in like fashion from correlations among the raters. Moreover, just as the alpha for items is driven by the magnitude of inter-item correlations and the number of items, the alpha for inter-rater reliability is determined by the inter-rater correlations and the number of raters. In both the item and rater cases of alpha, the Spearman-Brown equation can be used both to compute alpha and to determine the effect on reliability of adding items or raters. In general, the more numerous and more strongly associated the items or raters are, the higher coefficient alpha will be.

Intra-Class Correlation Coefficient

An analysis of variance (ANOVA) approach can be used to partition variance into discrete sources that can be compared to one another in meaningful ways. Certain ratios of variances can be constructed that correspond to the

common definition of reliability, and the proportion expressed by such a ratio is called an intra-class correlation coefficient. That same approach can be, and frequently is, used to assess inter-rater agreement. The suitability of the intra-class correlation coefficient for such purposes underscores the fact that inter-rater reliability is merely a special case of reliability more generally. As it happens, both kappa (weighted or unweighted) and coefficient alpha are special cases of the intra-class correlation coefficient. The latter is not one coefficient but a family of coefficients that varies depending on the nature of the data, research question, and other factors.

Whenever we obtain results from an ANOVA that allows for variance to be partitioned into effect (such as the true score of an observed event) and error (such as differences among raters), it is possible to construct one or more intra-class correlation coefficients. The intra-class correlation coefficient is a general representation of the ratio of effect variance relative to effect-plus-error variance. By constructing the ANOVA appropriately (often treating different indicators as repeated measures of a phenomenon) and then computing the ratio of the appropriate variance terms (i.e., those that correspond to true variation for the numerator and true-plus-error variation for the denominator), a variety of issues related to reliability can be addressed.

In a now-classic 1979 paper, Shrout and Fleiss laid out a series of guidelines for using the intra-class correlation coefficient to assess inter-rater reliability. They noted three issues that help to determine which of several possible analytic strategies should be used: (1) whether different raters observe the same or different events, (2) whether the investigator is interested in assessing the reliability of one rater relative to the others or of all raters as a group, and (3) whether the investigator wishes to generalize to the specific raters used only (as alpha does with items or raters) or to a broader population of raters represented by those sampled in the study. Depending on how the investigator views these three issues, the intra-class correlation coefficient takes on a different form. The advantage of the intra-class correlation coefficient and alpha over kappa is that they can make the most use of the information available (e.g., distinguish between near and far misses in the case of nonnominal data), whereas unweighted kappa cannot.

An extension of this general approach to identifying specific sources of error is generalizability theory. A good introduction to this highly versatile methodology is the 1991 text by Shavelson and Webb.

Conclusion

Assessing inter-rater reliability should be an integral part of all research that involves the use of raters or judges to

quantify phenomena. Using a single rater precludes the assessment of inter-rater reliability and thus should be avoided; inter-rater reliability is a special case of reliability more generally. The specific method chosen for assessing inter-rater reliability should be determined by the research questions and the nature of the data to be rated.

Inter-University Consortium of Political and Social Research (ICPSR) Data Sets

Christopher S. Dunn

Bowling Green State University, Bowling Green, Ohio, USA

Glossary

data archive A repository for computerized data files and data documentation.

data documentation Codebooks, record layouts, data collection instruments, descriptions of study procedures, and other materials that describe the contents and organization of computerized data files.

ICPSR study The computerized data files and data documentation from an empirical research study by the Inter-University Consortium of Political and Social Research.

Internet The vast collection of interconnected computer networks that all use TCP/IP protocols.

microdata Data about individual subjects or events; unaggregated data.

World Wide Web (WWW) Internet client-server hypertext distributed information retrieval system, which originated from the CERN High-Energy Physics laboratories in Geneva, Switzerland.

The Inter-University Consortium for Political and Social Research (ICPSR) is the largest social science data archive in the world. ICPSR provides faculty, students, and other researchers at over 550 member institutions with access to 5358 social science data collections (having separate titles). Collectively, these data collections comprise 94,082 available files and add up to nearly 1 terabyte of data—the exact number is 1,051,968,879,000 bytes. ICPSR also provides worldwide public access to some of those data collections through its externally sponsored topical archives. In 2002, ICPSR distributed 334,064 data sets to 1733 member and nonmember institutions, totaling over 8.8 million megabytes (almost 8.5 terabytes) of data. The amount of data distributed to all institutions is

the equivalent of nearly 13,650 completely filled CD-ROMs of data. ICPSR also provides educational programs through its well-known Summer Program, enrolling over 650 students from 200 institutions. The students select from among 45 statistics and social science methods courses taught by 40 guest faculty from 30 institutions. ICPSR's core activities of providing access to data and training in its analysis were important elements of its creation and continue to be central to its present mission.

ICPSR's Formation and Growth

The Inter-University Consortium of Political and Social Research (ICPSR) was established in 1962 by a founding set of 21 universities which created a formal organization to institutionalize informal collaborations that had developed during the 1950s for access to survey data about American national elections and participation in advanced quantitative analytical training. ICPSR was originally established as the Inter-University Consortium for Political Research (ICPR) because the impetus for sharing data and providing quantitative analysis training was concentrated among a small number of social scientists who focused on study of political values, attitudes, and voting behavior. Within the University of Michigan's Institute for Social Research, the Political Behavior Program had become a separate research program in 1956 under the leadership of Warren Miller. Throughout the 1950s and early 1960s, Miller's work, and that of Philip Converse and Angus Campbell, introduced methodological innovations into the field of political science through national surveys of the electorate. These included the successful

use of the panel survey design to study a mobile population, the integration of individual-level and aggregate data from multiple sources, and the use of social psychological theory and variables to study political attitudes and voting behavior.

Even then, the challenge of continued funding support for the elections studies was an issue for Miller. In part, he conceived of ICPR as an organization that could generate funds from dues-paying member institutions to maintain the 2-year sequence of national election surveys. He also thought that member institutions would provide important voices in support of the continuation of the election studies. Political scientists from other institutions were also convinced by another of Miller's concepts for the consortium. They and their students would have access to national survey data too expensive to develop at individual institutions and they would be able to obtain analytical and methodological training to enable them to stay abreast of the rapid innovations in quantitative research and analysis.

Warren Miller was the first director of ICPR and held that position until 1970 when the Political Behavior Program in the Institute for Social Research (ISR) became the Center for Political Studies and Miller became its first director. By that time, ICPR had grown into an organization with 134 member institutions, a staff of 60, and state-of-the-art computer facilities for cataloging acquired data and preserving it, processing it for use on multiple mainframe-computer-system platforms, and distributing it to member institutions on magnetic reel tape.

During the 1970s, major changes took place at ICPR. A new director, Richard Hofferbert, from Cornell University succeeded Warren Miller. Hofferbert directed ICPR during a time of tightening of federal research budgets in the latter years of the Nixon administration. That research belt-tightening was directly responsible for the withdrawal of some ICPR members and failures to pay dues by others. Reductions in National Science Foundation budgets also affected the ability of ICPR to pay stipends for participants in the Summer Training Program. ICPR responded by broadening the scope of the data in the archive to attract new member institutions and new sources of funding support. A massive historical data collection of county-level election returns from 1789 onward and roll-call records for the U.S. Congress was computerized. Extensive international relations data, including U.N. plenary session and committee voting records; social, political, and economic attributes of nations; and records of international conflicts, were added to the archive. ICPR also began to develop materials (data extracts and syntax setup files) that could be used for undergraduate instruction.

In 1975, ICPR's name was changed to the now familiar (and so easily pronounced) Inter-University Consortium

for Political and Social Research (ICPSR) to reflect the broadening of the scope of the data being archived. Also in 1975, Jerome Clubb, director of the Historical Archive, was named to succeed Hofferbert as the director. During Clubb's 16 years as director (1975–1991), ICPSR expanded its membership, its data collections, and its sources of external funding. By the end of Clubb's term as director, there were nearly 350 member institutions and two publicly funded topical archives: the National Archive of Computerized Data on Aging (NACDA) and the National Archive of Criminal Justice Data (NACJD). The basic organization of ICPSR data into 17 thematic categories had also been developed (see Table I). The data distribution system in which official representatives (ORs) at member institutions or their designees transmitted data requests to ICPSR and received requested data collections on reel tapes had been in operation for nearly 30 years. ICPSR became a national resource for the social sciences during the Clubb years.

With Clubb's retirement in 1991 and the appointment of Richard Rockwell from the Social Science Research Council, ICPSR entered a period of significant change. Three additional topical archives were added through externally sponsored projects. The Health and Medical Care Archive (HMCA), supported by the Robert Wood Johnson Foundation, was initiated in 1995. The Substance Abuse and Mental Health Archive (SAMHDA), supported by the Substance Abuse and Mental Health Services Administration of the Department of Health and Human Services (DHHS), was initiated in 1995. The International Archive of Education Data (IAED),

supported by the National Center for Education Statistics, was initiated in 1996. Also in 1996, the NACJD made all its data collections freely available to the public over ICPSR's first-generation World Wide Web (WWW) site. By 1998, almost all the data distribution at ICPSR data was being done over the WWW. With the shift to using the WWW as the primary tool for ORs to access data for their campus users, ICPSR was confronted with the need to provide data documentation in electronic format. This led to the documentation conversion project, which at its conclusion in 2003 had transformed over 500,000 pages of paper codebooks and data collection instruments into electronic files.

The dramatic changes in computing during the Rockwell years (1991–2000) also presented challenges to the original organizational structure and functions of ICPSR. A number of issues emerged concerning the value of membership, the function of the official representative system, the speed of data delivery, individual access to data, and the preservation of data. Essentially, the computing world had changed from a centralized mainframe environment to a decentralized individual environment. Research groups that previously needed a central warehouse for archiving data could by 2000 make their own project data available for downloading on their own WWW sites. Data users could download data from data producers directly to their own computers using only a few mouse clicks on the WWW. ICPSR itself had encouraged the rapid transfer of data directly to individual users by making some of its publicly funded topical archive data available directly to individual users who did not have to be affiliated with a member institution. By mid-2002, 28% of the ICPSR data collection titles were freely available from the ICPSR Web site.

These were the issues that confronted Myron Gutmann when he succeeded Rockwell as director of ICPSR in 2001. Almost immediately, Gutmann responded to these challenges by ordering the rapid implementation of ICPSR Direct, a system of individual access to ICPSR data by users affiliated with member institutions. ICPSR Direct had been in the planning and testing stages during the recruitment of a new director, but it required a leadership decision to fully commit to a data delivery system that bypassed the nearly 40-year tradition of data requests from and delivery to campus ORs. A majority of the 550-plus member institutions now provide direct access to ICPSR data at their campuses. Experience with ICPSR Direct suggests that ORs are still a hugely important link in the data availability chain. With ICPSR Direct, ORs now have administrative, certification, and tutorial responsibilities in the data delivery process rather than hands-on downloading of data and its transfer to users. With ICPSR Direct, the amount of data actually downloaded and used has increased.

Contents of the ICPSR Data Archive

Data collections in the ICPSR archive are organized according to the 17 thematic categories shown in Table I. Each of these thematic categories is the main category for a much more detailed outline and categorization of data collections. These detailed categorizations are used as search terms on the ICPSR Web site to search a database of metadata about the studies. The search returns a list of study titles in the specific category. For example, Table II shows the more detailed outline of subcategories for the first major thematic category, Census Enumerations.

Another way that ICPSR data can be categorized is according to the program units within ICPSR that are responsible for processing the data. This categorization scheme allows the description of collections brought into the archive and made available under the auspices of ICPSR's topical archives, according to data in the "general" archive and the topical archives, providing a more coherent program-related overview of data in the topical archives. In the next section, data are described in terms of the 17 themes, excluding data contained in ICPSR's topical archives. In the section thereafter, data from the ICPSR topical archives are described.

Census Enumerations: Historical and Contemporary Population Characteristics

There are 585 data collection titles in this ICPSR thematic data category. Over 260 of these titles are for data from decennial censuses of population and housing. The other

data collections are almost wholly from three U.S. Census Bureau surveys.

Census data prior to 1970 include a variety of collections. There are data about (1) rural households from northern states in 1860; (2) southern agricultural households in 1880; (3) southern cities from 1870 and 1880; (4) population census data from 1860, 1880, 1900, and 1910; (5) census tract data from 1940, 1950, and 1960; (6) public use microdata sample (PUMS) data from 1940, 1950, and 1960; (7) county-level demographic characteristics of the population from 1930, 1940, and 1950; and (8) one of ICPSR's first data collections, historical, demographic, economic, and social data in the United States from 1790 to 1970. Almost all the collections in the various groups contain multiple data files. Many of these historical census data were keypunched into electronic records from printed census materials and tables.

For the 1970 Census of Population and Housing, the public dissemination of census data on magnetic computer tapes took place for the first time, although electronic machines (keypunches and counter-sorters) had been used for a number of decennial censuses. Major 1970 census data in the ICPSR collection include (1) census tract data on population and housing characteristics and (2) public use microdata samples (PUMS).

The 1980 Census of Population and Housing was the first to have extensive computer files covering a broad range of geographic levels (from states to block-groups) produced by the Census Bureau. These files were released in four different groups, referred to by the Census Bureau as Summary Tape Files (STF) 1, 2, 3, and 4. STF 1 and STF 2 contain data presented at a number of geographic levels from the complete count (100%) of population and housing items. STF 3 and STF 4 contain unweighted and weighted sample data and complete count data on population and housing variables. For each STF group (1, 2, 3, and 4), separate data files were released for each state's data at all the geographic levels. So each STF group contains more than 50 data files. A variety of special-purpose 1980 census files and extract files are also part of the ICPSR collection.

The 1990 Census continued the Census Bureau's provision of data on computerized media. The summary tape file organization of data for the 1980 Census was maintained for the 1990 Census data. A large number of PUMS files are also available, as well as extracts on specific topics.

The 2000 Census represents the most detailed and extensive release of public data in history. When the release of the 2000 Census data is complete, ICPSR expects that there will be over 50,000 data files made available. Data for the 2000 Census are the first to be organized to facilitate their use with personal computers, which accounts for the large number of files. In order to cope

with this complexity, ICPSR has developed a topical archive Web site specifically devoted to Census 2000. The topical archive provides for general information about Census 2000 and an overview of the different kinds of data files available, user access to downloading Census 2000 data, and an extensive array of help pages. [Figure 1](#) shows the Census 2000 topical archive Web home page and [Table III](#) lists the different types of data available for Census 2000. Three other major Census Bureau data collections are also listed within this general ICPSR thematic section: the American Housing Survey (AHS), the Current Population Survey (CPS), and the Survey of Income and Program Participation (SIPP).

The AHS (formerly the Annual Housing Surveys) is a sample survey conducted by the Census Bureau for the U.S. Department of Housing and Urban Development (HUD). Data collected about the nation's single-family homes, apartments, mobile homes, and vacant housing units include information about household characteristics, household income, housing costs, housing and neighborhood quality, and household moves. An interesting feature of the AHS is that it has used the same sample of housing units since 1985, which facilitates the analysis of the flow of households through housing units (that is, movers and stayers). National sample data are collected every other year and data from 47 specific metropolitan areas are collected once every 4–6 years. Additional information about the AHS can be found at the Web sites for the U.S. Census Bureau, HUD, and ICPSR.

The CPS is a sample survey conducted monthly by the Census Bureau in cooperation with the U.S. Bureau of Labor Statistics (BLS). The Census Bureau describes the CPS as "the primary source of information on the labor force characteristics of the U.S. population. . . . Estimates obtained from the CPS include employment, unemployment, earnings, hours of work, and other indicators. They are available by a variety of demographic characteristics, including age, sex, race, marital status, and educational attainment. They are also available by occupation, industry, and class of worker. Supplemental questions to produce estimates on a variety of topics including school enrollment, income, previous work experience, health, employee benefits, and work schedules are also often added to the regular CPS questionnaire."

The SIPP is a continuous national panel survey conducted by the Census Bureau to collect information about the source and amount of personal income, labor force participation, program participation and eligibility, and demographic characteristics. In addition to these core topics, other questions are added in special topic modules. A comparison of SIPP with other national surveys about income and labor force, for example, the CPS and the Panel Study of Income Dynamics, is available on the SIPP Web site.

Economic Behavior and Attitudes

There are over 505 data collection titles in the ICPSR thematic category for data on economic behavior and attitudes. Surveys of consumers account for the largest subgroup of these economic behavior and attitude data collections. The three major data collections in this subgroup are the BLS Consumer Expenditure Survey,

the University of Michigan's Survey of Consumer Attitudes and Behavior, and the Federal Reserve Board's Survey of Consumer Finances. Data from the first two of these surveys are used in the construction and calculation of three of the best-known economic indicators in the United States: the Consumer Price Index, the Index of Consumer Expectations, and the Index of Consumer Sentiment.

The Consumer Expenditure Survey provides information on the purchasing practices of American consumers in regard to a variety of monthly and weekly expenditures on different categories of goods and services. The study involves two independent samples of approximately 7500 each, one which is interviewed quarterly about monthly expenditures and the other which maintains a diary of weekly expenditures. More information about the Consumer Expenditure Survey can be found at its BLS Web site and at the ICPSR Web site.

The University of Michigan's Survey of Consumer Attitudes and Behavior, now known as Surveys of Consumers, was one of the first surveys begun by the fledgling Institute for Social Research in 1946. The survey focuses on 50 core questions that measure aspects of consumer attitudes and expectations in three general areas: personal finances, business conditions, and buying conditions. Two important indexes developed from the survey are used nationally as leading economic indicators. The Index of Consumer Expectations was created using the survey data and is included in the Leading Indicator Composite Index

published by the U.S. Department of Commerce. The University of Michigan created and publishes monthly another well-known index, the Index of Consumer Sentiment. More information about these surveys and indexes can be found at the Survey of Consumer Attitudes and Behavior Web site.

The Survey of Consumer Finances was begun at the University of Michigan's Institute for Social Research in 1947 and was later transferred to the auspices of the Federal Reserve Board of Governors. The survey was conducted annually from 1947 to 1971, was also conducted in 1977, and beginning in 1983 has been conducted every 3 years. During the 1980s, the survey was transferred to the Federal Reserve System. Data are now collected for the Federal Reserve System by the National Opinion Research Center (NORC). The survey currently collects information on the income, pensions, balance sheet, and demographic characteristics of U.S. families, as well as their use of financial institutions. Additional information about the current Survey of Consumer Finances is available from the Federal Reserve System and NORC Web sites.

The last major data collection series appearing in the economic data section is the County Business Patterns Series. These data sets contain information about business establishments compiled from the U.S. Bureau of the Census Standard Statistical Establishment List. Data are available by county, state, and national summary levels about the total number of business establishments with one or more employees, the number of employees in mid-March of each year, payroll information, and type of business. Data are provided for the following types of businesses: agricultural services, mining, construction, manufacturing, transportation, public utilities, wholesale trade, retail trade, finance, insurance, real estate, and services. Data is not provided for agriculture production, railroad, government, or household employment.

Data on Political Participation, Politics, and Government

In its beginning (as reflected by its original name), ICPSR data collections came from the research of political scientists. The current ICPSR thematic categories representing those data include: 6. Elites and Leadership; 8. Government Structures, Policies, and Capabilities; 13. Legislative and Deliberative Bodies; and 14. Mass Political Behavior and Attitudes.

The section on Elites and Leadership contains 39 studies about political convention delegates, political party elites, presidential appointees, and foreign policy elites. The section on Government Structures, Policies, and Capabilities contains 32 studies on government employees and 77 studies on government organizations

and operations. The section on Legislative and Deliberative Bodies contains 11 studies on legislative roll-call voting records, primarily from the United States Congress, and 24 other studies on a variety of legislatures or legislative processes. The final category of this group, Mass Political Behavior and Attitudes, contains some of ICPSR's most familiar collections, including the American National Election Studies (ANES); other studies about election issues such as campaign finance; and many public opinion polls about political issues, values, and participation. There are 1355 studies in this category, 897 of which are U.S. public opinion polls. Another 72 are ANES data collections, 126 are election studies from other countries, and 116 are European public opinion polls from the Eurobarometer series.

The ANES were begun by Warren E. Miller, ICPSR's founder and first director, in 1948. The ANES studies collect data on Americans' social backgrounds, political preferences, social and political values, perceptions and evaluations of groups and candidates, opinions about public policy, and participation in political life. Most presidential election years and some congressional election years have preelection and postelection surveys. There is a cumulative data file for common questions from 1948 through 2000.

The Eurobarometers collection of public opinion surveys from the European Community (EC) countries began in 1970. The Eurobarometers collect data on public awareness of, and attitudes toward, the Common Market and other EC institutions, the priorities of an individual's own country, perceived quality of life, support for European integration, and a number of special topics. Information can be found on the ICPSR Web site.

Other General Archive Thematic Categories

Six other thematic categories contain most of the other ICPSR data collections not included in ICPSR topical archives: 2. Community and Urban Studies; 3. Conflict, Aggression, Violence, Wars; 7. Geography and Environment; 11. International Systems; 15. Organizational Behavior; and 16. Social Indicators. There are 73 study titles in the Community and Urban Studies thematic category, 44 of which are Detroit Area Studies. The Detroit Area Studies are a student learning project of the University of Michigan's Institute for Social Research (ISR) and the social science departments. Under the direction of ISR scientists and faculty, graduate students design and conduct these annual surveys about the quality of life in the Detroit, Michigan, metropolitan area. The surveys have been conducted since 1953.

There are 58 studies in the thematic category on Conflict, Aggression, Violence, and War. These studies examine various dimensions of conflict and stability within

nations and conflict between nations. Topics include civil strife and civil wars, assassinations, coups d'état, minority group conflicts, political violence, correlates of war, Middle East political events, and attributes of terrorist events.

The Geography and Environment thematic category contains only 14 studies, most of which are dated. With the recent attention to PC-based computerized mapping of social phenomena, this is certainly one category in which to expect growth. Some of the topical archives have geocoded data that might otherwise have been included in this section.

The thematic category on International Systems has 54 studies. These studies include data on dyadic or triadic relationships among nations, characteristics of international organizations, arms trade data, and military alliance and expenditure data.

The thematic category of Organizational Behavior has only 29 studies. The category has no large series collections on this topic. The few data sets in the category seem unrelated and are rarely used.

The thematic category of Social Indicators data has a total of 237 data collections, 86 about social indicators in the United States. The topics of these studies range from social problems such as alcohol use, gambling, and drug abuse to use-of-time and quality-of-life indicators. This category also contains the General Social Survey collections available from ICPSR. The major collection in that regard is ICPSR study number 3728, General Social Surveys, 1972–2002. From a comparative research perspective, the U.S. General Social Survey is complemented by its British equivalent, ICPSR study number 3095, the British Social Attitudes Survey, 1983–1991; its German equivalent, ICPSR study number 6523, the German Social Survey (ALLBUS) 1980–1992; and its Polish equivalent, ICPSR study number 3487, the Polish General Social Survey, 1992–1999. Another study that receives a good deal of attention is the World Values Survey, ICPSR study number 2790.

Data from ICPSR Topical Archives

ICPSR began segmenting collections into separate topical archives having both a topical identity and an organizational identity during the 1970s. The NACDA was formed in 1975 and has been continuously supported by the National Institute on Aging. The NACJD was formed in 1978 and has been continuously supported by the Bureau of Justice Statistics since 1978 and by the National Institute of Justice since 1992. Other topical archives were created during the 1990s. The HMCA archive was founded in 1995 and is supported by the Robert Wood Johnson Foundation. The SAMHDA was founded in 1996 and

is supported by the Substance Abuse and Mental Health Services Administration of the DHHS. The IAED was founded in 1998 and is supported by the U.S. Department of Education.

National Archive of Computerized Data on Aging

The NACDA seeks to advance research on aging by helping researchers use a broad range of data sets with information about older people, aging processes, or the gerontological sciences. Data identified by NACDA with this potential fall into six categories: (1) demographic characteristics of older adults; (2) social characteristics of older adults; (3) economic characteristics of older adults; (4) psychological characteristics, mental health, and well-being of older adults; (5) physical health and functioning of older adults; and (6) health care needs, use, and financing for older adults. A number of specific data sets with information about older adults have already been described. Data collections from NACDA's data series list are shown in [Table IV](#). NACDA also processes data collections for use in ICPSR's online statistical analysis system. NACDA data collections available to analyze on-line are listed in [Table V](#) and can be accessed at the ICPSR NACDA Web site. NACDA also hosts a resident scientist at ICPSR.

National Archive of Criminal Justice Data

The NACJD preserves and distributes computerized crime and justice data from federal agencies, state agencies, and investigator initiated research projects to users for secondary statistical analysis. Staff are available to assist those using NACJD data collections by (1) identification of appropriate criminal justice data collections on specific topics, (2) instruction in extracting customized subsets of selected data files through the ICPSR online data analysis system, and (3) assistance with the retrieval and use of files obtained from the archive.

NACJD has over 1000 criminal justice study titles. Criminal justice data are available in 12 topical areas: (1) attitude surveys; (2) community studies; (3) corrections; (4) court case processing; (5) courts; (6) criminal justice system; (7) crime and delinquency; (8) official statistics; (9) police; (10) victimization; (11) drugs, alcohol, and crime; and (12) computer programs and instructional packages. NACJD has created online Resource Guides to highlight popular criminal justice research topics and provide important information about complex data collections. [Table VI](#) shows the complex data collections for which online Resource Guides are available and their Web sites.

Table IV Data Series in the National Archive of Computerized Data on Aging (NACDA)^a

ABC News/Washington Post Poll Series
American Housing Survey Series
Americans' Use of Time Series
Annual Survey of Governments Series
Census of Population and Housing, 1960 [United States] Series
Census of Population and Housing, 1970 [United States] Series
Census of Population and Housing, 1980 [United States] Series
Census of Population and Housing, 1990 [United States] Series
Census of Population and Housing, 2000 [United States] Series
Center for Research on Social Reality [Spain] Survey Series
Civil War Veterans Series
Community Tracking Study Series
Consumer Expenditure Survey Series
Cost of Living Survey Series
Current Population Survey Series
Detroit Area Studies Series
The Dynamics of Population Aging in ECE Countries
Economics of American Negro Slavery Series
Eurobarometer Survey Series
General Social Survey Series
German Social Survey (ALLBUS) Series
High School and Beyond (HS&B) Series
Immigrants Admitted to the United States Series
Intergenerational Study of Parents and Children, 1962–1985: [Detroit] Series
Knowledge, Attitudes, and Practice of Contraception in Taiwan (KAP) Series
Marital Instability Over the Life Course Series
Medicare Current Beneficiary Survey Series
Mortality Detail Files Series
Multiple Cause of Death Series
National Ambulatory Medical Care Survey Series
National Education Longitudinal Study of 1988 (NELS) Series
National Health and Nutrition Examination Survey (NHANES) and Followup Series
National Health Examination Surveys, Cycles I–III Series
National Health Interview Survey Series
National Home and Hospice Care Survey Series
National Hospital Ambulatory Medical Care Survey Series
National Hospital Discharge Survey Series
National Longitudinal Study of the Class of 1972 Series
National Longitudinal Surveys of Labor Market Experience Series
National Medical Expenditure Survey Series
National Mortality Followback Survey Series
National Nursing Home Survey Series
National Postsecondary Student Aid Study (NPSAS) Series

Table IV *continued*

National Survey of Black Americans Series
National Survey of Families and Households Series
Nationwide Personal Transportation Survey Series
Panel Study of Income Dynamics (PSID) Series
RAND Aging Studies in the Developing World Series
Retirement History Longitudinal Survey Series
State and Metropolitan Area Data Book [United States] Series
Status of Older Persons in Economic Commission for Europe (ECE) Countries, Census Microdata Samples Series
Survey of Consumer Attitudes and Behavior Series
Survey of Consumer Finances Series
Survey of Income and Program Participation (SIPP) Series
Vital Statistics: Marriage Detail [United States] Series
Youth Studies Series

Table V NACDA Data Collections Available for Online Statistical Analysis^a

Longitudinal Study of Aging, 70 Years and Over, 1984–1990
Multiple Cause of Death, 1999
National Survey Of Self-Care And Aging: Follow-Up, 1994
National Health and Nutrition Examination Survey II: Mortality Study, 1992
National Hospital Discharge Surveys, 1994–1997, 1999–2001
National Health Interview Survey, 1994, Second Supplement On Aging

^a From NACDA Web site at: <http://www.icpsr.umich.edu/NACDA/das.html>

NACJD also has ICPSR's most extensive collection of geocoded data, and tools and other resources for computerized mapping and spatial analysis. NACJD has an online tutorial for using data with geographic information system (GIS) software and the CrimeMapTutorial, a program (available for downloading) that enables students to learn crime mapping from their desktop or laptop computers at home or at work and that is designed for self-paced instruction. NACJD also provides access to CrimeStat, a spatial statistics program for the analysis of crime incident locations. NACJD crime mapping resources can be accessed at the ICPSR NACJD Web site.

Health and Medical Care Archive

The HMCA preserves and disseminates data collected by research projects funded by The Robert Wood Johnson (RWJ) Foundation, the largest philanthropy

^a From NACJD Website at <http://www.icpsr.umich.edu/NACJD/archive.html#resguide>

devoted exclusively to health and health care in the United States.

The RWJ Foundation designates projects that it funds to submit their data to HMCA when it believes that secondary analysis would further its major prevention and health improvement goals. The four topical areas of data in the HMCA are (1) data about health care providers, (2) data about cost and access to health care, (3) data about substance abuse and health, and (4) data about chronic health conditions. (See the ICPSR HMCA Web site.)

Substance Abuse and Mental Health Data Archive

The SAMHDA promotes the use of substance abuse and mental health research data to understand and assess substance abuse and mental health problems and the impact of related treatment systems. SAMHDA data collections include large surveys and administrative record data about substance abuse and mental health. A list of the SAMHDA collections is shown in Table VII; a large number of these studies are available for online data analysis (marked with an asterisk in Table VII). (See the ICPSR SAMHDA Web site.)

International Archive of Education Data

The IAED archives and disseminates data about education inputs (funding, personnel, teaching resources, facilities, and teacher and student preparation), teaching and learning processes, and education outputs (graduation and matriculation rates, drop-out rates, test scores, job placements, life histories, and life assessments). The IAED is supported by the National Center for Education Statistics of the U.S. Department of Education. Data collections in the IAED are grouped into 10 categories of studies: (1) elementary/secondary surveys, (2) postsecondary surveys, (3) longitudinal surveys, (4) educational assessment, (5) libraries, (6) crime in schools, (7) census

in education, (8) vocational education, (9) international education studies, and (10) museum studies. The ICPSR IAED Web site provides listings of specific studies in these categories and also provides information about education research data found at a number of other locations, including the National Center for Educational Statistics.

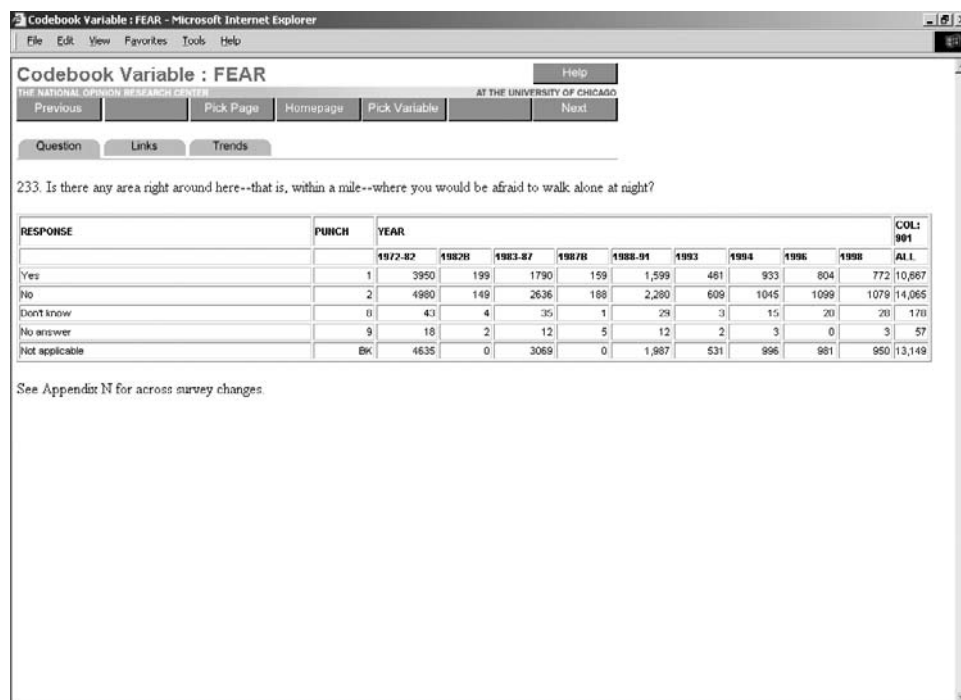

Figure 2 Example variable-level search and frequency distribution from the ICPSR GSS Web site.
Source: ICPSR Web site at <http://www.icpsr.umich.edu:8080/GSS/homepage.htm>, with permission.

Other ICPSR Topical Sites

Although not identified as specific topical archives, ICPSR maintains some other specific Web site collections of data, related documentation, and user tools about (1) Census 2000, (2) Election 2000, and (3) the General Social Survey (GSS).

The Census 2000 Web site has already been mentioned. It functions in much the same way as a topical archive by providing information about Census 2000 data, access to the data files, and other information about using the data or training opportunities related to the data.

Election 2000 is very similar to the Census 2000 Web site. It provides information about data in the ICPSR archive pertaining to the 2000 national and state elections and related public opinion polls. (See the ICPSR Election 2000 Web site.)

The GSS Web site is one of the most detailed topical sites at ICPSR. With National Science Foundation and ICPSR support, NORC, the GSS producer, and ICPSR have collaborated to create an online resource for learning about and doing data analysis and other research with the GSS. One of the most innovative features of the site is that users can do variable-level searches of questions asked in the GSS. This is especially useful because over the 34-year history of the survey, 3260 different questions have been asked across the varying time periods. Once the user locates a particular variable, the user can obtain the question text for that variable

and frequency distributions of responses to that question for the years it was asked.

For example, Fig. 2 shows the results for searching for a fear-of-crime variable named FEAR. The specific question text is given along with the distribution of responses over the different periods the question was asked.

New Developments and New Tools at ICPSR

Since Myron Gutmann became director of ICPSR in 2001, a number of new capabilities and tools have been developed and implemented at ICPSR. The first of these, ICPSR Direct, has already been mentioned. ICPSR Direct allows individual users at ICPSR member institutions to access and download data collections on their own. Users at member institutions that have enrolled in ICPSR Direct no longer need to obtain data collections by having the ICPSR OR for the institution download and transfer a data collection.

ICPSR has become more actively involved with providing data collections that have been developed specifically for instructional use. In the past, ICPSR has supported the development of a few teaching-oriented data sets from the National Election Studies. More recently, however, ICPSR has given a renewed focus to data for instruction by creating the Site for

Instructional Materials and Information (SIMI). SIMI is an effort by ICPSR to expand the number and quality of data collections designed specifically for instructional use in substantive or methodological undergraduate and graduate courses. Many of ICPSR's data collections require intensive file management and variable transformations once the data files, syntax files, and documentation have been downloaded to a user's computer. These tasks deter inexperienced student data analysts from conducting empirical research for college classes. They also deter faculty from including empirical exercises as part of a course. Under the general leadership of an ICPSR subcommittee and a group of interested faculty, SIMI has become an ICPSR topical Web site where faculty can submit data sets they have developed for instructional purposes, along with accompanying documentation and course materials. ICPSR uses member institution faculty to review these submissions to ensure that the data are clearly documented and their use in assignments or exercises is clearly explained. Once this review has been done, instructional modules are loaded onto the ICPSR SIMI Web site. There were over 45 instructional modules available as of January 2004.

ICPSR is also interested in developing new topical collections of data. One that is beginning to come to fruition is the Child Care Research Collaboration and Archive (CCRCA). This new topical archive will preserve and disseminate child-care data with the support of the

DHHS. It is part of a larger collaborative project with Columbia University's National Center for Children in Poverty. Another area that has been identified in preliminary discussions is a topical archive on population and demographic data.

New developments at ICPSR have also occurred in regard to tools that assist users in their research. In conjunction with work to revise and improve its Web site, ICPSR created a controlled vocabulary system. At the heart of this system are three databases that are used by the ICPSR staff and users: a social science subject thesaurus, a geographic names thesaurus, and a personal names authority list. Of most interest to the user community is the social science subject thesaurus, an alphabetical listing of social science subject terms from the disciplines represented in the ICPSR data collections. It is available for online searching for data collections, as well as for downloading to use in other applications.

Another related tool that ICPSR has developed with National Science Foundation support is a Social Science Variables Database (SSVD). The variables database allows searching at the variable level across studies. The variables database contains over 33,000 discrete variables and can be accessed at the ICPSR SSVD Web site. To search the variables database, a user types in a search term (see Fig. 3), which then returns a list of studies in which the search term links to a variable name (see Fig. 4). From that list, a user can see information

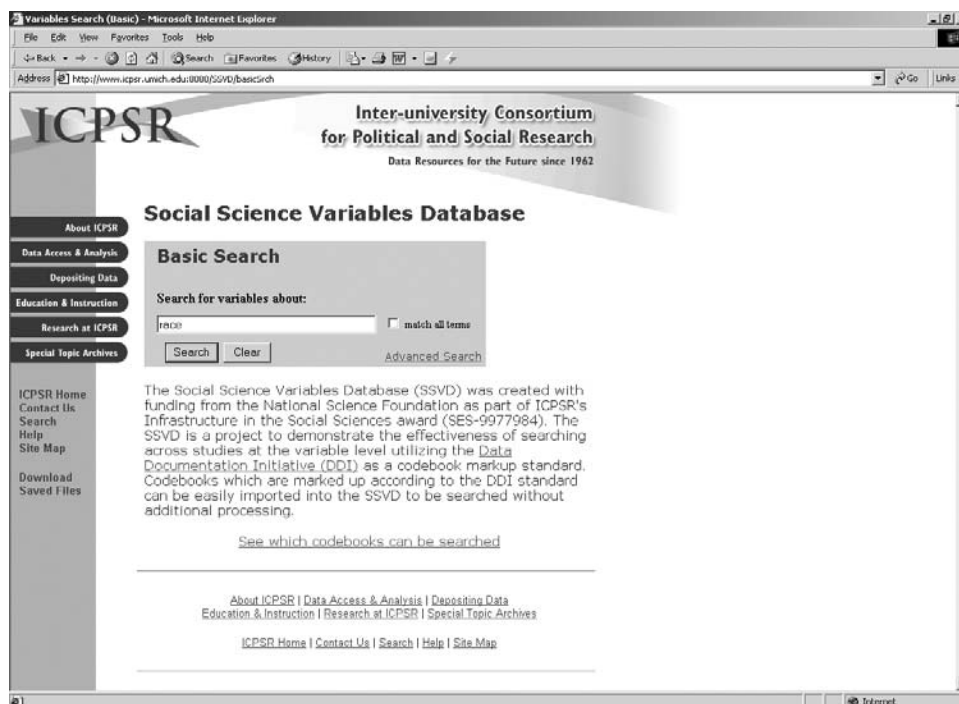

Figure 3 Social science variables database search entry window. *Source:* ICPSR SSVD Web site at <http://www.icpsr.umich.edu:8080/SSVD/basicSrch>, with permission.

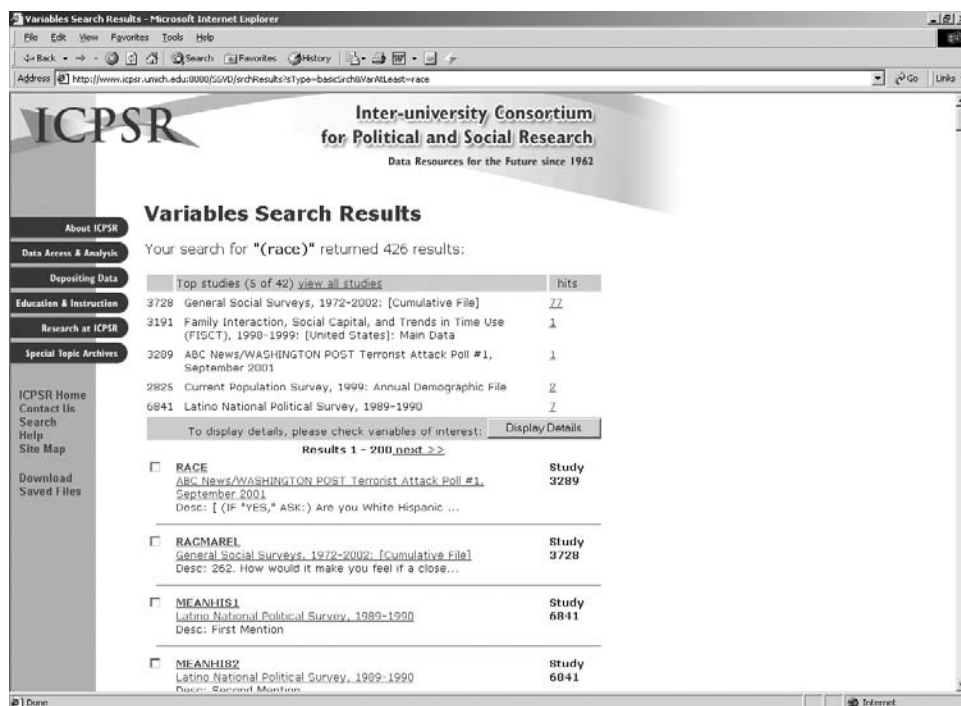

Figure 4 Variable level search results for “race.” Source: ICPSR SSVD Web site at <http://www.icpsr.umich.edu/8080/SSVD/srchResults?sType=basicSrch&VarAtLeast=race>, with permission.

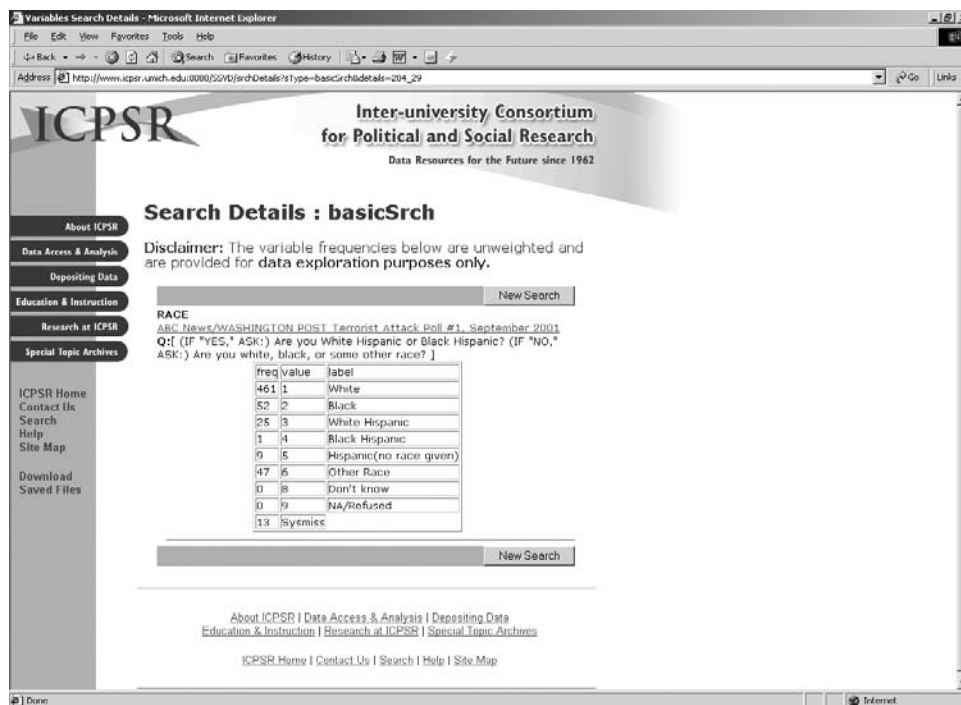

Figure 5 Variable level search detail results for race, first study listed. Source: ICPSR SSVD Web site at http://www.icpsr.umich.edu/8080/SSVD/srchDetails?sType=basicSrch&details=204_29, with permission.

about the question text for that variable and its frequency distribution (see Fig. 5). The variables database should greatly facilitate research on measurement comparisons and item construction.

Conclusion

ICPSR recently celebrated its fortieth anniversary in October 2003 with a public colloquium on the future of the census given by former Census Bureau director, Kenneth Prewitt, during ICPSR's biennial meeting of ORs. At that gathering, many people gave testimonials about the value and many contributions that ICPSR has made to the social sciences. Past performance notwithstanding, information technology and applications grow exponentially and provide many new capabilities annually. Many people have an erroneous view that ICPSR is just a warehouse for data. Nothing could be further from the truth. During the past 10 years, ICPSR has embraced the capabilities of the Internet and WWW, growing from a tape-copying operation to a sophisticated Web-based organization linking individual users dynamically to data sets, smart documentation, on-line statistical analysis, data and table extraction tools, and automated computer programs for analyzing complex data sets. In the past 2 years, ICPSR has completed the conversion of half a million pages of paper data set documentation to electronic format and developed the capability to search that documentation at the variable level across studies. ICPSR is collaborating with researchers on new difficult issues involved in protecting the confidentiality of microdata about human subjects in a contradictory environment in which there is public and political demand for enhanced protection of privacy juxtaposed with information technology and data producers capable of creating linked data sets with massive amounts of personal information from multiple sources and agencies. All in all, the state of social science data at ICPSR is excellent. Never before have social scientists had such easy and rapid access to so much data from so many different sources with so many tools to facilitate learning about and using the data accurately and correctly.

Glossary

Atlas conversion factor Used by the World Bank to reduce the impact of exchange rate fluctuations in cross-country comparisons of national income. For any given year, the Atlas conversion factor is the average of a country's exchange rate for that year and its exchange rates for the two preceding years, adjusted for the difference between the rate of inflation in that country and in the G5 countries (France, Germany, Japan, the United Kingdom, and the United States).

Basel II The New Basel Capital Accord issued in April 2003 by the Basel Committee on Banking Supervision. In 1988, the Committee introduced a capital measurement system that became commonly known as the Basel Capital Accord. The Basel II framework aims to introduce more effective supervisory standards for banking institutions.

knowledge-based economy An economy in which research and development, innovation, and the application of knowledge are widespread in all sectors.

purchasing power parity A comparison between any two or more currencies, on the basis of the real purchasing power of the currencies over a common basket of goods and services, rather than on the basis of market exchange rates.

Social measurement involves quantification of different aspects of social phenomena. Increasingly, the search for greater precision, rigor, and accuracy has driven social scientists toward substituting, when possible, the subjective with the objective and the qualitative with the quantitative. The ascendancy of multinational firms and the process of globalization have resulted, in recent years, in a sharp rise in internationalization of production of

goods and services (business) and international flows of capital (finance) and of goods and services (trade). These trends have been accompanied by rapidly increasing applications of social measurement techniques in international business, finance, and trade.

Aims of Social Measurement

The principal aim of social measurement is to provide quantitative values of the numerous variables that influence economic and social phenomena. Analysts, policy-makers, and other users of such information need to assess these variables with greater precision to gain better understanding of the nature of the underlying concepts and of the changes in the social indicators over time and across regions and nations. Because the concepts and the variables do not always lend themselves to easy quantification, the challenges in social measurement are not only to devise appropriate measures, but also to continue to improve the existing measures.

Role of Social Measurement in International Economics

International economics deals with issues arising from economic interaction among sovereign nations; fields such as international trade, international financial flows, international aid and technical assistance for developing countries, international migration, and exchange rate regimes present international economic challenges. In each of these areas, there are numerous examples of

the application of quantitative measurements to analyze the issues and evaluate the solutions. The use of social measurement is particularly important in specific fields of international economics—namely, international business, finance, and trade. These three specific examples have been selected with a view to demonstrating the relevance and the significance of social measurement in relation to purchasing power parity of national currencies, assessments of sovereign credit risk, and the impact of the knowledge economy.

Examples of Social Measurement

International Business: Purchasing Power Parity and International Comparisons

What is Purchasing Power Parity?

Purchasing power parity (PPP) is a form of exchange rate that takes into account the cost of a common basket of goods and services in the two countries compared. PPPs are often expressed in U.S. dollars. Therefore, the PPP between the U.S. dollar and another currency is the exchange rate that would be required to purchase the same quantity of goods and services locally that cost \$1 in the United States. Thus, the PPP between any two currencies is the measure of the actual purchasing power of those currencies at a given point in time for buying a given basket of goods and services. As the World Bank explained in its 2002 report *The International Comparison Programme and Purchasing Power Parities*, the PPP for, say, the Indonesian rupiah against the U.S. dollar is defined as the number of rupiahs needed to buy, in Indonesia, the same amount of goods and services as \$1 (U.S.) would buy in the United States.

Major Users of PPPs

The Organization of Economic Cooperation and Development (OECD)—Eurostat PPP program was first established at the OECD in 1980 with the aim of providing statistical measures for enabling price and volume comparisons of gross domestic product (GDP) and its components for the OECD member countries. Successive rounds in 1985, 1990, 1993, 1996, and 1999 have resulted in extended coverage from 18 to 43 countries. Procedures for collection of data have also been refined in the process.

The OECD multilateral benchmark studies incorporate price and expenditure data from all the countries included in the comparisons. In addition to the goods and services on the markets being compared, PPPs take into account the economic structure and the market composition in each country. Complexities arise from the different markets for consumers and investments and

from the variety of goods and services consumed in different countries. Parallel work is also proceeding through the World Bank and the Statistical Commission of the United Nations, under the auspices of the International Comparison Program (ICP), to extend the coverage of PPP countries not currently covered by the OECD—Eurostat PPP program. Originally launched in 1968 to cover only a small group of countries, the ICP now covers 160 countries in all regions of the world.

Over the past 20 years, the use of PPP-based conversions has grown rapidly, and many users, such as universities, research institutes, international banks, multinational companies and international organizations, have started to use PPPs in making international comparisons.

Significance of PPPs in International Economics

International comparisons of economic performance, standard of living, and productivity of labor force are made every day, for a variety of reasons, by international organizations (such as the United Nations, the World Bank, or the OECD), international banks, multinational companies, tourists and travelers, and researchers. The World Bank also publishes comparisons of national output, not only for individual countries but also for “low-income” or “high-income” groupings of countries. Aggregations and comparisons of this nature require that output be converted into a common currency, i.e., a common unit of value. Often, the U.S. dollar or the Euro is used as the common currency for this purpose. Conversion of national outputs of individual countries to the U.S. dollar basis, for example, is conventionally done by using market exchange rates, which are the rates at which national currencies are officially converted to the U.S. dollar at the relevant time. Because market exchange rates change all the time, generally an average of the exchange rates for a year may be used for representing annual figures. The World Bank irons out fluctuations in exchange rates by using a moving average of 3 years in its Atlas method of reporting.

In recent years, international organizations have also started to calculate and use purchasing power parities for converting variables such as national output or consumption to U.S. dollars. Thus, the World Bank now publishes figures for all countries based on both the exchange rate conversion and the PPPs in its annual *World Development Report*. For most countries, but particularly for the low-income countries, the amounts yielded by the two approaches are very different. Figures for a selected group of countries published in the *World Development Report 2003* are presented in [Table I](#) for illustration. It should be noted from [Table I](#) that, when converted into PPP gross national income, figures for all countries except Japan, Singapore, and the United States increase

Table I Gross National Income 2001: Two Methods of Measurement^a

Country	Gross national income		PPP gross national income ^b	
	Billion U.S.\$	% (of world)	Billion U.S.\$	% (of world)
Argentina	261.0	0.83	438	0.94
Australia	383.3	1.22	500	1.08
Bangladesh	49.9	0.16	224	0.48
China	1131.0	3.59	5415	11.67
Germany	1948.0	6.18	2098	4.52
India	474.3	1.51	2530	5.45
Japan	4574.2	14.52	3487	7.51
Singapore	99.4	0.32	100	0.22
United Kingdom	1451.4	4.61	1466	3.16
United States	9900.7	31.43	9902	21.34
Low income	1069.1	3.39	5134	11.06
Middle income	4922	15.63	15,235	32.83
High income	25,506.4	80.97	26,431	56.96
World	31,500	100.00	46,403	100.00

^a Data from *World Development Report 2003* (World Bank, 2003).

^b PPP, purchasing power parity.

in comparison to the exchange rate-based figures. Significantly, the PPP measures also have the consequence of narrowing the divergence between the low-income countries and the high-income countries. Instead of accounting for only 3.4% of the world economy, the low-income countries now account for 11% of the world economy.

In view of the deficiencies of international comparisons based on exchange rates, PPP is increasingly recognized as a more reliable measure for international comparisons of output, standard of living, and quality of life. Measurements of output based on exchange rates are now increasingly considered to be inappropriate and potentially misleading for making international comparisons. This is because exchange rates are determined by a multitude of factors and generally are not reliable measures of output. At any given time, many countries are known to have exchange rates that are either undervalued or overvalued, but are maintained by their governments for other considerations, such as export promotion or import substitution. The use of such exchange rates for international comparisons is likely to introduce distortions. As the World Bank acknowledges in the *World Bank Development Report 2003*, nominal exchange rates do not always reflect international differences in relative prices.

PPPs and Climate Change

The proper measurement of national output is not an end in itself. As the following example illustrates, proper measurement of output assists the users in making more meaningful judgments about a wide range of economic and social phenomena in which the level of national

output is directly or indirectly important—for example, climate change during the course of the 21st century. In 2001, the International Panel on Climate Change (IPCC) released its Special Report on Emission Scenarios (SRES). The purpose of this report was to assess the extent to which emissions of greenhouse gases may lead to a rise in global temperatures on Earth. Because emissions of greenhouse gases in a country are a function of its economic growth, the IPCC made separate projections of economic growth in developing and developed countries over the period 1990–2100, and reported that, based on these projections of growth in national output, global temperatures were projected to increase between 1.4° and 5.8°C over the period 1990–2100. These projections subsequently became what *The Economist* (February 15, 2003) described as the most frequently cited numbers in the field of environmental policy, and quite possibly the most widely cited numbers in any field of public policy. Significantly, the main reason for the controversy that surrounded these numbers was related to the use (or the absence of the use, in this case) of PPPs in estimating national output.

Critics of the IPCC projections argued that the SRES had calculated the rates of growth in the world GDP using market exchange rates. They further argued that, similar to the effect noted in Table I, the use of market exchange rates had the effect of understating the share of the economies of the developing countries in the world economy in 1990, and correspondingly overestimating the rates of GDP growth that the developing countries would achieve in catching up with the developed countries during the 21st century. Because higher rates of

growth are associated with higher levels of emissions of greenhouse gases, overestimation of rates of growth by IPCC resulted in a corresponding overestimation of levels of emissions and mean temperatures. The authors of the SRES responded sharply to this critique, arguing that SRES did indeed use both PPPs and market exchange rates, and that market exchange rates are appropriate for certain relevant purposes.

Calculation of PPPs

Calculation of PPPs involves sophisticated and rigorous procedures for selecting the products to be compared, collecting prices of these products, deriving average prices for the whole of a country and a particular year, and determining weights in compiling price indices for groups of products that constitute appropriate headings (such as gross private consumption, gross agricultural or industrial output, and so on). The World Bank and the OECD now coordinate the compilation of PPPs under the International Comparison Program (ICP). The *ICP Handbook 2004*, published by the World Bank in 2003, provides more detail on the procedure for calculating PPPs.

Limitations of PPPs

Notwithstanding increasing acceptance and popularity, PPPs are not without limitations, and are not going to replace exchange rate-based comparisons of international data. PPP rates are based on a limited set of observations and are not free from sampling errors. The World Bank acknowledges that although efforts are made to correct for quality differences, the ICP faces the problem of matching “like with like,” which, in some areas, such as services, may be difficult. One problem is that in some cases, price surveys do not cover the entire country or the entire year. As a result, the prices used in PPP calculation may not reflect fully the average national price prevailing in the country under investigation. For nonbenchmark countries, PPP data are basically desk estimates based on regression equations. Consequently, more caution should be exercised when interpreting PPPs for services.

Sovereign Credit Risk Ratings and International Finance

Introduction

Sovereign credit risk ratings, which play a major role in modern international finance, are another example of social measurement in the field of international economics. International movement of capital has been a key feature of globalization, as banks, superannuation funds, managed investment funds, and hedge funds all invest huge amounts in bonds and securities issued by borrowers from all parts of the world.

Both governments and firms borrow funds domestically and internationally to finance their investment projects. The governments of all those countries that borrow funds in the international capital market are obliged to obtain credit risk ratings for their bonds because investors generally prefer to invest in rated rather than unrated securities. Indeed, financial regulators in most developed countries allow their banks to invest only in investment-grade securities. Accordingly, demand for credit ratings comes not only from both borrowers and lenders, but also from financial regulators, such as the Securities and Exchange Commission (SEC) in the United States. Because the key function of sovereign credit ratings is to provide credible information about the risk involved in investment in underlying securities, the independence and the technical competence of the rating organizations are of paramount importance. The number of rating agencies in the business of assessing sovereign credit risk varies from time to time, but the business is dominated by three or four large international rating agencies, including Moody's Investor Services, Standard and Poor's Rating Services, Fitch International Services, and International Bank Credit Analysis.

Although each rating agency follows its own distinctive methodology and procedures, in general, the process of credit rating involves reviewing a broad range of economic, financial, social, and political information on the sovereign and the country, with a view to assessing the ability of the sovereign to meet its debt obligations in a timely manner, according to the contractual conditions of the transaction. Typically, an international rating agency has branch offices around the world and its staff will interview government officials, business leaders, and others for assessing all factors that could affect the capacity of the sovereign in this regard. When the rating agency has formed a preliminary view about the rating to be assigned in a particular case, typically the sovereign is invited to respond confidentially to the assessment, including by making presentations to the rating agency personnel. Before the credit rating is finalized for publication, a final opportunity is provided to the sovereign for contesting the assessment, if necessary, by providing additional information or analysis. Once published, credit ratings are kept under regular review and are updated as warranted by any change in the underlying assumptions and conditions.

Sovereign Risk

Lenders always take into account the risk of default or interruptions in repayments by borrowers. A government's potential inability to service its debt obligations is the main risk underlying sovereign risk. If a government suddenly stops repayments, a loss of income would occur for the bondholders. Sovereign defaults were more frequent in the 1920s and 1930s than they have been after World War II. Generally, outright repudiation of foreign

debt is quite rare now and the most common form of default is a temporary disruption in repayments, which requires a rescheduling of debt. Thus, the real risk loss of income and/or capital that may occur is due to such rescheduling of debt.

Rating of Sovereign Risk

A sovereign credit risk rating is an assessment of creditworthiness of a national government and it reflects the degree of confidence that creditors can place on the ability of that government to honor its international debt obligations as they fall due. Thus, for example, a triple-A rating assigned to a government indicates to the lenders that its creditworthiness is excellent and that securities issued by that government are investment grade (see Table II). This assessment would in turn be reflected in the high yield that the lenders would expect from their investment in the bonds issued by such a sovereign.

Many of the factors taken into account by the rating agencies are not quantifiable. Even for those factors that are quantifiable, it is not always clear how relative weights to such factors ought to be assigned and what their influence on final ratings ought to be. In their desire to isolate the most crucial factors, some economists have attempted to second-guess the rating agencies by seeking to replicate the ratings of the rating agencies. For example, one study showed that it was possible to match closely the

September 1995 sovereign ratings by Moody's and Standard and Poor's for a sample of countries. The study showed that high credit ratings were positively correlated with per capita income, GDP growth, price stability, and the absence of debt defaults. Although economic development (measured by the level of industrialization of a country) and external debt were also positively correlated, fiscal balance and external balance were not.

The Principle of Sovereign Ceiling

Sovereign ceiling refers to a practice, followed with rare exceptions by international credit rating agencies, according to which any public or private organization from a country is not rated higher than the rating assigned to its sovereign. For example, if the sovereign of a nation has been rated at AA by Standard and Poor's or Aa2 by Moody's, none of the other entities from that country can be rated higher than that rating. The underlying logic of the sovereign ceiling principle is that a financially distressed sovereign government would be likely to impose exchange controls or otherwise interfere with the ability of domestic firms to service their external debt. An exception to this principle occurs, however, when an internationally oriented corporate borrower structures an offshore collateral arrangement under which borrowed funds would never enter the country in which the corporation is domiciled. According to the Basel Committee on Banking Supervision, Standard and Poor's and Fitch are also willing to make exceptions to the sovereign ceiling principle for a high-quality corporate issue domiciled in a low-rated country with a "dollarized" economy, such as Argentina.

Significance of Sovereign Credit Risk Ratings

In addition to their impact on bond yield spreads, sovereign ratings also have an impact on stock prices in the countries for which the ratings are assessed. Indeed, researchers have found that the impact of a ratings downgrade for a particular country may go well beyond the stock markets of that country, impacting those of the neighboring countries as well. During the Asian financial crisis of 1997–1998, a contagion effect of this nature was seen to be the source of spreading the crisis from one country to another.

Sovereign ratings are also considered to be important indicators of fiscal discipline and of the ability of a government to manage the economy. Thus, government ministers, officials, and media generally attach considerable importance to the level of and variations in an international credit rating. Indeed, in Australia, employment contracts of some of the senior government officials have been known to include performance indicators involving the upgrading of the credit rating to the next higher level, the achievement of which would be rewarded by a predetermined bonus.

Table II Typical Sovereign Credit Risk Ratings of Long-Term Debt^a

<i>Moody's</i>	<i>Standard and Poor's</i>	<i>Basel II risk-weights</i>	<i>Interpretation</i>
Aaa	AAA	0%	Highest quality
Aa1	AA+	0%	High quality
Aa2	AA	0%	
Aa3	AA–	0%	
A1	A+	20%	Strong payment
A2	A	20%	capacity
A3	A–	20%	
Baa1	BBB+	50%	Adequate payment
Baa2	BBB	50%	capacity
Baa3	BBB–	50%	
Ba1	BB+	100%	Speculative grade
Ba2	BB	100%	
Ba3	BB–	100%	
B1	B+	100%	High-risk obligations
B2	B	100%	
B3	B–	100%	

^a Data from Cantor and Packer (1996) and Claessens and Embrechts (2002).

Note: To date, agencies have not assigned sovereign ratings below B3 or B–.

Because credit ratings are always used by lenders in conjunction with many other considerations, including their own internal credit assessments, and because credit ratings always leave room for subjective considerations, such as the ability of a government to defy trade union pressure for higher wages, the impact of sovereign credit ratings cannot be determined with any degree of precision. It is difficult to say, for example, that a variation in credit ratings of a country was responsible for a particular event. Consistent with this caveat, results of research on the causality from risk ratings to level of bond yields remain inconclusive. Before the Asian financial crisis of 1997, it had been claimed that credit ratings appear to have some independent influence on yields over and above the other publicly available information. One study showed that although rating announcements had a significant impact on spreads of speculative-grade sovereign bonds, no such influence was found on yields of investment-grade sovereign bonds. The international credit rating agencies were widely criticized in the wake of the Asian financial crisis for failing to anticipate the crisis and forewarn investors.

Critics argue that most often credit ratings are grounded in the past and are inappropriate indicators of future events. Indeed, it has been suggested that credit ratings are likely to exacerbate macroeconomic fluctuations, because they tend to be higher in the boom conditions and lower when economic conditions are bad. This procyclical nature of credit ratings has been cited as a possible source of accentuations of business cycles. For example, in one study, rating agencies were criticized for focusing on the “wrong” set of fundamentals, such as debt-to-export ratios, when it came to anticipating financial crises. Similarly, others have observed that instead of leading the market, agencies lag the market and are rather slow to adjust their ratings.

Knowledge Economy, Knowledge Intensity, and International Trade

The Concept of the Knowledge Economy

In times of rapid economic and social change, many new concepts emerge as attempts are made to describe and analyze the process of change. In recent years, the term “knowledge economy” has been the focus of a great deal of comment and has been described variously as the global knowledge economy, knowledge-based economy, information economy, and new economy. The concept of the knowledge economy describes fundamental aspects of the present period of economic change. Quite new activities, structures, and arrangements are emerging on a global basis, characterized above all by rising knowledge intensity in, and increasing globalization of, processes for the creation, production, and distribution of goods and

services. This is described as the emergence of the knowledge economy.

The unique role of knowledge as a driving force in economic growth has been extensively discussed and is now widely accepted. The extensive literature on the knowledge economy is concerned with many aspects of the subject, but two main strands deal with (1) the conceptual issues of what is meant by knowledge economy and the other associated terms; and (2) the policy implications for nations flowing from the concepts. Defining the knowledge economy is important for several reasons. First of all, by putting a circle around the factors or features constituting it, a clear definition helps to crystallize the scope of the knowledge economy. Second, a clear definition would permit comparisons to be made between countries in terms of their standing and performance with respect to the knowledge economy. Comparisons would also be possible in the future within a country, tracking its performance over time. Third, and perhaps most importantly, a clear definition of the knowledge economy would sharpen the focus on the enabling reforms and policies and would help in prioritizing those reforms. “A definition offers no shortcut strategy for reforms,” noted the APEC Economic Committee in its 2000 report, “but it is the correct starting point for deeper analysis of what the New Economy is and upon what it depends.”

Different people have defined the knowledge economy differently, conveying often a partial rather than complete picture of the underlying concept. According to some scholars, the knowledge economy refers to the new overall structure that is emerging, together with its associated institutions, activities, and arrangements. Attention is often given to individual aspects of the emerging economy, such as the new economy or the online economy, the network economy, the learning economy, and the information economy. But these are specific aspects rather than the overall reality. The Internet plays an important part in the knowledge economy, and networks of many different types are also vital. Learning is clearly central to a knowledge economy, as is the rapid exchange of information and other forms of knowledge. Innovation, being the process of applying ideas new to the firm in many different areas, is clearly at the heart of a vibrant knowledge economy. Each of these concepts views the overall reality of the knowledge economy through a different lens, thereby illuminating an important part of the picture.

According to the APEC Economic Committee, the four dimensions that characterize the knowledge-based economy (KBE) are (1) pervasive innovation and technological change, (2) pervasive human resource development, (3) efficient infrastructure, particularly in information and communications technology (ICT), and (4) a business environment supportive of enterprise and innovation. In its attempt to capture the essence of

the KBE, the World Bank has developed a more inclusive “knowledge assessment scorecard” consisting of 20 variables, each of which has been normalized on a scale of 0 to 10, so that the lowest value for a variable is at 0 and the highest is at 10. The normalized values of these variables are depicted in a star diagram for comparison among a large group of developed and developing economies with respect to their preparedness for KBE.

Knowledge Intensity, Industry Structure, and Trade

Application of knowledge to economic activities of all types lies at the heart of the knowledge economy. The process of creating and applying economically relevant knowledge is called innovation, and it consists not only of the big discoveries and the high-technology industries, but of “a million little things” that improve the operations of the firms and other economic institutions, to use Paul Romer’s characterization in “Two Strategies for Economic Development: Using Ideas and Producing Ideas,” published in the World Bank’s *Annual World Bank Conference on Development Economics 1992*. It is widely accepted that the process of research and development is only a part of technological innovation. The international standard for the measurement of innovation is the *Oslo Manual*, published by the OECD in 1992, which designates the following activities as components of technological innovation: design; research and development; acquisition of technology; tooling, start-up, and pre-production; training; and marketing new products. In many OECD countries, research and development expenditure accounts for 30–50% of spending on innovation, and expenditures on product design and production start-up also constitute substantial proportions.

The OECD ranks manufacturing industries based on their relative research and development intensity, which is measured in terms of the share of research and development spending in value added in each industry. The high-technology and medium-high-technology industries have played a major role in international trade in the 1990s. Before the Asian economic crisis, between 1990 and 1996, exports of products of these industries by OECD countries increased at the annual average rate of 7%, as compared with 5% for other types of exports. The fastest rates of growth in high-technology exports occurred in Mexico, Iceland, Ireland, New Zealand, and Turkey, which are countries where foreign enterprises had played a major role in developing these industries. Outside OECD, economies of the East Asian countries in general, and of Indonesia, Thailand, China, Malaysia, and Taiwan in particular, benefited enormously from rapid growth in international trade in knowledge-intensive industries. Worldwide high-technology exports accounted for 21% of total exports in 1999. For the countries in the East Asia and

Pacific regions, however, the corresponding figure was 31%. These countries also suffered severe setbacks to their economies following the Asian economic crisis of 1997, however, when foreign capital outflows led to a sharp downturn in industrial production and exports.

International Relations

Bruce Russett

Yale University, New Haven, Connecticut, USA

Glossary

dyad A pair of units, typically countries; may be balanced (same value for both units) or unbalanced.

hierarchy A system that can be ordered from most powerful to least powerful units.

international system A set of interacting countries.

level of analysis The degree of aggregation, from individual decision makers to international system.

polarity The number of major power centers in a system.

political stability The longevity of a political system's or a leader's rule, or the degree to which that rule is challenged.

power The ability to change another's behavior; also the resources that may be used to produce change.

Measurement in international relations scholarship is directed to the development of comparable and valid measures of theoretically important concepts according to international standards of reliability and validity, to developing procedures for their analysis, and to making the data available to a wide range of social scientists.

Introduction

The founding of the scientific study of international relations is properly credited to two scholars, Lewis Frye Richardson and Quincy Wright, both working just before the middle of the 20th century. Both were major theorists, but both also devoted great energy and ingenuity to devising techniques for measuring many aspects of international relations. In the 1960s, the U.S. National Science Foundation made substantial financial support available, and a critical mass of researchers in Europe and North America emerged to improve, extend, and

utilize this information. Vast improvements in the quality and quantity of information have combined with comparable improvements in theory and statistical analysis to permit the emergence of international relations as a scientific endeavor. Moreover, the widespread availability of electronic databases for sophisticated analysis is producing greater scholarly convergence on measurement techniques—a necessary though not sufficient condition for scientific success.

Variables and Units of Measurement

What is to be measured of course depends on theory, and theories of international relations operate at several levels of analysis, commonly identified in increasing aggregation as individual decision makers, political unit (i.e., the nation-state, or country), dyads (pairs of countries), and the entire international system. This article concentrates on measurements that can be compiled, with acceptable comparability across countries and years, for most or all countries that are members of the system of international relations.

Individual Decision Makers

Policy-relevant individuals may in principle range from individual voters to heads of state and other key persons responsible for making foreign policy choices. Public opinion surveys measure the direction and intensity of voters' preferences and special-sample surveys can measure the preferences of citizens more directly involved in shaping opinions and policies. Such surveys are possible only in reasonably democratic countries. Even in democracies, the influence of citizens'

preferences on actual decisions is a topic of intense inquiry and debate.

The public writings and pronouncements of heads of state can be studied through systematic content analysis, not only for their preferences but for their affective content (friendship or hostility), perception of threat, and complexity of cognition. Formerly a very labor-intensive task, such analysis is now usually carried out on electronic databases compiled from government sources and news organizations. Consequently, the information base has become much richer, and although computational routines rarely match the subtlety of human coders, the gains in quantity and reliability of coding are substantial.

Country

The primary focus of international relations theory has been on the behavior of countries, rather than of individuals or nonstate actors such as international organizations. Often this requires an assumption that the country, or state, behaves as a unitary rational actor. Although this assumption is often sharply challenged, heads of state typically speak in the name of their countries, so information about their pronouncements and actions may be treated as information about the country itself. Country-level information, however, includes much more, notably about the economic, political, and social characteristics and institutions of the country.

Any analysis of international relations must be concerned with power, as the ability to persuade or coerce another actor to do something. The actual ability to affect decisions in this relational sense is difficult to measure, due to the conceptual problems in determining what the other would have done in the absence of coercion or persuasion. At one extreme, if the leader of country A makes a threat so as to deter country B from attacking country C, the mere fact that B subsequently does not attack C does not necessarily indicate that A exerted power over B. Possibly, B's leader had no intention of attacking C anyway. Such problems can be addressed with sophisticated models of strategic actors, with analysis of counterfactuals, and if possible, with detailed *post hoc* documentary information on leaders' deliberations.

More subject to systematic analysis, however, is information on the power bases of nation-states. Much of this involves reasonably straightforward use of preexisting information, often from national censuses or sample surveys. These include levels and growth rates of demographic data (total population, population in the labor force or of military age, literacy and education, health conditions) and economic data (total national income or income per capita, production of various commodities, value and composition of exports and imports, internal and foreign investment, size and composition of government expenditure), and distributional equality

within the population of income and wealth. All these data are produced by public agencies in most countries and are subjected to scrutiny and revision by international organizations, economists, demographers, and other scholars. Analysts of international relations also evaluate the cross-national comparability of this information, but are not primarily responsible for their compilation. Similarly, information on military capabilities (quality and quantity of troops under arms, military expenditures, number and types of weapons) is produced by governments—concerning their own countries and their allies and rivals—and critiqued by scholars.

Much analysis, however, requires measuring capabilities and actions within conceptual frameworks arising from theories of international relations. Such measures may be derived from standard measures compiled by other disciplines and agents, but do not exist in any off-the-shelf condition. They may need to be aggregated, disaggregated, or recombined with other existing information or information compiled for the purpose. For example, it is not obvious what the most useful measure of national power is. For nuclear deterrence, of course one counts and evaluates nuclear weapons delivery systems. But for a general-purpose measure of a country's power, one needs a composite indicator of military, economic, and demographic power bases. Moreover, if one wishes to compare all types of countries, and over long time periods, one must take account of the availability and comparability of the measures that make up the composite. Numbers of nuclear weapons are irrelevant before 1945; despite massive research by economists, national income data for many countries in the 19th century are unreliable; demographic data are also of uneven quality depending on national information-gathering capability.

Beyond these data is information on data not so obviously part of standard demographic and economic statistics. One example concerns distribution of services and goods that may affect national power or political stability: relative equality of access to health care, equality of distribution of land and wealth. Some theories of international conflict concern how ethnically homogenous the country is in terms of linguistic/racial/religious characteristics; heterogeneous countries may be less politically stable, especially if major ethnic minorities overlap across national borders with neighbors. These measures must be compiled painstakingly by scholars and evaluated for their reliability and validity.

More directly political measures concern types of political systems, such as relative size of the government in the economy or its degree of democracy or authoritarianism. The latter requires some degree of judgment, but great advances have been made in compiling reasonably objective and internationally accepted codings of types of political systems that cover all countries

over a time-scale approaching two centuries. Originally compiled by scholars of comparative politics, they have proved to be very important in testing theories about whether democratic countries are less likely to become involved in international conflict. Still other theories assert that politically unstable countries may be more (or less) likely to engage in international conflict than are stable ones, for example, that unstable governments may attempt to divert their populace toward foreign adversaries and away from problems internal to the country. Depending on the conceptualization, stability may be measured either in terms of the longevity of a particular ruler, party, or constitution, or by the degree of internal conflict manifested in violent protest, rebellion, or civil war. Measures of involvement in international conflict include merely diplomatic disputes in the context of peaceful relations as well as the use of military instruments of violence. The latter may range from relatively low-level military threats up through border skirmishes to full-scale war (conventionally defined in the scholarly literature as involving at least 1000 combat deaths). Hardly any of this kind of information is reported on a comparable basis by national governments. Rather, to be made comparable across countries and time periods, it requires detailed compilation from news media, scattered documentation, and historical documents by teams of scholars. The temporal unit of analysis may be a day or aggregated into monthly or annual slices. Many scholars scrutinize these compilations of political data for accuracy and completeness.

On the whole, country-unit analyses of international behavior have not proved very productive. One exception is the convincing evidence that great powers, with wide-ranging political and economic interests combined with the military power to exert force far from the home country, are many times more likely to become involved in violent conflict than are small or weak states. Other than this, however, strong generalizations about the risk factors for violence by particular kinds of states have proved elusive. There is some evidence that democracies are less likely to engage in violent conflict than are autocracies, but that evidence is contested, the relationship is fairly weak, and the class of autocracies is too varied (communist and fascist regimes, military dictatorships, traditional monarchies) for easy generalization. Many individual state behaviors, of course, are better understood as part of patterns of strategic interaction with at least one other state, in a dyad.

Dyad

A major conceptual breakthrough, focusing on the characteristics of pairs of states, has, however, contributed to greater success in identifying, both theoretically and empirically, the risk factors of international conflict. It drew

on the insight that it was less the characteristics of individual countries than their relationships with other countries that mattered. Most countries are neither especially peaceful nor very war-prone in general; their readiness to engage in violent conflict varies over time and with regard to particular other countries. One such hypothesis is that countries will be reluctant to fight other countries of comparable power (with whom the outcome of a war might be unpredictable) but readier to fight weaker countries with which they could be much more confident of victory. This perspective, however, leads to a competing hypothesis for war frequency: the rulers of weak countries, knowing that they would likely lose a war, might make great concessions to powerful ones, making war between very weak and very strong countries unnecessary and rare. Thus, the risk of war might be greatest between two countries of comparable power, leading to great uncertainty as to which would win the war and thus using war as an empirical test of relative capability. Of the two competing hypotheses, the logic beyond the latter (power equality leads to wars, power differential discourages war) seems stronger, but there can be no substitute for empirical investigation over many dyads and years. Such empirical analyses have become possible, since an international system of, for example, 100 countries, has 4850 *pairs* of states ($(N \times N - 1)/2$), each of which can be compared over many time intervals. Thus, taking 1-year data slices over a period of a century would give a potential for 485,000 observations—enough observations to make possible the statistical testing of competing hypotheses. In turn, the hypotheses could be refined by careful strategic analysis, including the application of game theory to questions of how states would behave under conditions of uncertainty about each other's intentions or capability.

Thus, dyadic information—typically compiled initially on a country-year (one observation for each year a country is a member of the system) basis and then converted into dyad-year format—permits testing hypotheses about a variety of conditions thought to affect the risk of violent conflict, with enough cases to make statistical generalizations about relative risks. In effect, violence and war can be considered as cases in an epidemic and social scientists can investigate competing hypotheses about what factors promote the onset of violence.

Relevant variables for dyadic analyses include traditional concerns for power and its projection: relative military and economic strength, geographic proximity (contiguous borders, or distance between countries, often transformed into logarithms to represent the rate of decline of power capability over space), and the presence or absence of formal alliance agreements between members of the dyad. Others concern the similarity or difference between political systems (as by subtracting the score for the less democratic country on the democracy—autocracy scale from that of the more democratic

one), or the similarity of their behavior internationally (do they ally with more or less the same other countries?), or vote similarly in international organizations (such as the United Nations General Assembly). Still others concern a wider range of economic and institutional ties between countries: trade in goods and services or investment flows, preferential trade agreements, the number and types of international organizations in which they share membership. All of these have been found to be related—sometimes just correlationally, often with plausible grounds for inferring causation—to the degree to which the members of the dyad engage in a wide range of cooperative or conflictful activities. Cooperation and conflict in turn are measured as merely diplomatic cooperation/conflict or as militarized disputes up to and including war. With large databases, it has become possible to assess the relative risk of conflict associated with each variable and to begin to untangle the web of causation. The evidence is that both traditional measures of power and measures of political similarity and political–economic linkage make an impact. A theoretically integrative move has been to combine several measures, such as power, distance, and alliance patterns, under the concept of expected utility; that is, the value or utility of an act weighted by the probability of achieving it.

It is not just the static levels of power or economic relationships that matter. Some analysts have addressed changes, such as if the risk of conflict is greater when one member of the dyad is becoming more democratic from an autocratic base, or if the trend in mutual trade in the dyad is downward. Thus far, these empirical analyses are inconclusive. More productive may be a focus on changes in relative power between potentially antagonistic countries, on the grounds that a narrowing power gap creates larger uncertainty about which country might win a military contest and hence raises the risk of such a contest. It is especially useful to concentrate the analysis on particular kinds of dyads, namely, those with long-standing territorial disputes that periodically erupt into military confrontations, and on the associated political, economic, and military changes in their relationship.

International System

Other efforts have been directed to understanding risk factors according to different kinds of international systems, including both the global international system and regional subsystems. An international system is identified as a group of interacting countries, in which strategic actors make interdependent decisions. For much of history, a truly global international system did not exist, as the level of technology to permit a high level of interaction among distant countries was too low. A system of warring state-like units existed in China at least 3500 years ago, however, and even earlier in Mesopotamia. A regional

interstate system existed among Mayan city-states in Central America from approximately 800 B.C. to 800 A.D., with some revival up to the Spanish conquest. But until the conquest, none of them had had any interaction with or even knowledge of a European system, nor European states of them. Not until the 19th century did a sufficiently high level of interaction develop for the concept of a global system to be very useful.

A global system, like a regional system, can be characterized by its degree of hierarchy, or by its polarity. If it were dominated by one great power, a hegemon, it would be unipolar. By contrast, a system dominated by two great powers would be bipolar and a system of three or more great powers would be multipolar. Different theories led to expectations that some kinds of systems were more prone to large-scale international violence than were others, for example, that bipolar systems were likely to experience more small wars than were multipolar systems, but fewer large wars directly between the two great states. The Cold War era between the United States and the Soviet Union was such a system. The evidence available for generalization, however, was so mixed as to prevent any consensus on relative risks. One problem was the small number of different international systems from which to attempt to make any reliable generalizations. For example, most international systems in the “modern” era (even as dated from the Treaty of Westphalia in 1648) have been multipolar, with the less than 50-year Cold War era the major exception. Another was imprecision or lack of consensus on theory. In measuring polarity, some analysts would focus attention more on the structure of alliance systems than on the number of great powers; for example, in 1914 there were perhaps as many as eight great powers in the international system, but only two competing alliance configurations of great powers (Great Britain, France, and Russia versus Germany, Austria-Hungary, and Italy). Consequently, no near-consensus has emerged from the empirical analyses comparing bipolarity with multipolarity.

There is somewhat more agreement that major wars may be less likely to occur under conditions of unipolarity or hegemony, but the empirical base for that generalization is very limited, perhaps only to the years since the end of the Cold War. Moreover, conceptual agreement as to the relevant measures of unipolarity (population, military power, economic strength, even cultural dominance) is elusive. More promising may be attention to changes in the relative power of the leading country or alliance system in the system and that of its putative challenger, as on the dyadic level of analysis.

Another and possibly more productive way to conduct analyses at the system level is to ask whether certain political or economic characteristics become more or less common in the system. Just as systemic measures of power concentration are built up from country-level

data on the components of national power, other systemic measures can similarly be constructed. For example, are a larger proportion of countries democratic in one period or another, is the level of economic and financial interdependence higher or lower, and are the number and strength of international organizations greater? Such systemic characteristics do vary over time. The proportion of democratic countries in the system has been higher since the 1990s than at any previous time in world history and by many (but not all) measures the level of economic interdependence has also been at an all-time high. This coincides with the increasing interest in the effects of “globalization” on the world political economy and specifically on constraints that may reduce the incentives to violent conflict. It suggests that system-level changes in, for instance, the proportion of democracies might have an effect in addition to the effects at the national or dyadic levels. That is, a need to obtain commercial ties and foreign investment might constrain even those governments that were not yet closely tied into the global economy. Or the growth of international norms and institutions for peacefully settling disputes, deriving from democratic practice, might constrain even governments that were not themselves democratic. It would thus be useful to analyze the international system as a set of feedback relationships among political, economic, and institutional elements and operating at different levels of analysis.

Analytical Issues

Data Problems

As noted, great progress has been made in creating worldwide information on structural and behavioral phenomena that were not previously well measured and the process of international scholarly scrutiny of these measures has narrowed the range of subjectivity and cultural bias that may infect such measures. Yet data problems go beyond the matter of crude or imperfect measures of the relevant phenomena to situations where data are simply missing for a substantial number of units needed for the analysis. Typically the pattern of missing data is not random, but correlated with and caused by economic underdevelopment or political systems that are closed to external scrutiny. Limiting the analysis to countries where data are reported or can be directly compiled risks introducing serious bias into any “sample” that is subjected to analysis. An analysis confined largely to democratic countries because of missing data for most autocracies, for example, might find that the small variation in their degree of democracy made little difference in their international behavior, whereas analyzing the full number and range of political types might show great behavioral differences.

Fortunately, the existence of large databases on many variables, and the creation of new statistical routines for analysis, often can mitigate these problems. If one knows from previous analyses, for example, that country-level data on income per capita, literacy, life expectancy, and educational achievement are highly correlated with one another, one can estimate the level of any one variable that is missing for a particular country from its levels on the other three measures. Sophisticated computational routines can impute such missing data from a large body of information and even supply a range for the probable error in estimation. Unlike many substantive analyses that require theories about causation, knowledge of correlational patterns is sufficient for this purpose.

Some kinds of selection biases are more insidious. If, for example, one looks at military crises in which a government must decide whether to come to the defense of an attacked ally, one finds many instances where the alliance is not honored. Does this mean alliances do not deter conflict? To reach that conclusion, one would have to look at the many situations where the ally is never attacked. A strong, credible military alliance could deter even the threat of an attack, whereas the alliances that are perceived as weak may attract attack. For repeated interactions, as in a process from normal peace to diplomatic dispute, through military challenge to war or settlement, one must control for selection bias at every step.

Conceptual Problems

The data may be well measured, but if not matched to appropriate concepts they may be useless at best and misleading at worst. In principle, interval measures are preferable to binary ones, if the equal-interval assumption of monotonicity is reasonable or can be made so by some transformation. In the dyadic context, some measures are inherently balanced; e.g., the distance from A to B is the same as that from B to A. Other dyadic measures, however, are inherently unbalanced. To measure the importance of trade to a country's economy and political system, the trade total should be divided by the country's gross national product (GNP). But the same total trade (exports plus imports) between the countries will produce a highly asymmetric measure if the two countries' GNP totals are very disparate. Presumably, the political importance of that trade will be much greater for the smaller country. Behavior is often best measured as that of a directed dyad. Rather than measure the mere existence of a militarized dispute between A and B, one should try to identify the initiator of the dispute. From theory, one should expect a small country to initiate a dispute with a large country far less often than vice versa. Directed measures are especially appropriate for studying sequential patterns of strategic behavior. Behavior may be

measured as scales of cooperation or of conflict between countries. Some efforts combine the concepts of cooperation and conflict into a single scale, but this is very problematic. Countries that are politically or economically salient to each other often experience rather high levels of both conflict and cooperation; putting the two concepts on one dimension obscures this reality.

Rare Events

Many aspects of international relations represent common behaviors, especially many acts of cooperation. Trade volumes between countries may vary greatly over time, but the individual commercial transactions are numerous. Other events, such as conflict behavior, are quite rare events. Militarized disputes, for example, arise infrequently. In most years, only approximately 3% of dyads in the international system will experience any such disputes and only one-tenth of those are at war. Popular statistical procedures, such as logistic regression, can sharply underestimate the probability of rare events.

Cross-Sectional versus Cross-Temporal Analysis

Most measures in international relations are utilized both cross-sectionally (comparison across countries at the same point in time) and cross-temporally. Measurement error may be serious in either kind of comparison. Many analyses are performed with pooled time-series, e.g., panels of the same countries or dyads measured at regularly repeated time intervals. Such analyses often raise difficult problems of independence of observations across space and time that are increasingly being addressed in this discipline. The behavior of France, for example, is in part dependent on that of its allies as well as that of its adversaries. War, and even changes in political systems, such as the spread of democracy, may be contagious across space. Trade patterns are relatively constant over time. And, of course, if France had a militarized dispute with Germany in the past year it is much more likely to have one this year than with a country with which it was previously at peace. Most statistical packages contain routines to correct for non-independence of

observations, but the choice of correction depends on good theory as well as on statistical options. For instance, controlling current disputes by a term for disputes in the preceding year may obscure the effect of theoretically important variables that raise the risk of a dispute in both years.

In summary, issues of measurement in international relations are inseparable from theoretical issues. The rise of large-scale data sets of quantitative indicators has forced the refinement and formalization of theories that were initially expressed verbally; in turn, mathematical theories have demanded far greater rigor of measurement.

Internet Measurement

Antonio Marturano

University of Exeter, Exeter, England, United Kingdom

Glossary

computer-mediated communications (CMCs) Text-based, interactive communication processes involving computer usage. Examples are chat rooms, Instant Messenger, and ICQ ("I seek you"), programs that allow communication and reveal when other program users are on-line.

epistemic (cognitive) access The possibility of rationally accessing an object, event, or a person's mental state in order to reach a complete understanding.

Internet protocol/transmission control protocol (IP/TCP) Computer software technology that converts messages into streams of packets at the source, then reassembles them back into messages at the destination. IP handles the addressing, seeing to it that packets are routed across multiple nodes and even across multiple networks with multiple standards (not only the early Advanced Research Projects Agency Network's pioneering standard, but also other standards, including Ethernet, Fiber-Distributed Data Interface, and X.25).

virtual community A community of people sharing common interests, ideas, and feelings over the Internet or other collaborative networks. Internet virtual communities are social aggregations that emerge when enough people carry on public discussions long enough and with sufficient human feeling to form webs of personal relationships in cyberspace.

virtual identity In the physical world, there is an inherent unity to the self, for the body provides a compelling and convenient definition of identity. The virtual world is different; it is composed of information rather than matter: a person can have, some claim, as many electronic personas as there is time and energy to create.

The Internet is one of the most important social phenomena today. The Internet is going to be a huge basin for data collection, and Internet measurement is likely to

be one of the most valuable means to explore how the human society is evolving. The main feature when considering the social side of the Internet, namely, computer-mediated communications, is the fact that the social boundaries of the physical world are meaningless. On-line communications, indeed, are marked out by the disappearance of the dichotomy of concepts such as private/public and true/false. Because of the very nature of computer-mediated communications (CMCs), qualitative measurement, and in particular observational techniques, turn out as a more fruitful means of inquiry in "opaque" environments. Ethnographics or narrative explanations of on-line behaviors are more powerful than are the classical quantitative analyses. A quantitative explanation of phenomena, or prescriptive analysis, is based on clear causal propositions, which presuppose a wider transparency by the explanandum, but such a transparency is rather problematic in the case of on-line participants. Nonetheless, quantitative measurements are quite useful when used for the application of classical market research to electronic business (e-commerce). Finally, the application of quantitative as well as qualitative measurement to on-line activities raises several ethical concerns, in particular about access and the informed consent.

What Is the Internet?

Internet Protocol/Transmission Control Protocol

The Internet is meant to be a series of computer- and network-assisted activities using the so-called Internet protocol (IP), or transmission control protocol (TCP). These activities, actually, are purely semiotics, namely, they involve only exchange or manipulation of data (for

example, credit card number), signs (such as e-mail), and icons (such as photos).

How the Internet Works

The Internet is a development of the Advanced Research Projects Agency (ARPA) system, designed by the Rand Corporation for the United States Department of Defense as a military communications network able to work in the case of nuclear war. The system was designed without a central control in order to keep working if some of its parts were eliminated. The principles were simple. The network would be assumed to be unreliable at all times. All the nodes in the network would be equal in status to all other nodes, each node with its own authority to originate, pass, and receive messages. The messages would be divided into packets, each packet separately addressed. Each packet would begin at some specified source node, and end at some other specified destination node. Each packet would wind its way through the network on an individual basis. The particular route that the packet took would be unimportant. Only final results would count. Basically, the packet would be tossed like a “hot potato” from node to node to node, more or less in the direction of its destination, until it ended up in the proper place. If big pieces of the network had been destroyed, that simply would not matter; the packets would still stay routed, literally wildly across the field by whatever nodes happened to survive. From this design started the legend of an “anarchical” Internet, i.e., the very idea that control of the whole system was impossible. In the autumn of 1969, the first node was installed at the University of California in Los Angeles. By December 1969, there were four nodes on the infant network, which was named ARPANET, after its Pentagon sponsor.

ARPANET remained fairly tightly controlled, at least until 1983, when its military segment broke off and became MILNET. But TCP/IP linked them all. And ARPANET, though it was growing, became a smaller and smaller neighborhood amid the vastly growing galaxy of other linked machines. As the 1970s and 1980s advanced, many very different social groups obtained and used powerful computers. It was fairly easy to link these computers to the growing network of networks. As the use of TCP/IP became more common, other entire networks fell into the digital embrace of the Internet, and messily adhered. Because the TCP/IP software was public domain, and the basic technology was decentralized and rather anarchic by its very nature, it was difficult to stop people from barging in and linking up somewhere within the networks. In point of fact, nobody wanted to stop them from joining this branching complex of networks, which came to be known as the “Internet.”

How to Use the Internet

But what is done with the Internet, technically? Four things, basically: e-mail and newsgroup communications, group discussions (computer-mediated communications), long-distance computing (personal web pages), and file transfers. Every kind of Internet usage starts from these original four types of activities. The main focus in the following discussions is on two uses of the Internet: as a tool for e-commerce, namely, as a measurement tool for improving the quality of the on-line selling of products; and as a computer-mediated communication tool.

Measurement and the Internet

The Concept of Measurement

The concept of measurement is widely used to study the Internet. In particular, the “technical” idea of measurement (used by computer scientists and practitioners) is applied to assess data packages flowing in and out of a server, a computer, or a web page. In other words, there are ways of measuring, analyzing, and reporting the services provided to a user’s network via the Internet. Engineers, computer scientists, and practitioners use such a notion to measure the data flow. The interest here, however, is in the “social,” rather than the technical, measurement of the Internet, although the technical concept could have an interesting role within the quantitative approach.

Internet Research

Another useful distinction to be drawn here is between the Internet as a source of data and the Internet as a social field of study. Internet research is concerned not only with the study of on-line behavior (what people do in virtual and mediated environments), but is also concerned with using computer-based tools and computer-accessible populations to study human behavior in general. On the one hand, then, Internet researchers can access if not potentially infinite data, at least a larger amount of data than is possible in the physical world. The Internet indeed allows researchers to interview participants in different continents and across a complex matrix of university colleges and faculties. It also facilitates participation, which might otherwise have been inhibited due to disability, financial constraints, difficult cultural contexts (socially marginalized communities, such as gay fathers), and/or language and communication differences. But it has been pointed out that those people who assume that the social world of cyberspace is readily accessible once there is technological mastery, once they have more

experience, begin to realize that the on-line world has also its hidden areas. On the other hand, the exponential growth of virtual communities makes the Internet one of the most important modern social phenomena: loves, friendships, and contacts are rising and falling daily over the web in a very peculiar way. That makes the web a new and rather sophisticated terrain for research about new forms of human behavior.

Some techniques already used for conventional market research (such as data crossing) are used in e-commerce. An example is the Amazon web site (<http://www.amazon.com>). Amazon, one of the most widely known Internet business-to-business companies, sells a huge variety of goods. Amazon is quite popular in the academic community as one of the most comprehensive web sites for book purchases. Before approaching the problems encountered in Internet research, the terms “quantitative” and “qualitative” are briefly defined as they relate to measurement.

Quantitative and Qualitative Measurement

There is no agreement about the very notion of quantitative and qualitative research. Some scholars view the two measures as mutually exclusive methodologies for social inquiries, and as such they are essentially divergent clusters of epistemological assumptions—that is, of what should pass as warrantable knowledge about the social world. Others claim that quantitative and qualitative methodologies are just denotations of separate ways of conducting social investigations, which can be integrated in the research design if this strategy addresses the research questions; in this case, they are just simply different approaches to data collection, so that preferences for the first or the latter or some hybrid approach are based on technical issues. Finally, there are claims that much of the discussion in the literature about these two research traditions has created a somewhat exaggerated picture of their differences.

In any case, “quantitative research” here will mean, roughly, a particular kind of research, indeed very similar to the natural science approach, which takes the form of causal propositions. The quantitative approach as used to study causes of delinquency, for example, reflects a concern to follow methods and procedures of positivistic epistemology. In particular, the social survey is the main research tool used with the quantitative approach. Indeed, the survey has a capacity for generating quantifiable data on large numbers of people who are known to be representative of a wider population; this allows testing the validity of pre-existent theories and/or hypotheses, and has been viewed by several scholars as a means of capturing the essence of a science.

“Qualitative measurement” is used here to mean, instead, a kind of approach based on the interpretation or narration of a social phenomenon, starting from a “destructured” understanding of the social reality. The milestone study in this field was the work by Adler on upper-level drug dealers. Adler used a somewhat unstandardized approach, relying on observations, conversations, and some informal interviewing. Adler’s approach, indeed, seemed to intentionally avoid the positivistic paradigm, preferring instead to ground the investigations in people’s own understanding of their social reality, as phenomenological perspectives are taken to imply. Importantly, it is doubtful whether a group such as Adler’s drug dealers would have been accessible to methods that even remotely resembled those used in the previously mentioned quantitative delinquency study, because of the undercover nature of the drug dealers’ operations and their considerable secretiveness. This suggests that quantitative and qualitative research are different approaches to carrying out research; the choice between them looks then to be a technical matter about their appropriateness in answering of particular research questions. In the following discussions, it can be seen that the choice between the application of qualitative and quantitative methods, because of their very epistemological nature, will also depend, and in particular regarding the Internet, on the opacity of the studied field.

Applying Qualitative Measurement

The qualitative approach, because of its real nature, seems to be more fruitful for measuring phenomena such as computer-mediated communications (namely, chat rooms, ICQ, or Instant Messenger). Indeed, in such social practices, the boundaries between truth and falsehood, private and public are meaningless. What is the real meaning of sociodemographic data obtained through a structured on-line questionnaire? Importantly, what is really happening when a regular participant in an Internet Relay Chat (IRC) channel, one of the hypothetical cases for a survey sample, says that her name is Mary, she is 30 years old, and she works as secretary? Such information, even if true, provides not the actual data about Mary’s real life, but rather provides answers about her on-line symbolic universe, her on-line self-representation. Therefore, accordingly, it is never correct to accept these data without keeping in mind that obtaining information about someone’s real physical life through on-line communications, although seemingly easy and convenient, is always a hazardous and uncertain procedure.

A full understanding of Internet usage requires examination of other factors, such as economic and social class

issues of access to the technology: Such factors, added to the opacity of data (namely, an ambiguous epistemic access to the real intention by the interviewed), make Internet measurement a very problematic one from a quantitative point of view. Moreover many of the virtual communities are exclusive, and intrusion by an academic researcher could easily be rejected. It is very important to be “a native” when conducting an on-line measurement in a CMC.

A study that tried to set up a game experiment (a typical tool used for quantitative researching) among regular users of Bulletin Board Systems (BBSs) was found to be ineffective in discovering the basic process by which such on-line communication strategies evolve. The artificial and predetermined nature of experiments does not permit participants to manipulate the context creatively, thus it is not surprising that the social-related aspects of CMCs have hardly been explored in laboratories. Issues of anonymity and authenticity remain the core methodological stumbling block for researchers using on-line methods. In structured interviews, the researcher attempts to control the interview by standardizing questions and constraining responses. It is in nonstandardized interviews that the focus moves from the preformulated ideas of the researcher to the meanings and interpretations that individuals attribute to events and relationships.

In the very nature of CMCs lies the difficulty of applying the quantitative approach to the study of virtual communities. The ethnographic approach therefore seems more fruitful when researching with virtual communities. The ethnographic approach, which goes back to Malinowsky's works, entails the sustained immersion of the researcher among those who are being studied, with a view to generating a rounded, in-depth account of the group or organization. The ethnographic approach, however, does not explain phenomena in the classical and impersonal sense of scientific explanation (in the deductive sense, or according to the Hempel–Popper model), whereby explaining a phenomenon means the deduction of a proposition that describes it, using as deductive premises one or more universal laws together with some singular propositions, i.e., the starting conditions. The ethnographic approach means explanation as an “interpretation” of particular phenomena; the ethnographic methodology views human behavior as a product of how people interpret their world. The task for qualitative methodologists is then to capture this process of interpretation in order to grasp the meaning of a person's behavior—that is, to attempt to see things from that person's point of view.

In the ethnographic approach, the main research tools are observational techniques such as participant observation. Such techniques allow the researcher to participate in the activities of the group they are observing. They may be viewed as members of the group, but minimize

their participation; they may assume the role of observer without being part of the group, or their presence may be concealed entirely from the people they are observing. Thus, ethnographic methods focus on ordinary, mundane, naturally occurring talk to reveal the way in which meaning is accomplished by everyone involved. Qualitative researchers with an interest in these approaches can, so to speak, observe the natural conversation in various kinds of newsgroups or synchronous conferencing (real-time chat-rooms). By lurking unseen, researchers are able to watch the interaction without intervening in any way.

Some scholars have noted that one of the main problems in applying such techniques to CMCs is the lack of some of the ingredients of face-to-face communications, including nonverbal behavior (such as body language), spatial behavior (such as issues of physical closeness and distance), linguistic behavior (such as parasegmental tracts), and extralinguistic behavior (such as rate of speaking or loudness). A compensatory tool for this lack of physical contact has evolved in the form of “emoticons,” typed symbols representing nonverbal and extralinguistic behavior. Although researchers and participants are not in visual or vocal contact, researchers may observe emoticons such as ☺, for smiling; paralinguistic and non-linguistic cues have also evolved into electronic paralinguistic, such as “eheheh” for laughing, or “lol” for “lots of laughs,” and the use of capital letters for emphasis.

Applying Quantitative Measurement

The Internet is not only virtual communities, but is also a worldwide supermarket, where shopping can be done at any time. For on-line Internet shopping practices, a quantitative study is more fitting. Classical market research tools can be applied. Such research is based on an underlying design called “correlational” or “cross-sectional,” in which data are collected on a cross-section of people at a single point in time in order to discover the ways and degrees to which variables relate to each other. An example of how such a research approach is used on the Internet is the “recommendation for you” section in the Amazon.com website. Based on data pertaining to searching Amazon's website for a particular book title or author, and on purchasing data, Amazon, using a cross-sectional method, is able to recommend and display titles that are likely also to be of interest to the customer (see [Figs. 1](#) and [2](#)). The Amazon example represents well a way in which quantitative research (based on the data-flow analysis, similar to that used in the technical sense of measurement and statistical

comparison between customers) can be helpful in understanding some social phenomena. (Amazon.co.uk was kindly asked to provide the author some material illustrating how their system works, but said, “due to the extensive number of inquiries that we receive and the competitive nature of our business, our policy is not to give out information to people doing research on the subject.”)

Conclusions

Although Internet technology is changing fast, the focus of computer-mediated communications has been primarily on text-based virtual realities, because a majority of studies reflect the fact that only text-based technology is available on-line. Such a technological limitation, rather than being a communication handicap,

is an imagination-enhancing challenge. It seems reasonable to suppose that in certain situations, people will prefer textual interactions, even when more advanced technology becomes widely available in the future. Writers such as Neruda, Fo, Hemingway, or Gao Xingjian show us how text alone, without pictures or sounds, is enough to express emotions, experience, and complex ideas. Excellent writing evokes internalized, personal interpretations of sounds or pictures. Nonetheless, on-line technologies are moving toward multimedia systems. Voice and video ("cam") conferencing are becoming affordable and thus very popular among virtual communities, and researchers of virtual communities cannot ignore these new environments. The argument can be made that these technologies have the potential to take the task of the researchers extraordinarily close to that of the traditional field of anthropology.

Internet measurement does raise some ethical issues. A pressing problem in Internet research is privacy; researching as an unobtrusive observer and collecting data, for example, inevitably poses a major ethical problem. Neither can this problem be avoided ad hoc, by using laboratory experiments, because those involve a small number of consenting people. Such techniques are less fruitful compared to "natural" observational techniques, because laboratory findings cannot be generalized to all domains of electronic communication. Some researchers solve this problem by asking for explicit permission from the observed Internet participants; others do not ask for permission and use some obscuring data to mask the real source of their data. The Project H Research Group, focusing on quantitative rather than qualitative methods, after a long debate, issued an ethical policy claiming that they would not seek permission for recording and analysis of publicly posted messages, because such messages are public acts deliberately intended for public consultation (as opposed to private letters or e-mails), and as such do not require specific protection, although they always need to be treated with ordinary care.

A different approach can be taken regarding the protection of privacy for data collected in virtual communities. As stated previously, in CMCs, the classical boundaries between public and private disappear; the interviewer is given data that are not about the participants' physical world, but rather about their on-line self-representation. What happens to the notion of privacy, which is very linked to the very notion of the (physical) private sphere? Indeed, those data, collected using responses from virtual citizens, are likely not expressions of sensitive characteristics. In virtual environments, it could be said, finally, that the notion of privacy plays a less central, if not a marginal, role than it does in the physical world. On the contrary, in on-line shopping, the notion of privacy seems fundamental, because correlated data methods make it possible to obtain very personal

profiles of individual consumers. The same databases used by the Internet researcher can be used to construct extremely accurate personal profiles concerning everything from finances to what a person eats, drinks, and wears, as well as revealing intimate personal details.

The notion of informed consent plays an important role in both qualitative and quantitative measurement: giving participants comprehensive and correct information about a research study, and ensuring that they understand fully what participation would entail before securing their consent to take part, should be a key issue to be addressed when creating a framework for ethical Internet research practice. This does raise some problems when applying the ethnographic method to study virtual communities. For example, how will people know when they are the objects of a study? If the researcher "discloses" the intention of studying a particular web-based community, will the result of the research be altered? Is ethnographic electronic research the equivalent to hanging out on street corners (where researchers would never think of wearing large signs identifying themselves as "researchers")? Again, in this field of social measurement, there is a lack of consensus; it is therefore not surprising that researchers do not always declare explicitly in their study logs whether they obtained permission from the observed. The issue of whether a requirement for informed consent of authors, moderators, and/or archiving institutions applies to a quantitative content analysis, when only publicly available text is analyzed, has been questioned, particularly when all necessary measures are taken to separate names of authors and groups from the database.

From an ethical and legal point of view, the field of social measurement shares with the Internet a general lack of legal certainty. Ethical guidelines are insufficient, and very little agreement about how to proceed in a virtual arena has been reached. Because Internet research practice is still in its infancy, the critical researcher will be confronted by quandaries at almost every point in the research process. e-Mail interviews, real time focus group participation, and on-line observations all present dilemmas that Internet researchers must face, yet there are few research practice conventions available. Confidentiality is also quite a problematic issue, because data collected on-line are subject to multiple privacy risks, and there are no easy solutions, although disguising identities still remains the best solution.

To sum up, the Internet does not appear, generally, to be a new or discipline-challenging research ground for social measurement, although virtual communities do represent an exciting exception.

Interviews

Casey A. Klofstad

Harvard University, Cambridge, Massachusetts, USA

Glossary

close-ended question A question in an interview to which the respondent chooses his or her answer from a set list of choices.

error Any instance in which the data collected through an interview are not an accurate representation of what the researcher thinks he or she is measuring or any instance in which data are not completely representative of the population under study.

focus group A group interview; a moderator leads a group of similar people in discussion on a topic of interest to the researcher. The moderator encourages participants to share their opinions with one another in order to collect data on the topic under study.

incentive A way of increasing the benefits of participating in an interview, relative to the costs, in order to increase participation. Incentives can be solidary or material.

open-ended question A question in an interview to which the respondent must create his or her own answer because a set list of choices is not provided.

personal interview A one-on-one conversation between an interviewer and a respondent; akin to the work of journalists.

questionnaire A predetermined list of interview questions that is either filled out by the interviewee or the researcher. Synonyms include interview schedule and instrument.

respondent A participant in an interview. In some fields, the word subject can be an analogous term.

response rate The number of completed interviews as a percentage of the entire sample size.

response scale The set of answers a respondent chooses from in answering a close-ended question.

sample The subset of a population that is selected to participate in the interview.

posed by the researcher and answers provided by a respondent.

Introduction

What is an Interview?

An interview is a method of collecting data on the attitudes and behaviors of individuals through some form of conversation between the researcher and a respondent. Unlike research methods that rely on less direct sources of information about social phenomena (for example, indirect observation, archival research, and formal theoretical approaches), interviews are unique because data are collected directly from the individuals who are creating and experiencing the social phenomenon under study.

Direct measurement of social phenomena has its advantages. The data collected are timely. Information can be collected on topics for which archival or other preexisting data sources do not exist, are unreliable, or are incomplete. The social measures derived from interviews, in theory, directly reflect the attitudes and behaviors of individuals in society. And, unlike an archive or a set of economic indicators, the researcher can interact with the subject under study in order to gain a richer understanding of social phenomena. However, interviews can be time-consuming and costly to implement correctly and often require hiring the services of trained professionals. Interview subjects may be less likely to reveal certain types of sensitive or detailed information to a researcher. Interviews also can create a tendency to focus too much on the individual and not enough on his or her social context. Also, as discussed later in this article, direct measurement of social phenomena through interviews can also invite biases and errors in social measurement.

An interview is a method of directly collecting data on the attitudes and behaviors of individuals through questions

Types of Interviews

Personal Interviews

Personal interviews, akin to the work of journalists, involve one-on-one conversations with a set of respondents. An example here would be a researcher who is interested in the role of lobbyists in policymaking interviewing a number of lobbyists and members of Congress. This type of interview has a tendency to be less structured than the other types discussed in this article because the process can be more spontaneous and open-ended. The interview schedule may be defined in some manner by the interviewer before the interview takes place, but the conversation may deviate from this preset format as the researcher discovers new information. Because of the relatively large amount of work involved in comprehensively studying each respondent, this type of interview often forces the researcher to focus on interviewing a smaller number of respondents. However, this procedure also allows the researcher to obtain rich narrative information from those few individuals.

Focus Groups

A focus group is conducted by engaging a group of respondents who are of interest to the researcher in a group conversation. The individuals are often similar to one another in some way that is germane to the research question (for example, a group of teachers could be gathered to conduct a focus group on the resource needs of educators). During the discussion, participants are encouraged by the moderator to share their opinions, “without pressuring participants to vote or reach consensus” (Krueger and Casey, 2000: p. 4). The moderator strives to create a nonjudgmental environment in order to make the participants more willing to express their opinions openly. It is standard practice for the researcher to conduct many focus group sessions in order to discover potentially meaningful trends across the groups. Like the personal interview, this type of interview can be structured *a priori*. However, because focus group respondents are engaged in free discussion, the researcher does not have complete control over the path of the conversation. In addition, because of the cost and effort involved in gathering and running focus groups, the method often allows the researcher to interview a relatively small number of individuals. Therefore, focus groups are not commonly used when the researcher needs to generate data that are statistically representative of a large population. However, the more open mode of a focus group discussion allows the researcher to find out what matters are of greater interest to respondents. Such data can also be used to develop more formally structured questionnaires (see below). The ability to dig deeper into

issues through focus groups can also allow the researcher to untangle complicated topics.

Questionnaires

A questionnaire is a predetermined list of interview questions that is filled out by either the respondent or the researcher. This form of interview is highly structured because the path of the conversation is determined before it begins and is not deviated from. As questionnaires came into wider use, these types of interviews were likely to be conducted in person, usually in the respondent's home. However, with the spread of telecommunications technology during the 1970s, along with decreasing success and increasing costs associated with administering questionnaires face-to-face, these types of interviews began to be increasingly conducted through the mail and over the telephone. Self-administered questionnaires have also been conducted over the Internet. However, because the number of individuals in the general public that have access to the Internet is relatively small, this method is controversial in certain applications. A key benefit of questionnaires is that they can be administered to many people. This allows the researcher to make more reliable inferences about the entire population under study. However, the tradeoff involved is that the researcher is usually not able to obtain as much rich narrative information as with other methods, because respondents are often reluctant or unable to provide detailed or in-depth information on a predefined questionnaire. Either respondents can be unwilling to supply such information or the format of a questionnaire can be too constrictive to allow for the collection of such detailed information.

What Type of Interview is the Best?

In the end, choosing what type of interview method to use comes down to determining what the particular needs of the research project are and how those needs are best met within budgetary constraints. There are, therefore, many different issues that can be taken into consideration when deciding what type of interview procedure to use. However, one very important way to determine what type of interview technique to utilize is to determine what type of data is needed and how generalizable the data need to be. Research designs that allow the researcher to interview many people (questionnaire-based studies) can have the benefit of allowing the researcher, if enough interviews are completed, to make reliable statistical inferences about the population under study. However, questionnaire-based interviews can be less effective if the researcher does not know what specific types of questions to ask or if the researcher needs to

obtain a sizable amount of deep narrative information about specific types of respondents. Interview designs that commonly yield fewer interviews (focus groups and personal interviews) typically have the benefit of allowing the researcher to gather a large amount of rich narrative data from a smaller subset of the population. The method also allows the researcher to learn about topics that he or she might not have much knowledge on yet. However, this method is likely to be less useful if the researcher is looking to make more generalizable statistical inferences about a large population.

It is important to note that there are cases where a mixed-mode approach may be useful. For example, a researcher may want to learn about how many individuals feel about a certain issue, but he or she may also be unsure what specific issues are important to cover in the interviews. In this case, it may be useful to begin with a series of focus groups in order to learn what questions to ask in questionnaire-based interviews conducted on a larger sample. In these and other cases, results from one style of interview can serve to augment and inform the results of another. However, it is important to consider that different interview modes can produce incompatible findings. For example, the type of person that is more likely to complete a telephone interview might be different from the type of person that is more likely to respond to a mail survey.

Issues in Interview Design and Execution

Types of Interview Questions: Closed- and Open-Ended

There are two ways to structure the responses that respondents offer: open- and close-ended questions. Open-ended questions are “fill-in-the-blank” items, where the respondent offers his or her own answer. Close-ended questions are those that give the respondent a finite set of specified responses from which to choose. In general, close-ended questions are more appropriate when the respondent has a specific answer to give (for example, gender), when the researcher has a predefined set of answers in mind to a question, when detailed narrative information is not needed, or when there is a finite number of ways to answer a question (for example, gender). Open-ended items are more useful when the respondent is able to provide a ready-made answer of his or her own, when the researcher is not certain what answers to provide or wants to conduct more exploratory research, when the researcher wants to obtain narrative data, or when the number of potential responses to a question is known but large and difficult to specify *a priori* for the respondent (for example, occupation). Both types of questions can

be used in the same interview because the different types allow researchers to accomplish different goals.

Use of Response Scales in Close-Ended Questions

A key issue to consider in using close-ended questions is how to structure response scales. The type of scale chosen should reflect what the question is trying to measure. Ordered scales ask the respondent to place himself or herself on an opinion continuum. For example, Likert-type scales are 4- or 5-point scales that probe for feelings on issues in reference to agreement or disagreement with a statement (for example, “agree,” “somewhat agree,” “somewhat disagree,” “disagree”). The Likert-type scale can also be modified to measure other types of opinions and behaviors (for example, a scale that runs from “Poor” to “Excellent” to measure how individuals rate a governmental program or from “All of the Time” to “Never” to see how often individuals engage in a certain behavior). Feeling thermometers allow the respondent to choose a number from 0 to 100 in order to rate how “warm” or “cold” he or she feels toward a certain concept, policy, person, or the like. Polar point scales ask the respondent to place himself or herself on a numbered scale, where the ends signify opposite opinions. Unlike the scales just discussed, unordered or nominal scales offer different classes or categories to choose from (for example, types of sports that the respondent plays, or, of the options listed, which public policy should be funded).

Question Ordering

It is important to consider how to order questions in an interview. Research on “context effects” in interviews has shown that the content of a question can affect responses to the questions that follow it. This occurs because respondents create their answers to interview questions, in part, based on what material they have been thinking about beforehand. As one example of such context effects, in thinking about how a respondent might answer a question about Bill Clinton’s integrity, Moore shows that if a “. . . question about Clinton’s integrity is preceded by a similar question about Al Gore’s integrity . . . it is likely that some people, to varying degrees, will include their assessment of Gore as a part of the comparative standard by which they judge Clinton” (2002, p. 82). In short, the order of questions matters because individuals make use of the context that they are in when they form responses.

Potential Sources of Error

Measurement Error

Measurement error, a case in which the respondent has somehow provided inaccurate or uninterpretable information, has many potential sources.

Question Wording In thinking about the errors that question wording can produce, it is helpful to consider the following two questions:

1993 Roper Poll Question: "Does it seem possible or does it seem impossible to you that the Nazi extermination of the Jews never happened?"

1993 Gallup Poll Question: "Does it seem possible to you that the Nazi extermination of the Jews never happened or do you feel certain that it happened?"

These questions, although seemingly similar, produced strikingly different results. The Roper poll showed that over one-third of Americans were either unsure or thought that the Holocaust was a hoax. In sharp contrast, the Gallup poll question showed that only 10% of the population were Holocaust doubters.

What this example highlights is how question wording can significantly impact the data collected. As Dillman aptly points out, "The goal of writing a survey question . . . is to develop a query that every potential respondent will interpret in the same way, be able to respond to accurately, and be willing to answer" (2000, p. 32). In other words, in order to reduce measurement error, researchers need to construct questions that are understandable and that give the same "stimulus" to each respondent. To achieve this, Dillman suggests that numerous questions need to be considered when wording questions: Will the respondent be able to understand the question? Does the respondent have the knowledge to answer the question? Does the question wording somehow "frame" the question in a certain manner? Does the wording bias, *a priori*, how the respondent is likely to answer? Will the respondent be willing to answer the question or is the question too personal or sensitive in nature? Are all of the questions worded in a fairly consistent manner?

Issues with Respondents Measurement can also be in error in terms of how the respondent understands and responds to the question. Respondents may not understand a question, may not know how to use the scales provided, may become fatigued or disinterested in the interview, or may feel that the researcher wants them to answer in a certain "socially desirable" way. Any and all of these factors can lead to inaccurate measurement.

Issues with Interviewers Measurement error can also occur because of the traits or behaviors of the interviewer. These errors can occur because of the intentional actions of the interviewer, e.g., if questions are not read accurately or if respondents are encouraged to answer questions in a specific way by the interviewer. Research has also shown that there are various unintentional sources of measurement error caused by interviewers.

For example, a 1993 study by Kane and Macaulay shows that in some cases, respondents provide more "pro-woman" responses when interviewed by a female. A 1991 study by Finkel *et al.* finds similar results due to race. Numerous other examples exist.

Sampling and Coverage Error

Interview data can also be imprecise because of errors in sampling and coverage. Sampling error is the product of collecting data from only some, and not all, of the individuals in a population. If one were to interview every individual in a population, the social measures constructed from those data would be a statistically accurate representation of the population with 100% confidence. One would know how everyone in the population responded to the question and hence there would be no error in one's assessment of how the population responded to the question. However, if every member of a population is not interviewed, statistically random error creeps into the measures calculated from interview data because one cannot know with 100% confidence how the population as a whole would have responded to the interview questions. Sampling error accordingly reduces confidence in the precision of measurement. Because of this, the size or margin of this random sampling error must be presented whenever presenting interview results.

Similarly, coverage errors occur when each individual in the population does not have an equal chance of being included in the sample. For example, consider a study of political participation that has generated a sample from voter registration records. This sample would clearly be biased because it failed to cover individuals who are not politically active, in this case nonvoters.

Nonresponse Error

Nonresponse errors result when the individuals who complete the interview are somehow systematically different than those who were unable to be contacted and those who chose not to participate. For example, consider an interview project that is being conducted on political participation. Based on its content, individuals who are more politically active may be more interested in participating in the interview, leaving the attitudes and behaviors of those who are less politically active out of the analysis. Thus, in order to reduce such errors, it is essential to conduct interviews with as many individuals in the sample as possible. It is also helpful to examine interview data carefully to see whether the individuals who are choosing to respond are somehow different than the population at large in a way that is germane to the topic under study.

Getting People to Respond: The Key to Any Interview Project

Maximizing response rate is vital to the success of any interviewer project. As alluded to in the section above on sampling and coverage error, higher response rates translate into more precise and representative measures of the population under study.

Scores of ideas about how to increase respondent participation exist, but these various techniques can be easily summarized through the concepts of costs and benefits. Social relationships are defined by a system of social exchange; individuals engage with others socially if the benefits that others provide exceed the costs of social interaction. Thus, in order to encourage a potential respondent to participate in an interview, the costs of participation need to be reduced and the benefits need to be increased. Numerous techniques are utilized to reduce costs, including trying to gain the trust of the respondent, wording questions in a way that makes them easy to understand and respond to, and laying out self-administered questionnaires in a way that makes them easy to follow. Benefits are increased through offering the respondent material benefits (for example, money, a souvenir) or solidary benefits (for example, communicating how participation will aid the researcher in resolving an important public policy issue of interest to the respondent).

Although reducing costs and increasing benefits is effective, the greatest challenge facing those who use interview techniques will be to adapt and apply this theory of social exchange to new technologies and a changing society. It usually takes a great amount of effort and skill on the part of many professionals in order to finish an interview project with a high response rate. However, it is becoming harder to maintain high response rates. Three related reasons likely account for falling response rates. The first is technology: from caller ID to answering machines and Internet spam filters, households are becoming more equipped to block out messages from strangers. Second, direct marketing through the mail, telephone, and Internet has left the public "fatigued" and less willing to converse with or respond to strangers. Finally, researchers have also documented that the American public has become more withdrawn and less socially engaged since the mid-1900s.

Item and Test Bias

Howard Wainer

*National Board of Medical Examiners, Philadelphia,
Pennsylvania, USA*

Stephen G. Sireci

University of Massachusetts, Amherst, Massachusetts, USA

Glossary

construct The unobservable attribute purportedly measured by a test.

differential item functioning A statistically significant difference in performance on a test item across two or more groups of examinees, after the examinees have been matched on the construct of interest.

differential predictive validity A statistically significant difference across two or more groups of examinees, in the degree to which test scores predict a relevant criterion.

item bias A statistically significant difference across two or more groups of examinees due to characteristics of the item unrelated to the construct being measured.

test bias A systematic increase or reduction in test scores for one or more groups of examinees due to factors unrelated to the construct measured by the test.

validity The credibility and the relevance of the evidence provided by the measuring instrument for the inferences that the users of the test want to draw.

A test is an instrument that provides evidence from which inferences can be drawn. A test score is a summary of this evidence. The degree to which test evidence is credible and relevant is characterized by the psychometric term “validity.” Valid decisions based on test scores for a particular purpose must be supported by theory and empirical evidence. Biases in test scores diminish validity, and so great effort is expended in ameliorating them. In this article, some of the relevant issues related to this topic are discussed, as well as some of the statistical

methodologies that are commonly used to detect both bias and differential item functioning.

Introduction: Validity and Invalidity

Understanding Validity Nomenclature

Bias in measurement instruments is a concern for all scientists, which is why scales for measuring weight and other physical properties are regularly recalibrated. However, in the social sciences, the more intangible, psychological attributes measured are much more susceptible to error. For this reason, evaluation of the measurement instrument is intertwined with measurement of the construct of interest. In 1955, Cronbach and Meehl introduced the term “construct” to acknowledge the fact that the “thing” being measured by educational and psychological tests is often an unobservable, postulated attribute “constructed” by theorists and test developers.

Sources of bias in testing are typically attributed to either construct-irrelevant variance or construct under representation. Construct-irrelevant variance refers to one or more systematic sources of variation in test scores irrelevant to the construct the test is trying to measure. Examples of such bias in test scores include contextual effects and response biases. A context effect may occur, for example, when a mathematics test includes a preponderance of word problems that are related to baseball. In such a case, baseball knowledge may interfere with measurement of mathematics proficiency. Response biases would include “yea-saying” and other types of

social desirability on surveys and personality inventories, or test-taking strategies on educational exams. In such cases, test scores are influenced by a construct different from the one the test is designed to measure.

Construct underrepresentation occurs when the test measures the construct too narrowly and some important aspects of it are left out. Some obvious examples might be a general science test that includes optics and thermodynamics but not genetics, a licensing test for physicians that includes scientific but not clinical knowledge, or tests of physical ability, such as those used for selecting fire fighters, that focus on physical strength to the exclusion of flexibility and dexterity. It is easy to imagine how the difference in the distribution of scores of men and women could be manipulated by arbitrarily varying the composition of the test.

Quality assessments strive for adequate construct representation and try to eliminate or minimize construct-irrelevant factors that may influence test performance. If such factors affect test scores, bias is present and the interpretations based on test scores may be invalid.

Bias and Impact

To understand test and item bias requires, first, understanding the difference between impact and bias. Impact refers to significant group differences in performance on a test or on a test item. The observation that women, as a group, score noticeably lower in height than men is an example of impact. Such observed differences do not necessarily signify that the ruler is biased, because the difference in heights could very well reflect a true difference between the groups. The potential causes of such a difference are a separate issue beyond the scope here, but the important point is that between-group differences in test scores could reflect true group differences, and so impact does not necessarily signify bias. A determination of bias requires additional evidence indicating that systematic and construct-irrelevant material does differentially affect scores.

A large number of methods have been developed to investigate item and test bias. Four methods that have been suggested for investigating item bias, and one for investigating test bias, are described in the following sections. One method, the delta plot, is included for historical reasons. Two others, the Mantel–Haenszel procedure and the item response theory (IRT)-based maximum likelihood method, are included because they are representative of the two broad classes of methods (observed score and model based) that are widely used. Moreover, each of these procedures is statistically optimal under plausible conditions. Other, similar methods are sometimes used, but do not enjoy either the same breadth of usage or the same level of statistical efficiency. This latter characteristic is very important, because organizations that produce tests

would like to look for differential item functioning (DIF) and not find any. Thus it is a moral imperative that any attempts to find DIF must use the largest samples and the most powerful statistical procedures possible. It is only in this way that it can credibly be claimed that the test has been examined for fairness and no flaws were discovered.

Item Bias and Differential Item Functioning

Item bias refers to the situation wherein a statistically significant difference in performance on an item is observed across two or more groups of examinees, and the reason for the difference can be traced to a source other than the construct measured by the test. When there is a quantitative criterion that the test is predicting (e.g., using a college admissions test to predict freshman grade point average), the conclusion that an item is biased can be based on purely empirical evidence. But in those circumstances when the criterion is not so easily characterized quantitatively (e.g., a medical licensing exam in which the criterion is whether the person will become a good doctor), the decision about bias requires both statistical and judgmental information. In either instance, it must first be concluded that the item “functions” differentially across groups. When there is a quantitative criterion, “functions differently” means the test underpredicts one group relative to the other. When such a criterion does not exist, subject-matter experts and other experts familiar with the groups of examinees must be able to identify a source of bias that explains the differential performance.

The assessment of differential performance can be done on all tests using information contained in the scores, without reference to an external criterion. Such assessments are called differential item functioning. DIF analyses evaluate whether examinees from different groups (e.g., females and males) who are of comparable ability on the entire test have equal probabilities of success on an item. In DIF analyses, conditioning procedures are used systematically to match examinees of similar proficiency across groups, to distinguish between overall group differences on an item (item impact) and potential item bias. That is, DIF procedures focus on differences in item performance across groups after the groups are matched on the construct measured by the test. In DIF analyses, test-takers from different groups are matched on the psychological attribute measured, and the probability of differential responses across matched test-takers is evaluated. Items are considered to be functioning differentially across groups if the probability of a particular response differs significantly across test-takers who are equivalent (i.e., matched) on proficiency. The most

common conditioning variable used in DIF analyses is the total test score. If the conditioning variable is the criterion score, what is uncovered is bias and not merely DIF.

Adverse Impact and Test Bias

Score differences between two or more groups of examinees are common in educational and psychological testing. Such differences are called “impact,” and in some cases when a minority group exhibits lower average performance, it is called “adverse impact” or “disparate impact.” Disparate impact has received significant attention in the courts because Title VII of the Civil Rights Act of 1964 (Title VII, 1999) forbids employers from refusing to hire individuals on the basis of race, color, religion, sex, or national origin, and so when disparate impact appears on employment tests, minorities get hired at lower rates, as compared to nonminorities. A common definition of disparate impact is when the “passing” (or selection) rate for members of a particular protected group is less than 80% of the passing rate for the group with the highest rate of selection. However, impact does not signify bias, and so the courts require testing agencies to establish that there is a sound scientific basis for use of the test and that the test is not biased against the protected group. Test bias occurs when the test scores for one or more groups are systematically increased or reduced due to factors unrelated to the construct measured by the test. If a test is biased against one or more groups, the differences observed between groups are misleading and the test scores cannot be assumed to have the same meaning across groups.

As for item bias, several statistical methods for investigating test bias exist. One way test developers reduce the likelihood of test bias and disparate impact is to pretest items and screen them for DIF before assembling the final test form. Thus, before describing methods for evaluating test bias, methods for evaluating DIF must first be described.

Evaluating Item Bias

There are many statistical methods for evaluating DIF. The four methods most commonly used in high-stakes testing environments are the delta plot, standardization, Mantel–Haenszel, and a method based on item response theory. All DIF procedures have, as their goal an estimate of the difference between groups, after controlling for the construct measured on the test. Typically, DIF detection methods evaluate item functioning across two groups. The group about which there is concern is denoted the focal group. The other group is called the reference group.

The Delta Plot Method

The delta plot method provides a visual comparison of item difficulty statistics to allow the identification of items that function differentially across groups. This relatively early procedure was designed for identifying potentially biased educational test items that were scored correct or incorrect. The procedure involves first calculating the proportions of examinees in the reference and focal groups who answer an item correctly (p -values). Next, the normal transform of these p -values is calculated and scaled to any convenient metric (historically, they were scaled so that the mean over both groups is 13 and the standard deviation is 4). These transformed p -values were originally called “group-specific item difficulties” and denoted as “item deltas,” the eponymic source of the method’s name. These calculations yield group-specific deltas for each item. They are then plotted against one another, with the reference group on the horizontal axis and the focal group on the vertical one. If the relative difficulties of the items are consistent across groups, they will fall on a 45° line. If the difficulty of any item is different in the two groups, that item will deviate from this line.

The overall difference in ability between groups in a delta plot is characterized by the intercept of the regression line running through the scatter plot. If the intercept is at 0, the two groups have the same ability distributions. If the intercept on the focal group’s axis is, say, 1, it means that the mean of the focal group’s ability distribution is 1 delta (a fourth of a standard deviation) lower than the mean of the reference group. Items that fall within a narrow ellipse around the 45° line have approximately equal difficulty in both groups and thus can be considered as equivalent or unbiased. Items that deviate significantly from this line are said to have demonstrated DIF. The delta plot makes clear that DIF is a concept of interaction. The main effects represent overall item difficulty and group mean ability. When an item deviates from the simple combination of these two main effects and shows a significant interaction, it is singled out for closer study. The delta plot example in [Fig. 1](#) presents the delta values computed from fictitious examinees. The fact that the 45° line does not emanate from the origin reflects the overall difference in proficiency between the two groups, which is 1.0 (in favor of group 1) in this case. A confidence band is drawn around this line, and the four items that fall far enough outside this band are flagged for DIF.

The delta plot method is relatively easy to do and interpret. However, it has been shown to miss items that function differently across groups if the discriminating power of the item is low, and to flag items for DIF erroneously if the discriminating power of the item is high. For these reasons, although it is of historical interest, the delta plot is rarely used today.

Figure 1 An example of the graphical method (delta plot) of differential item functioning (DIF) detection, now of primarily historical interest.

The Standardization Index

In 1986, Dorans and Kulick suggested using traditional standardization methods to construct an index for detecting DIF. This method is a “conditional p -value” procedure, whereby separate p -values are computed for each item conditional on total test score for each group. The difference between these estimates is then calculated between the reference and the focal groups. A summary statistic is then calculated by summing up these differences weighted by score distribution of the reference group. In practice, test score intervals are computed to match examinees (i.e., thick matching) so that the sample sizes per test score interval are not too small. The standardized proportion (STD-P) index that Dorans and Kulick proposed is computed as follows:

$$\text{STD-P} = \frac{\sum_m w_m (E_{fm} - E_{rm})}{\sum_m w_m}, \quad (1)$$

where w_m is the relative frequency of the reference group at score level m , and E_{fm} and E_{rm} are the proportion of examinees at score level m who answered the item correctly in the focal and reference groups, respectively. The standardization index ranges from -1 to 1 . (Although Dorans and Kulick did not propose a statistical test for this statistic, one can easily be computed using the jackknife technique introduced by Rupert Miller.) The STD-P has an easy and direct interpretation. For example, if STD-P is 0.10 , it means that, on average, examinees in the reference group who

are matched to examinees in the focal group have a 10% greater chance of answering the item correctly.

The Mantel–Haenszel Method

In 1959, Mantel and Haenszel developed a summary statistic for examining the efficacy of a cancer treatment. Patients were stratified by the severity of their illness, and at each level of severity, a 2-by-2 frequency table was constructed. One factor of this table was “treatment” or “control” and the other factor was “survived” or “didn’t.” Computing a measure of the independence of the two factors at each level was well established. Mantel and Haenszel’s contribution was the derivation of a clever weighting scheme to combine the results of all of these 2-by-2 tables across the severity strata in a statistically optimal fashion. The resulting summary statistic has become known as the Mantel–Haenszel statistic, in their honor.

It is clear that if we substitute performance on the test for severity, “reference” and “focal” for “treatment” and “control,” and “correct” and “incorrect” for “survive” or “didn’t,” the Mantel–Haenszel statistic can be directly applied to the problem of estimating DIF. The recognition that Mantel–Haenszel (MH) was well suited for this problem took almost 30 years; it was not until 1988 that Holland and Thayer suggested it. MH is similar to the standardization index in that examinees from two different groups are matched on the proficiency of interest, and the likelihood of success on the item is compared across groups. It is different, however, in that it looks at the odds ratio of success on each item rather than the difference in the probabilities. More importantly, it was a well-researched summary statistic with optimality characteristics that fit well with the moral imperative described earlier. Moreover, it is cheap and easy to compute and so is currently the most commonly used DIF method.

To compute the MH statistic, the following frequencies are calculated at each level of the conditioning variable: the total numbers of examinees in each group, and the numbers of examinees in each group who answered the item correctly and who answered the item incorrectly. An example of the necessary data at just one level of the conditioning variable is presented in Table I.

The null hypothesis tested is that the ratios of the proportions (correct to incorrect) for each group are the same. Using the notation in Table I, the common-odds ratio α_{MH} is estimated by

$$\hat{\alpha}_{MH} = \frac{\sum_j A_j D_j / T_j}{\sum_j B_j C_j / T_j}. \quad (2)$$

When $\alpha_{MH} = 1$, the likelihood of responding correctly to the item is the same for both the focal and reference group, across j score levels. The significance of the

Table I Frequencies Needed to Compute the MH Statistic at Each Level of Conditioning Variable

Group	Answer ^a		Total
	Correct	Incorrect	
Reference	A_j	B_j	N_{rj}
Focal	C_j	D_j	N_{fj}
Total	M_{1j}	M_{0j}	T_j

^a M denotes one level of conditioning variable.

deviation of the MH statistic is easily determined through a one-degree of freedom chi-square statistic:

$$\text{MH-}\chi^2 = \frac{[|\sum_j A_j - \sum_j E(A_j)| - 0.5]^2}{\sum_j \text{Var}(A_j)}, \quad (3)$$

where

$$\text{Var}(A_j) = \frac{N_{rj}N_{fj}M_{1j}M_{0j}}{T_j^2(T_j - 1)}. \quad (4)$$

In addition to providing a test for statistical significance, an effect size can also be computed, and rules of thumb exist for classifying these effect sizes into small, medium, and large DIF (Dorans & Holland, 1993).

The MH method has been shown to be particularly powerful in detecting DIF. For this reason, it is often used as the standard for comparison in studies that compare DIF detection methods. The MH statistic achieves its power by focusing all evidence on the detection of a single parameter (hence the single degree of freedom), which is the extent to which the log-odds ratio is consistently different than one across all strata. It is trying to detect what has come to be called uniform DIF. The cost of this single-mindedness is that it cannot detect other sorts of deviations; specifically, it cannot detect deviations that vary systematically across strata ("nonuniform" DIF). Many studies have shown that both types of DIF can occur on educational tests. Other methods do not have these limitations, and the most powerful of these are discussed next.

Methods Based on Item Response Theory

The three methods for DIF detection described previously were all observed score methods in that they do not posit a strong model for item responses. Because of its optimality characteristics, the MH does about as well as is possible with observed score methods. Thus the most logical way to try to achieve greater flexibility and power is to lean on a stronger test response model. This path has been followed and there are several methods for detecting DIF based on item response theory, which is the

most common test scoring methodology in current use. All these methods test whether a common set of item parameters can be used to describe the functioning of an item in each group. If different parameters are needed to describe the functioning of the item in each group, then the item is flagged for DIF.

Fitting an IRT model to an entire test in which all items are assumed to behave the same in both groups, and then fitting a slightly more general model in which the studied item is allowed to have different parameters in the two groups, immediately suggests a likelihood ratio procedure to determine if the fit is improved with the more general model. If the fit is improved, there is DIF; if it is not, there is no DIF. Such a procedure has both flexibility and power. It is flexible in that it can assess differences in item behavior in any way that can be characterized by the model. It is powerful in that it has all of the optimality of maximum likelihood. Thissen, Steinberg, and Wainer developed this procedure, in two papers in 1988 and 1993, following a suggestion by Lord in 1980.

This procedure requires rather heavy computing; for each item, multiple IRT models must be fit to the data. When the assessment comprises a large number of items, and the no-DIF model is rejected, isolating the specific DIF items can be an arduous process. Modern computing has eased this task considerably. In 2001, Thissen prepared a computer program that does the analyses for long sequences of items automatically, and so the computing is a long way from the back-of-the-envelope calculations required for the observed score methods; it is no longer as daunting a task as it was when first proposed. Even for operational-length tests, a full IRT DIF analysis can be done on a standard desktop computer in the time it takes to get a cup of coffee.

Evaluating Test Bias

The evaluation of test bias focuses on test scores rather than on test items. In most cases, evaluation of bias operates within a predictive validity framework. Predictive validity is the degree to which test scores accurately predict scores on a criterion measure. A conspicuous example is the degree to which college admissions test scores predict college grade point average (GPA). Given this predictive context, it should not be surprising that regression models are used to evaluate predictive validity. The analysis of test bias typically investigates whether the relationship between test and criterion scores is consistent across examinees from different groups. Such studies of test bias are often referred to as studies of differential predictive validity.

There are two common methods for evaluating test bias using regression procedures. The first involves

fitting separate regression lines to the predictor (test score) and criterion data for each group and then testing for differences in regression coefficients and intercepts. When sufficient data for separate equations are not available, a different method must be used. This method involves fitting only one regression equation. In one variation of this method, the coefficients in the equation are estimated using only the data from the majority group. The analysis of test bias then focuses on predicting the criterion data for examinees in the minority group and examining the errors of prediction (residuals). In another variation of this method, the data from all examinees (i.e., majority and minority examinees) are used to compute the regression equation. The residuals are then compared across groups.

The simplest form of a regression model used in test bias research is $y = b_1X_1 + a + e$, where y is the predicted criterion value, b_1 is a coefficient describing the utility of variable 1 for predicting the criterion, a is the intercept of the regression line (i.e., the predicted value of the criterion when the value of the predictor is zero), and e represents error (i.e., variation in the criterion not explained by the predictors). If the criterion variable were freshman-year GPA and the predictor variable were Scholastic Aptitude Test (SAT) score, b_1 would represent the utility of the SAT for predicting freshman GPA. To estimate the parameters in this equation, data on the predictor and criterion are needed. The residuals (e in the equation) represent the difference between the criterion value predicted by the equation and the actual criterion variable. Every examinee in a predictive validity study has a test score and criterion score. The residual is simply the criterion score minus the score predicted by the test.

Analysis of the residuals in a test bias study focuses on overprediction and underprediction. Overprediction errors occur, for example, when the predicted GPA for a student is higher than her/his actual GPA. Underprediction errors would occur when the predicted GPA for a student is lower than her/his actual GPA. By examining the patterns of over- and underprediction across the examinees from different groups, evidence of differential predictive accuracy is obtained. For example, if the errors of prediction tended to be primarily underprediction errors for females, it could be concluded that the test is biased against females.

This method is flawed, because it can indicate test bias when there is none if the group means are different. Such a result, illustrated in Fig. 2, is merely a regression effect and the use of this methodology when group means are different on both the test and the criterion leads to incorrect inferences. The confusion of impact with bias in the popular media has long added confusion to discussions of this delicate issue. The use of regression methods for detection is not an unmixed blessing.

Figure 2 A graphical counterexample to provide a warning for those who would use regression methods to detect test bias when the groups being investigated show substantial differences in level. The two ellipses represent the bivariate distributions of scores on the prediction and the criterion for two different groups (group A and group B). The principal axes of both ellipses lie on the 45° line, but the regression lines are tilted, yielding differential predictions based on group membership. This is not bias, but rather an example of a regression effect.

Bias and Fairness for the Future

Tests have assumed an important role in all meritocratic societies in which the positions within those societies are based principally on the promise of what a person can do, rather than on the ancient criteria of family connections and wealth. Any society that has limited resources must make triage decisions concerning who shall be granted admission to an elite school or who is to be chosen for a particular job opening, for example. Meritocracies use empirical evidence related to the openings to make those decisions. Tests are a special form of evidence. In a real sense, a test score is the result of an experiment. As such, it can be studied, flaws can be detected, and it can be improved. Contrast this with other kinds of evidence, such as interviews and letters of recommendation. These are very much the result of an observational study. A biased letter writer is hard to detect and almost surely cannot be corrected. The methods discussed here are a sampling of a powerful set of statistical procedures designed to examine and improve test scores. Recent trends in education suggest the future holds an ever-increasing role of tests in policy decisions. Because of statistical methods such as these, there is the hope that tests can be made fair enough to satisfy that need properly.

Item Response Models for Nonmonotone Items

Herbert Hoijtink

University of Utrecht, Utrecht, The Netherlands

Glossary

dominance relation The relationship that, the higher the location of a person is on the latent trait, the larger the probability is that the person will respond positively to an item.

item characteristic curve The probability of an item response as a function of the location of a person on the latent trait.

item response models Models in which the probability of an item response is related to the location of both the person and the item on a latent trait.

latent trait A characteristic of either a person or an item that is not directly observable.

measurement instrument A joint one-dimensional representation of individuals and items.

monotone items Items for which the item characteristic curve is a monotonically increasing function of the latent trait.

nonmonotone items Items for which the item characteristic curve is a single-peaked function of the latent trait.

proximity relation The relationship that the closer the locations of a person and an item are on the latent trait, the larger the probability is that the person will respond positively to the item.

Item response models can be used to infer the locations of individuals on a latent trait from the responses of the individuals to a set of items indicative of the latent trait. Item response models for nonmonotone items are developed for the situation in which the trait of interest is an attitude or a preference. A distinguishing feature of these models is the use of proximity relations—the closer the locations of a person and an item on the latent trait, the larger the probability is that the person will respond positively to the item. Goodness-of-fit tests can be used to evaluate the appropriateness of the model and the quality

of the resulting measurement instrument (a joint one-dimensional representation of individuals and items) for the data at hand.

The Models of Guttman and Coombs

Guttman's Scalogram Model

In the mid-1950s Guttman developed the first item response model—the scalogram model. The scalogram model assumes that there is a joint one-dimensional representation of person $i = 1, \dots, I$ with location θ_i and items $j = 1, \dots, J$ with location δ_j such that the item response x_{ij} equals 1 if $\theta_i > \delta_j$ and 0 otherwise. The scalogram model assumes that the item responses result from dominance relations among individuals and items; that is, it is especially suited for the measurement of traits that are abilities. Table I presents a data matrix for $I = 5$ and $J = 4$ that is typical for the scalogram model. The table shows that person 1 is not very able (none of the items are dominated), and person 3 is more able (two of the items are dominated). Based on Table I, it can be concluded that $\theta_1 < \theta_2 < \dots < \theta_5$ (i.e., person 1 is least and person 5 is most able) and also that $\delta_1 < \dots < \delta_4$ (i.e., item 1 is the easiest and item 4 the most difficult). A drawback of

Table I Data Matrix Typical for the Scalogram Model

i	x_{i1}	x_{i2}	x_{i3}	x_{i4}
1	0	0	0	0
2	1	0	0	0
3	1	1	0	0
4	1	1	1	0
5	1	1	1	1

the scalogram model is its deterministic nature, that is, $P_{ij} = P(x_{ij} = 1 | \theta_i, \delta_j)$ is either 1 or 0. This is illustrated in Fig. 1, in which the item characteristic curve of item j (P_{ij} as a function of θ_i) is displayed. Guttman's scalogram model has been the point of departure for the development of probabilistic dominance relation-based item response models such as the Rasch model, the two-parameter logistic model, and the Mokken model, which do not have this drawback.

Coombs's Parallelogram Model

In the mid-1960s, Coombs developed the model on which all the models discussed in this entry are based—the parallelogram model. Where the scalogram model assumes dominance relations among individuals and items, the parallelogram model assumes proximity relations; that is, the item response x_{ij} equals 1 if $|\theta_i - \delta_j| \leq \tau$ and 0 otherwise. The parameter τ is a threshold; that is, it is the largest distance between a person and item still leading to a response of 1. The parallelogram model is especially suited for the measurement of traits that are attitudes or preferences. Table II presents a data matrix for $I = 5$ and $J = 4$ that is typical for the parallelogram model. According to this data matrix, individuals and items can be ordered along the latent trait using i and j , respectively, to indicate the rank number in the

Figure 1 Item characteristic curve for Guttman's scalogram model.

2	1	1	0	0
3	0	1	1	0
4	0	0	1	1
5	0	0	0	1

Figure 2 Item characteristic curve for Coombs's parallelogram model.

ordering. As can be seen the item responses are positive if the person and item are located close to one another. The parallelogram model has the same drawback as the scalogram model—it is deterministic. In Fig. 2, the item characteristic curve of item j is displayed. As can be seen, P_{ij} can attain only the values 0 and 1. Coombs's parallelogram model has been the point of departure for the development of probabilistic proximity relation-based item response models such as the Parella model and the hyperbolic cosine model. The hyperbolic cosine model has a counterpart that can accommodate both dichotomous and polytomous item responses, called the generalized graded unfolding model.

Probabilistic Models for Dichotomous Item Responses

The Parella Model

In the early 1990s the Parella model, a probabilistic counterpart of the deterministic parallelogram model, was developed. In this model:

$$P_{ij} = P(x_{ij} = 1 | \theta_i, \delta_j, \gamma) = \frac{1}{1 + |\theta_i - \delta_j|^{2\gamma}} \quad (1)$$

As indicated in Fig. 3, γ is a parameter that governs the degree with which the model deviates from the deterministic parallelogram model. If $\gamma = \infty$ the Parella model equals Coombs's model with $\tau = 1$; that is, a person will respond positively to all items within a distance of 1 of his or her location. As can be seen in Fig. 3, if γ decreases, both the probabilities of responding negatively to items located within a distance of 1 and responding positively to items located outside a distance of 1 are increasing. This is an important feature of the model because data as perfect as the data in Table II are rarely (if ever) observed.

Figure 3 Item characteristic curves for the Parella model.

The Parella model is not just defined by Eq. (1); an additional assumption is that θ_i is a random effect. The distribution of θ_i is a step-function with nodes β_q and weights π_q , where $q = 1, \dots, Q$. The step-function is preferred over the more traditional normal distribution for random effects because, especially when attitudes and preferences are measured, bimodal distributions of θ_i are rather common. The (nonrandom) parameters of the Parella model are estimated using marginal maximum likelihood (MML). Because the addition of a constant to both the person and the item locations does not change the likelihood, identification problems are avoided using the restriction $\sum_j \delta_j = 0$. An additional restriction (used to reduce the complexity of the estimation procedure) is the use of equidistant nodes. The (random) person locations are estimated using an expected *a posteriori* estimator.

Two goodness-of-fit procedures have been developed for the Parella model: a diagnostic with which the adequacy of the item characteristic curve can be investigated and a test for differential item functioning. According to Eq. (1), the expected proportion of individuals located at node q responding positively to item j is:

$$P_{qj} = \frac{1}{1 + |\beta_q - \delta_j|^{2\gamma}} \quad (2)$$

The “observed” proportion of individuals located at node q responding positively to item j is:

$$O_{qj} = \sum_i \frac{x_{ij} P(\mathbf{x}_i | \beta_q) \pi_q}{\sum_q P(\mathbf{x}_i | \beta_q) \pi_q} / (\pi_q N) \quad (3)$$

where observed is placed between quotation marks because both data and parameters are used to compute O_{qj} , and $P(\mathbf{x}_i | \beta_q) = \prod_j P_{qj}^{x_{ij}} (1 - P_{qj}^{1-x_{ij}})$. In Fig. 4, for a hypothetical item, the P_{qj} and O_{qj} are displayed for $q = 1, \dots, Q$. As can be seen in the figure, the “observed” threshold of this item is larger than the threshold predicted by the Parella model.

Also according to Eq. (1), the response probabilities depend only on θ_i and not on other person characteristics.

Figure 4 Comparison of observed and expected item characteristic curves for a hypothetical item.

In item response models this characteristic is usually referred to as the absence of item bias or the absence of differential item functioning. Consider, for example, a latent trait that ranges from “progressive” to “conservative.” Consider also one of the items used to operationalize this trait: “When the baby is born, I will happily quit working in order to be able to take care of the baby.” If a man responds “yes” or “agree” to this item, it is usually considered to be an indication of a progressive attitude. Stated otherwise, for men this item is located at the progressive side of the latent trait. If a woman responds “yes” or “agree” to this item, it is usually considered to be an indication of a conservative attitude. For women this item is located at the conservative side of the latent trait. Because the item location depends on gender, Eq. (1) is not sufficient to model the item responses. However, the Parella model has been generalized so that it can be tested for one or more items about whether their locations depend on some person characteristic such as gender, and for one or more items the locations can be estimated for each of a number of subgroups of individuals. Furthermore, it can be tested whether or not γ is subgroup dependent, and γ can be estimated for each subgroup separately.

The Hyperbolic Cosine Model

In 1993 the hyperbolic cosine model was introduced. This model is a derivative of the partial credit model for polytomous dominance data. The principles involved in this derivation are presented in the next section. In the hyperbolic cosine model:

$$P_{ij} = P(x_{ij} = 1 | \theta_i, \delta_j, \lambda_j) = \frac{\exp(\theta_i - \delta_j + \lambda_j)}{1 + \exp(\theta_i - \delta_j + \lambda_j) + \exp(2(\theta_i - \delta_j))} \quad (4)$$

Figure 5 Item characteristic curves for the hyperbolic cosine model.

where λ_j denotes unit parameter of item j . As indicated in Fig. 5, the unit parameter influences both the threshold and the maximum of the item characteristic curve—the larger λ_j , the larger the threshold and the maximum. Because the addition of a constant to both the person and the item location does not change P_{ij} , like the Parella model the hyperbolic cosine model is not identified. Here too problems are avoided using the restriction that $\sum_j \delta_j = 0$.

Both MML (treating the θ_i as random parameters, as described for the Parella model) and joint maximum likelihood (JML; treating the θ_i as fixed parameters) have been used to estimate the parameters of the hyperbolic cosine model. From a theoretical perspective, MML has to be preferred over JML. JML estimates are known to be inconsistent. Furthermore, it is not very natural to assume that a renewed data collection involves the same individuals. The latter is a direct consequence of treating the θ_i as fixed parameters. Whereas MML assumes that both the individuals and the item responses are sampled, JML assumes that only the item responses are sampled. However, as shown by a number of simulation studies, in practice JML appears to perform quite well. All authors agree that parameter estimation using the restriction $\lambda_j = \dots = \lambda$ for $j = 1, \dots, J$ is unproblematic. Without this restriction a large correlation between λ_j and δ_j may lead to inflated parameter estimates, especially if an item is located at either end of the latent trait of interest. A pragmatic solution for this problem is to estimate λ and, subsequently, to estimate the λ_j using the restriction $\sum_j \lambda_j = \lambda$.

As far as the hyperbolic cosine model is concerned, goodness-of-fit tests have not yet received a lot of attention. The only model-based test reported in the literature is a likelihood ratio test for differential item functioning for the model where the unit parameters are restricted to be equal. The null hypothesis being tested was equality of item locations and unit parameter across two subsamples of individuals.

Probabilistic Models for Polytomous Item Responses

Towards the end of the 1990s models for dichotomous item responses were generalized so that polytomous or graded responses could be handled. The most general model, the generalized graded unfolding model (GGUM), was derived from the generalized partial credit model (GPCM). The GPCM can be used to analyze graded dominance data. Let $y_{ij} \in \{0, \dots, k, \dots, K\}$ denote the response of person i to item j . Then, according to the GPCM:

$$P_{ikj} = P(y_{ij} = k | \theta_i, \delta_j, \alpha_j, \lambda_{j1}, \dots, \lambda_{jK}) \\ = \frac{\exp(\alpha_j[k(\theta_i - \delta_j) - \sum_{v=1}^k \lambda_{jv}])}{\sum_{z=0}^K \exp(\alpha_j[z(\theta_i - \delta_j) - \sum_{v=1}^z \lambda_{jv}])} \quad (5)$$

For a hypothetical item and $k = 0, \dots, 5$, the item category characteristic curves (P_{ikj} as a function of θ_i) are displayed in Fig. 6. Note that λ_{jk} marks the intersection of the response curves for categories k and $k - 1$. Because this entry deals with models that can handle proximity data, a straightforward interpretation of the parameters of the GPCM is not given here. However, if K is an odd number, using the restrictions $\lambda_{j,(K+1)/2} = 0$ and $\lambda_{j,k} = -\lambda_{j,K+1-k}$ (which applies to Fig. 6) the GPCM can be interpreted as a proximity relation-based model for the analysis of polytomous or graded responses.

Let $x_{ij} \in \{0, \dots, c, \dots, (K - 1)/2\}$ denote the responses to an item used to operationalize a preference or an attitude. With $K = 5$ these responses could, for example, be labeled 0 = Disagree, 1 = Undecided, and 2 = Agree or 0 = No, 1 = Don't know, and 2 = Yes. In proximity relation-based models, it is assumed that the distance between individuals and items is the main determinant of the item responses. In the example at hand, a response

Figure 6 Item characteristic curves for the generalized partial credit model.

of 2 indicates that a person is located closely to the left or right of the item, a response of 1 indicates that a person is located some distance from (either to the left or to the right of) the item, and a response of 0 indicates that a person is located relatively far to the left or right of the item. Based on the GPCM, the probability that person i responds in category c of item j can consequently be modeled as:

$$\begin{aligned} P_{icj} &= P(x_{ij} = c | \theta_i, \delta_j, \alpha_j, \lambda_{j1}, \dots, \lambda_{jK}) \\ &= P(y_{ij} = c | \theta_i, \delta_j, \alpha_j, \lambda_{j1}, \dots, \lambda_{jK}) \\ &\quad + P(y_{ij} = K - c | \theta_i, \delta_j, \alpha_j, \lambda_{j1}, \dots, \lambda_{jK}) \end{aligned} \quad (6)$$

The resulting item category characteristic curves are displayed in Fig. 7 ($\alpha_i = 1$). As shown in the figure, the probability of responding 2 decreases with increasing distance between person and item. The probability of responding 0 increases with increasing distance. On a relatively moderate distance of the item, response 1 is the most likely. These curves show nicely that the response probabilities depend mainly on the distance between person and item. The effect of the unit parameters λ_{jk} on the shape of the curves is similar to the effect of the unit parameter in the hyperbolic cosine model—the larger the values, the larger the thresholds and maximum of the associated curves. As is illustrated in Fig. 8 ($\alpha_i = 8$), increasing values of the discrimination parameter α_i lead to larger maxima and smaller thresholds. Stated in another way, the larger the α_i , the more the item responses are determined by the distance between person and item.

The GGUM model is not defined only by Eq. (5); an additional assumption is that θ_i is a random effect having a standard normal distribution. Consequently, the (nonrandom) parameters of the GGUM are estimated using MML. The (random) person locations are estimated using expected *a posteriori* estimates. Two goodness-of-fit procedures have been developed for the GGUM. First,

Figure 7 Item characteristic curves for the generalized graded unfolding model ($\alpha_i = 1$).

Figure 8 Item characteristic curves for the generalized graded unfolding model ($\alpha_i = 8$).

there is a likelihood ratio test for the comparison of GGUMs of increasing complexity. The simplest GGUM is the model for which $\alpha_1 = \dots = \alpha_j$ and $\lambda_{1c} = \dots = \lambda_{jc}$ for $c = 0, \dots, (K-1)/2$. In the most complex GGUM, none of the parameters are restricted. Second, a diagnostic has been proposed to roughly investigate the adequacy of Eq. (5). If individuals are grouped using the expected *a posteriori* estimates of their locations, then, for each item, the observed and expected item responses can be compared for each group.

Nonparametric and Monotone-Nonmonotone Models

The focus of this entry is on parametric models for nonmonotone items. The interested reader is referred to the work of van Schuur and Post to learn about nonparametric models for nonmonotone items. These models use nonparametric assumptions about the response process to order items (and individuals) along the latent trait. The most important assumption is that the item characteristic curves are single-peaked.

Baarsen, van Duijn, Klinkenberg, and Post have evaluated the performance of item response models for nonmonotone items in practical applications. They concluded that it is not always clear whether models assuming nonmonotone items or models assuming monotonically increasing and decreasing items were most appropriate for the data at hand. Note that the latter can be translated into dominance relation-based item response models via a reversion of the responses to the items with monotonically decreasing item characteristic curves. The interested reader is referred to Gunther Maris's 1991 dissertation, in which the first model able to handle both nonmonotone and monotonically increasing and decreasing items is proposed.

Item Response Theory

Wim J. van der Linden

University of Twente, Enschede, The Netherlands

Glossary

ability parameter Generic name for the parameter in a response model that represents the person's ability, skill, personality trait, or any other human property measured by the item.

computerized adaptive testing A mode of testing based on sequential item selection in which the person's ability estimate is updated after each item and the next item is selected to be optimal at the last update.

dichotomous response models Response models for items with dichotomously scored responses, such as correct-incorrect, true-false, and agree-disagree items.

information function Fisher's measure for the information on an ability parameter in an item or test score.

item parameters The parameters in a response model that represent such properties of the item as its difficulty, discriminating power, and probability of a correct response when guessing randomly.

monotone items Dichotomously scored items with a monotonically increasing response function for the correct response.

multidimensional response models Response models with a vector-valued ability parameter.

nonmonotone items Dichotomously scored items with a singly peaked response function for the agree response.

optimal test assembly The use of techniques from mathematical programming to assemble a test from a calibrated pool that is optimal with respect to an objective function and meets a potentially large set of constraints representing the content specifications of the test.

polytomous response models Response models for items with polytomously scored responses, such as nominal response, graded response, rating, and partial credit items.

response function The probability of a response as a function of the ability parameter.

Item response theory (IRT) consists of probabilistic models for responses of individuals to test items,

procedures for the statistical treatment of the models, and principles that can be used in their application. The models are probabilistic in that they specify a probability distribution over the set of possible responses. The mathematical function used for describing a response probability as a function of the parameter for the person's property measured by the test, such as an ability, skill, attitude, or personality trait, is known as a response function. If the responses are scored as correct-incorrect, we usually present the model as a response function for the correct response. In addition to the person's property, IRT models have parameters for such item properties as its difficulty, discriminating power, and the probability of a correct response when the person guesses randomly. In more complex models, we can also have parameters representing the different conditions under which the individuals respond to the items, properties of possible raters who evaluate the responses, more specific mental operations needed to solve the item, or the speed at which a person responds. As a rule, any factor with a systematic impact on the probability of a response should be represented by a parameter in the model.

History

Although item response theory (IRT) has its roots in a few papers published in the 1940s, the original idea of a response model can be traced back to the method of absolute scaling developed by Thurstone in the mid 1920s. Thurstone's method is based on the assumption of a latent scale underlying the responses on which both the items and individuals can be mapped. No doubt his idea of a scale was inspired by earlier developments in psychophysics, in which probabilities of psychological responses to physical stimuli are modeled as a function of the strength of the stimulus. An example of a psychophysical response function is one that represents the probability

of detecting a tone of a certain frequency as a function of its loudness. The unique twist by Thurstone was that, although these psychophysical functions were defined on a measurable physical variable, the response functions in his model were defined on a hypothetical, unmeasured variable. For this reason, Thurstone's model can be considered as one of the first models of a kind now generally known as latent variable models.

The idea of a response function was picked up again by authors such as Ferguson, Lawley, and Mosier in the 1940s. Their papers were somewhat confusing for two reasons. First, some of them struggled with the latent nature of the person parameter and modeled the response function as a regression function of the item score on the observed test scores instead of this parameter. Second, Thurstone's method of absolute scaling did not distinguish clearly between a normal-ogive response function defined over replicated item administrations and a normal distribution function for the sampling of a person from a population. As a result, it took later authors some time to entangle these two notions.

The first to present a coherent treatment of a response model for dichotomous items that did not suffer from these problems was Lord in 1950. His model had a normal-ogive response function. Birnbaum replaced Lord's model by a logistic model in the late 1960s. Statistical procedures for his model were introduced in the 1970s to 1980s, and the model obtained its current position as the main instrument in the test specialists' tool kit in the 1990s.

IRT has been developed in interaction with two other statistical areas of response modeling. The first is the area of bioassay with its models for data on the biological responses of organisms exposed to varying doses of a chemical substance. Although IRT and bioassay models have the same structure of a regression function for a response on a variable, the critical difference between them is the latent nature of the variable in the former and a known experimental dose in the latter. The second area is latent-structure analysis, developed by Lazarsfeld. Although the major portion of latent-structure analysis has been devoted to models with individuals classified in a finite number of latent classes, this area has also produced models with continuous responses functions. The most important contributions of latent-structure analysis to IRT have been conceptual, however. It introduced the essential distinction between manifest (= observed) qualitative data and latent (= unobservable) quantitative parameters or variables, and convinced test theorists that the two quantities can only be related by a probabilistic model.

Review of Response Models

It is hard to give a comprehensive review of the current types of response models. In all, some 30–40 models are

available in the literature for which sound statistical procedures have been developed. The models reviewed in this section are examples of the more popular models for items with dichotomous and polytomous response formats, multidimensional abilities, and nonmonotone items. In addition, we review nonparametric approaches to response probabilities on items with a dichotomous and polytomous format. We thus skip cognitive-component models, which specify success probabilities at the level of the individual cognitive operations needed to solve an item and use probability calculus to model the entire solution process. Also omitted are models for response times on items. These models typically have separate parameters for the time required by the item and the speed at which the individual works, and they have become increasingly important due to computerization of testing. Other models not reviewed are models for items with continuous response formats, models with multilevel parameter structures to deal with sampling of individuals from subpopulations defined by differences on background variables or with sampling of items from families sharing important structural characteristics, as well as several models developed to deal with more specific applications.

Dichotomous Models

Lord's model for dichotomous items was based on the choice of the normal distribution function as response function. Let U_i denote the response to item i , where $U_i = 1$ if the response is correct and $U_i = 0$ if it is incorrect. The response function for the correct response is:

$$p_i(\theta) = \Pr\{U_i = 1\} = \int_{-\infty}^{a_i(\theta - b_i)} \frac{1}{\sqrt{2\pi}} \exp^{-z^2/2} dz \quad (1)$$

where $\theta \in (-\infty, \infty)$ is the ability parameter, $b_i \in (-\infty, \infty)$ the item-difficulty parameter, and $a_i \in [0, \infty)$ the item-discrimination parameter.

The model soon became unpopular for the following two reasons. First, it did not allow for guessing on multiple-choice items and could therefore not be used for high-stakes testing programs in which testees always guess if they do not know the answer. Second, the use of the normal distribution function in Eq. (1) led to computationally intensive procedures for parameter estimation, and the computer power needed to estimate the model parameters on a routine basis simply was not yet available at the time. (In an ironic twist of history, the normal distribution function has recently regained its popularity, just for computational reasons.)

An important impetus to the popularity of IRT was Birnbaum's suggestion in 1968 to replace the two-parameter normal ogive (2PNO) model in Eq. (1) by a logistic model with an additional guessing parameters.

Birnbaum's three-parameter logistic (3PL) model has the following response function:

$$p_i(\theta) = c_i + (1 - c_i)\Psi(\theta; a_i, b_i) \quad (2)$$

where

$$\Psi(\theta; a_i, b_i) = \frac{\exp(a_i(\theta - b_i))}{1 + \exp(a_i(\theta - b_i))} \quad (3)$$

is the logistic distribution function.

Parameter $c_i \in [0, 1]$ represents a lower asymptote for the probability of a correct response, which is approached for $\theta \rightarrow -\infty$. It is easy to show that the structure of this model is the result of a knowledge-or-random-guessing assumption; the structure in Eq. (2) reflects the assumption that the person knows the correct answer with a probability given by the logistic part of the model equation in (3) or does not know it and guesses with a probability equal to c_i . Parameter b_i can be interpreted as the difficulty parameter of item i because it represents the location of the distribution function in Eq. (3) on the θ scale; more difficult items are located more to the right and require a higher level of ability for the same probability of success. Parameter a_i is proportional to the slope of the logistic function in Eq. (3) at $\theta = b_i$ and can be interpreted as the discrimination parameter of item i . A larger value for this parameter means a steeper slope for the response function and, hence, an item that discriminates better between the success probabilities for individuals with ability levels just to the left and right of $\theta = b_i$.

Because of its parameter structure, the 3PL model is flexible and has been shown to fit large pools of items written for the same content domain in educational and psychological testing. In fact, it has become the standard of the testing industry for tests with dichotomous items that are neither multidimensional nor nonmonotone.

The models in Eqs. (1) and (2)–(3) are not yet identified. We can easily change the unit or origin of the scale of the parameters θ , a_i , or b_i and compensate for this by a change in the scales of the other parameters. In practice, we remove this indeterminacy by fixing the scale of θ to a convenient unit and origin. All later models discussed in this entry need a comparable kind of fixing to become identifiable.

Polytomous Models

Responses to an item with a polytomous format can be denoted by a response variable U_i with possible variables $h = 1, \dots, m_i > 2$. The dependency of m_i on i indicates that different items in the test may have different numbers of possible responses. To choose an appropriate polytomous model, the structure of the responses should be charted more precisely. In particular, we should

distinguish between a format with responses that can only be classified and one with an *a priori* order of the responses. The former is known as a nominal response format, the latter as a graded response format.

Nominal Response Model

The nominal response model specifies the response function for $U_i = h$ as:

$$p_{ih}(\theta) = \Pr\{U_i = h\} = \frac{\exp(a_{ih}(\theta - b_{ih}))}{\sum_{h=1}^{m_i} \exp(a_{ih}(\theta - b_{ih}))} \quad (4)$$

The function for response $U_i = h$ has parameters a_{ih} and b_{ih} . These parameters keep their interpretation as discrimination and difficulty parameters. The difficulty parameter represents the location of the response function on the θ scale (i.e., the point at which it shows its largest change in curvature), whereas the discrimination parameter a_{ih} is proportional to this change.

Although the responses are not ordered *a priori*, the estimates of the parameter b_{ih} do show an empirical order. That is, the response data always indicate that some responses are more typical of lower ability values and others of higher values. Graphically, the model can be displayed as a set of response functions with a function for the “lowest” response that is monotonically decreasing with θ , a function for the “highest” response that is monotonically increasing with θ , and functions for the remaining responses that have a single peak.

The model in Eq. (4) does not allow explicitly for guessing. If guessing occurs, the response functions should be taken to represent a mixture of the probabilities of “knowing the response” and “not knowing any response but guessing the current one.” A version of the nominal response model with explicit mixing parameters is available, however.

Graded Response Model

If the responses are ordered *a priori*, a different type of modeling becomes necessary. Suppose the values of index h reflect the order of the responses. We consider the probabilities of the compound events $U_i \geq h$ as a function of the ability parameter, θ , and define:

$$P_{ih}(\theta) = \begin{cases} \Pr\{U_i \geq h | \theta\} & \text{for } h = 1, \dots, m \\ 0 & \text{for } h > m \end{cases} \quad (5)$$

Observe that $P_{ih}(\theta) = 1$ for $h = 1$. Obviously, for $h = 2, \dots, m$ these functions increase monotonically with θ ; for any of these values, the probability of responding with h or a higher response goes to 1 if $\theta \rightarrow \infty$.

It follows that the response function for response h can be written as:

$$p_{ih}(\theta) = P_{ih}(\theta) - P_{i(h+1)}(\theta) \quad (6)$$

A convenient choice for the functions $P_{ih}(\theta)$ in Eq. (6) is the logistic function in Eq. (3) for $h = 2, \dots, m$. More stringent versions of the logistic function are obtained if we set $a_i = 1$ for all i . This case is known as the homogeneous case of the graded response model in Eq. (6).

Partial Credit Models

Polytomous model for ordered responses that have gained considerable popularity because of their statistical tractability are the partial credit models. These model are appropriate for the case in which increasing credit is given to the responses $h = 1, \dots, m_i$. The first version of the partial credit model was based on the assumption that the probability of response h relative to adjacent response $h - 1$ can be represented by the version of the logistic function in Eq. (3) with $a_i = 1$. After some probability calculus, this assumption can be shown to lead to the following response functions:

$$p_{ih}(\theta) = \frac{\exp\left(\sum_{k=1}^h (\theta - b_{ik})\right)}{\sum_{h=1}^{m_i} \exp\left(\sum_{k=1}^h (\theta - b_{ik})\right)} \quad (7)$$

A generalized version of the model exists in which the parameter structure in Eq. (7) is extended with discrimination parameters a_{ik} .

Alternatively, suppose that the number of possible responses for each item is a common constant, m . If we constrain the parameters b_{ih} for the responses in this model to $b_{ih} = b_h$ for all i , with $\{b_1, \dots, b_m\}$ being a set of equidistant numbers, the model becomes appropriate for analyzing responses to a set of rating scales of the Likert type. The equidistant numbers b_1, \dots, b_m are the parameters for the fixed number of categories that the person can check on such scales.

Multidimensional Models

The need for a multidimensional response model arises if the items appear to be sensitive to more than one ability. For some areas of testing, this happens out of necessity. For example, if we test a nonverbal ability (e.g., a mathematical ability), it may nonetheless be necessary to use items with a considerable verbal component. If so, the items may become sensitive to a verbal ability too. But testing for multidimensional abilities can also be intentional. Now that the statistical methods for dealing with such items have matured, it becomes more efficient to measure multiple abilities by a single multidimensional test instead of multiple unidimensional tests.

If the items are multidimensional, we need to adjust the unidimensional model that otherwise would have been appropriate for their response format and by including more than one ability parameter. If our choice is the

3PL model in Eq. (2), an obvious generalization of this model to the case of two ability parameters, θ_1 and θ_2 , is:

$$p_i(\theta_1, \theta_2) = c_i + (1 - c_i) \frac{e^{a_{i1}\theta_1 + a_{i2}\theta_2 - b_i}}{1 + e^{a_{i1}\theta_1 + a_{i2}\theta_2 - b_i}} \quad (8)$$

This model defines the probability of a correct response as function of (θ_1, θ_2) . It is customary to refer to a multidimensional response function as a response surface. The model in Eq. (8) has two discrimination parameters, a_{i1} and a_{i2} , which control the slope of the response surface along θ_1 and θ_2 , respectively. But it has only one generalized difficulty parameter b_i ; a parameter structure with two parameters $b_{i1} - b_{i2}$ would have lead to a nonidentifiable version of the model. If $\theta_1, \theta_2 \rightarrow \infty$, the probability of a correct response goes to c_i .

The generalization of the model to an ability space with more than two dimensions is straightforward. But in practice, for a professionally constructed test, unless it consists of different sections with items written to entirely different specifications, we seldom need more than two or three ability parameters to obtain a fitting model.

Models for Nonmonotone Items

An item is called monotone if the response function for its correct response is monotonically increasing with the ability measured by the items. Monotone items are usually found in "power tests," such as achievement tests.

Items in an attitude scale cannot be expected to be monotone. Such items typically consist of statements that the person is asked to endorse or not to endorse. It is not uncommon to meet statements with a low probability of endorsement by individuals with an opposite attitude. For such nonmonotone items, a response function with a single peak is more appropriate.

Instead of an algorithmic approach to scoring tests with nonmonotone items, using what is known as an unfolding algorithm, an approach based on probabilistic modeling and parameter estimation, can be followed. An example of a model appropriate for nonmonotone items is the hyperbolic cosine model.

Let $U_i = 1$ denote an agree response to the item and $U_i = 0$ denote a disagree response. The model can be represented by the following function for the agree response:

$$p_i(\theta) = \frac{\exp(\lambda_i)}{\exp(\lambda_i) + 2 \cosh(\theta - b_i)}, \quad (9)$$

where $\cosh(\cdot)$ is the hyperbolic cosine function, parameter b_i represents the location of the agree response for item i , and λ_i is the common distance from b_i to the locations of the two disagree responses at the opposite ends of the scale.

The model seems to differ from all previous models in that it has an expression with a hyperbolic cosine function that is not exponential. But this conclusion is wrong—this part of the model is the result of an assumption of an underlying structure with two opposite latent disagree responses that do have an exponential type of response function.

Nonparametric Approaches

Nonparametric approaches in IRT avoid the parametric families of response functions assumed in the preceding sections. Instead, they depart from ordinal assumptions on the response functions.

As an alternative to the dichotomous models, a nonparametric approach assumes probabilities p_{ij} for a correct response by a person $j = 1, \dots, J$ to an item $i = 1, \dots, n$ that are constrained by monotonicity conditions. Weaker and stronger assumptions of monotonicity are possible.

The assumption of monotonic homogeneity stipulates that the individuals $j = 1, \dots, J$ be ordered by each item; that is, for every possible $j, j' = 1, \dots, J$, it holds that

$$p_{ij} < p_{ij'} \quad \text{if} \quad j <_i j'. \quad (10)$$

A stronger assumption requires the individuals to be ordered similarly by the probabilities for each item; that is, for every j it holds that

$$\begin{aligned} &\text{if} \quad p_{ij} < p_{ij'} \quad \text{for any } i = 1, \dots, n, \\ &\text{then} \quad p_{ij} < p_{ij'} \quad \text{for all } i \end{aligned} \quad (11)$$

The assumption in (10) is necessary for each item to be monotone according to our definition. The assumption in (11) is necessary for a unidimensional representation of the probabilities, that is, for the constraint $p_{ij} = p_i(\theta_j)$ to hold for the same scalar θ for all person-item combinations.

The set of assumptions becomes stronger still if we also require all items to be ordered similarly by the probabilities for each person. This assumption, which is known both as the assumption of double monotonicity and monotonic homogeneity, stipulates that for every pair items $i, i' = 1, \dots, n$ it hold that

$$\begin{aligned} &\text{if} \quad p_{ij} < p_{i'j} \quad \text{for any } j = 1, \dots, J, \\ &\text{then} \quad p_{ij} < p_{i'j} \quad \text{for all } j \end{aligned} \quad (12)$$

This assumption is necessary for a representation of the probabilities by response functions that do not intersect.

A nonparametric approach to items with a polytomous format also exists. This approach is based on the reduction of the polytomous format to sets of dichotomous variables:

$$U_{ijh} = \begin{cases} 1 & \text{if } U_{ij} \geq h \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

for the responses $h = 1, \dots, m$ to item i by person j . The sum of these variables over all responses for an item is the person's actual score h on it.

Let

$$p_{ijh} = \Pr\{U_{ijh} = 1\} \quad (14)$$

For these probabilities, the same monotonicity assumptions can be made as in Eq. (10)–(12) for the dichotomous case. These assumptions hold trivially for the probabilities for the same item, but do constrain the relations between the probabilities for different items.

Statistical procedures for checking these monotonicity assumptions have been developed. These allow us to see if an entire tests admits a unidimensional representation. If it does not, these procedures help us to identify the items and individuals that do not fit the assumptions. Nonparametric IRT is less appropriate for dealing with problems that involve missing data, however. We discuss test-item banking, optimal test assembly, and adaptive testing as examples of such problems in a later section.

Discussion

Several generalizations of the models in the preceding sections exist. Some of these models, for example, the partial credit model in Eq. (7), specify a family of response distributions that belong to the exponential family in statistics. The recognition of this relation helps us to profit from the body of statistical procedures valid for this family.

The graded response model is based on the definition of the probabilities for the compound events in Eq. (5). It is interesting to note that the nonparametric polytomous approach in the preceding section is based on the same type of probabilities in Eq. (14). Models of this type are more generally known as cumulative models in ordinal categorical data analysis. On the other hand, the partial credit model in Eq. (7) is based on the assumption of a logistic model for the pairs of dichotomous events $\{U_{ij} = h, U_{ij} = h - 1\}$. Models of this type are known as adjacent category models. It is also possible to model the events $\{U_{ij} = h \mid U_{ij} \leq h - 1\}$. Models of this type are known as continuation ratio or sequential response models.

Statistical Treatment of Models

The statistical treatment of IRT models usually consists of two stages: item calibration and measurement. During the stage of item calibration, the item parameters are estimated from response data and the validity of the model for the data is checked. If the model is used as a measurement model, the item parameters are treated as known and the

value of the ability parameter for a person is estimated from his or her vector of responses to the items in the test. In this section, we briefly outline these activities for the case of the 3PL model in Eqs. (2)–(3).

Parameter Estimation

If a test of n items is administered to individuals $j = 1, \dots, J$, we can collect the responses for each person in a vector $\mathbf{u}_j = (u_{j1}, \dots, u_{jn})$. Let $\mathbf{a} = (a_1, \dots, a_n)$, $\mathbf{b} = (b_1, \dots, b_n)$, and $\mathbf{c} = (c_1, \dots, c_n)$ be vectors with the item parameters, and $\boldsymbol{\theta} = (\theta_1, \dots, \theta_J)$ the vector with the ability parameters for the individuals. The likelihood function for all parameters associated with the response vectors $(\mathbf{u}_1, \dots, \mathbf{u}_J)$ is:

$$L(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c}; \mathbf{u}_1, \dots, \mathbf{u}_J) = \prod_{j=1}^J \prod_{i=1}^n p_i(1; \theta_j, a_i, b_i, c_i)^{u_{ji}} \times p_i(0; \theta_j, a_i, b_i, c_i)^{1-u_{ji}} \quad (15)$$

Suppose we have a prior distribution with density function $f(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c})$ for these parameters. All parameters in this distribution can be taken to be independent, with the exception of the parameters for the same item. The posterior distribution of all parameters is given by:

$$f(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c} | \mathbf{u}_1, \dots, \mathbf{u}_J) \propto L(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c}; \mathbf{u}_1, \dots, \mathbf{u}_J) \times f(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c}) \quad (16)$$

To obtain maximum likelihood (ML) estimates for the parameters, we have to find values for them at which the likelihood function reaches its maximum. In Bayesian estimation, we estimate the parameters by their joint posterior distribution or by a measure of its central tendency, such as the mode. If the prior distribution is uniform, ML and Bayes modal estimates are equal.

The estimation based on the joint likelihood in Eq. (15) is known as joint maximum likelihood (JML) estimation. Unfortunately, in item calibration the interest is in the item parameters, whereas the ability parameters behave as incidental parameters. Under this condition, the estimators of the item parameters are inconsistent. A standard way of getting rid of incidental ability parameters in item calibration is to assume that their values have been drawn from a common ability distribution, integrate the parameters out of the joint likelihood, and estimate their values from the remaining marginal likelihood function. This method, which results in the following likelihood function,

$$L(\mathbf{a}, \mathbf{b}, \mathbf{c}; \mathbf{u}_1, \dots, \mathbf{u}_J) = \prod_{j=1}^J \int \prod_{i=1}^n p_i(1; \theta_j, a_i, b_i, c_i)^{u_{ji}} \times p_i(0; \theta_j, a_i, b_i, c_i)^{1-u_{ji}} d\varphi(\theta_j) \quad (17)$$

with $\varphi(\theta)$ the density function for the ability distribution in the population, is known as the method of marginal likelihood (MML) estimation.

In a Bayesian approach, we would integrate the ability parameters out of the joint posterior distribution in Eq. (16) and use the marginal posterior distribution:

$$f(\mathbf{a}, \mathbf{b}, \mathbf{c} | \mathbf{u}_1, \dots, \mathbf{u}_J) \propto \int L(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c}; \mathbf{u}_1, \dots, \mathbf{u}_J) \times f(\boldsymbol{\theta}, \mathbf{a}, \mathbf{b}, \mathbf{c}) d\boldsymbol{\theta} \quad (18)$$

MML estimates of the item parameters as well as the mode of the marginal posterior distribution in Eq. (18) can be found using the well-known expectation-maximization (EM) algorithm.

For models with response distributions that belong to the exponential family, sufficient statistics for the ability parameters exist. We can get rid of the ability parameters in these models by conditioning the likelihood on these statistics. This method of conditional maximum likelihood (CML) has been popular for the Rasch model—that is, the logistic model in Eq. (3) with $a_i = 1$ for all items, as well as for the partial credit model in Eq. (7).

If the items have been calibrated and the model is used as a measurement model, it is customary to treat the estimates of the item parameters as their true values. We then estimate θ for person j from the likelihood function of this parameter for a vector of responses $\mathbf{u}_j = (u_{j1}, \dots, u_{jn})$ on the test. The likelihood function is

$$L(\theta_j | u_{j1}, \dots, u_{jn}) = \prod_{i=1}^n p_i(1; \theta_j)^{u_{ji}} p_i(0; \theta_j)^{1-u_{ji}} \quad (19)$$

Alternatively, in a Bayesian approach, we can estimate θ_j by the (mode or mean of) its posterior distribution, which is calculated as:

$$f(\theta_j | u_{j1}, \dots, u_{jn}) \propto L(\theta_j | u_{j1}, \dots, u_{jn}) f(\theta_j) \quad (20)$$

where $f(\theta_j)$ is the density function of the prior distribution for θ_j .

Model Validation

When the validity of a model for the response data is checked, we assess the fit of the model to the items and the individuals. If misfitting items or individuals are detected, we try to find an explanation and improve the fit. For example, it may be necessary to reformulate

some of the items, move to a multidimensional model, break up the set of items into subsets with different abilities, or change the instructions of the test. But if the items have been well written, in most cases we have to remove no more than an occasional item to get a satisfactory fit of the model.

IRT has had a relatively long tradition of evaluating the fit of the 3PL model using informative but rather informal statistical procedures. One of these procedures was to group the individuals in the sample into ranges of ability estimates and calculate Pearson's chi-square statistic on the differences between the proportions of correct responses and the average response probabilities for these groups predicted by the model. Another informal procedure was to inspect visually the residual responses after fitting the response probabilities to a response vector for a person or an item.

More recently, statistically correct goodness-of-fit tests for the 3PL model have become available. These tests are more diagnostic in that they are sensitive to specific assumptions underlying the model, such as on the unidimensionality of θ , monotonicity of the response functions, or local independence between responses. The recent arrival in IRT of Bayesian procedure for model checking has further enlarged our repertory of procedures for diagnosing item and person fit.

Applications

IRT can be used for solving any problem for which classical test theory offers a solution. In addition, IRT has special advantages when solving problems that involve scaling or have missing data. The following sections illustrate the IRT approach to some of these problems.

Variable Construction

A traditional social science approach to establishing a new variable is to define a theoretical construct, write a set of items for measuring it, and define a total score on the item responses. However, deeper insight is gained if we fit an IRT model and study the location of the items on the scale.

A graphical technique for doing so is item mapping. In this technique, we identify a sample of items critical of the definition of the variable, calibrate them, and mark their location on the scale by labels with a brief content description. It is possible to use the value of the difficulty parameter for locating an item on the scale, but a fixed probability of a correct response indicating a higher level of mastery of item content (0.80, say) may be more meaningful. Item maps help us to illustrate how the empirical content of a variable develops with an increase in its numerical values.

We can also place individuals on the scale using their ability score, or parameters of certain distributions, such as average abilities for subpopulations of individuals after a certain program or with a certain symptom. The same can be done, for example, with minimal levels of ability required to be admitted to a program.

The idea of item mapping originated with Thurstone, who applied the technique to his method of absolute scaling in the mid-1920s to give a behavioral interpretation to the scale of an intelligence test in use at the time.

Item Banking

Traditionally, test construction went through a cycle in which a set of items was written that represented the variable best. The set was typically somewhat larger than needed to allow for some items to fail an empirical pretest. The set was then pretested and the item statistics were analyzed. The final step was to put the test together using the item statistics. If a new test was needed, the same cycle of item writing, pretesting, and item analysis was repeated.

In item banking, items are written, pretested, and calibrated on a continuous basis. Items that pass the quality criteria are added to a pool of items from which new tests are assembled when needed. The advantage of item banking is not only a more efficient use of the resources, but also tests of higher quality assembled from a larger stock of pretested items, less vulnerability to the consequences of possible item security breaches, and stable scales defined by larger pools of items.

In item banking, problems of item calibration and person scoring are always subject to large numbers of missing data, due to the fact that no person responds to all items in the pool. IRT deals with these problems in a natural way. If new items are calibrated, a few existing items from the pool are added to the tests and their known item parameter values are used to link the new items to the scale already established for the pool. Likewise, if a person is tested, any set of items from the pool can be used as a test. When estimating the person's score, the estimation equation has known values for the item parameters and automatically accounts for the properties of the items. Consequently, in more statistical terms, differences in item selection do not create any (asymptotic) bias in the ability estimates.

Optimal Test Assembly

Although item selection does not create any bias in the ability estimates, it does have an impact on their accuracy. For example, if a test is too difficult, it is hardly possible to discriminate between the ability levels of less able individuals.

An obvious measure of the inaccuracy of an estimator of θ is the variance of its sampling distribution, $\text{Var}(\hat{\theta}|\theta)$. But instead of this variance, we often use Fisher's information measure, which for a dichotomous item is equal to

$$I_i(\theta) = \frac{(p'_i(\theta))^2}{p_i(\theta)[1-p_i(\theta)]} \quad (21)$$

where $p'_i(\theta)$ being the first derivative of $p_i(\theta)$ with respect to θ . In IRT, this measure is treated as a function of θ ; it is therefore known as the item information function. If $p_i(\theta)$ is the response function of the 3PL model in Eqs. (2)–(3), the item information function can be written as

$$I_i(\theta) = \frac{a_i^2[1-p_i(\theta)]}{p_i(\theta)} \left(\frac{p_i(\theta) - c_i}{1 - c_i} \right)^2 \quad (22)$$

A fortunate property of information functions is their additivity due to conditional independence between item responses. Hence, for the test information function, $I(\theta)$, it holds that:

$$I(\theta) = \sum_{i=1}^n I_i(\theta) \quad (23)$$

Another well-known property of the test information function is that if $\hat{\theta}$ is an ML estimator, it holds (asymptotically) that:

$$I(\theta) = \frac{1}{\text{Var}(\hat{\theta}|\theta)} \quad (24)$$

The two properties explain why we generally prefer using $I(\theta)$ over $\text{Var}(\hat{\theta}|\theta)$ —both are a measure of the accuracy of the ability estimator, but $I(\theta)$ is additive in the items.

Optimal test assembly in IRT is based on the idea of a target for the test information function chosen to represent the goal of the test, for example, a uniform target over a certain ability range if the test has to be diagnostic or a peaked function at the cut-off score in a decision problem. Because of the additivity in Eq. (23), the optimization problem involved in matching a target for the test information function is linear in the items.

Let $i = 1, \dots, I$ be the items in the pool. We use 0-1 decision variables x_i to indicate whether ($x_i = 1$) or not ($x_i = 0$) item i is selected in the test. If $T(\theta_k)$ is the value of the target function at a set of well-chosen points θ_k , $k = 1, \dots, K$, the optimization problem for selecting a test of n item can be formulated as

$$\text{minimize } \sum_{k=1}^K \sum_{i=1}^I I_i(\theta_k) x_i \quad (25)$$

subject to

$$\sum_{i=1}^I I_i(\theta_k) x_i \geq T(\theta_k) \quad \text{for } k = 1, \dots, K \quad (26)$$

$$\sum_{i=1}^n x_i = n \quad (27)$$

$$x_i \in \{0, 1\} \quad \text{for } i = 1, \dots, I \quad (28)$$

The objective function in Eq. (25) minimizes the sum of the test information function values at the points θ_k , whereas Eq. (26) requires these values to be larger than the target values $T(\theta_k)$. The constraint in Eq. (27) sets the length of the test equal to n .

The problem in (25)–(28) is an example of a linear integer programming problem and can easily be solved using standard commercial software for such problems. It is an example of a problem from an area known as optimal test assembly, which addresses test assembly problems with various objective functions and sets of constraint that model the specifications for the test.

Computerized Adaptive Testing

In computerized adaptive testing (CAT), the items in the test are selected sequentially from a pool of calibrated items while the person takes the test. After the response to an item in the test, the person's ability estimate, $\hat{\theta}$, is updated. The next item is selected to be optimal at the last estimate. During the test $\hat{\theta}$ converges to θ , and consequently the composition of the test moves to the ideal of items with maximum information at θ .

The most popular criterion of item selection in CAT is the maximum-information criterion. This criterion selects the item with the maximum value for its information function at the last estimate, that is, for which $I_i(\hat{\theta})$ is maximal. Bayesian item selection criteria have also been developed. One of the best-known Bayesian criteria is based on the principle of posterior prediction. This criterion selects as the next item the one with the largest predicted reduction of the posterior variance of θ in the pool.

The idea of adaptive testing was already well developed during the early days of IRT. But we had to wait for the first applications until computers became powerful enough for real-time ability estimation and item selection. The first large-scale testing programs introduced the adaptive format for their tests in the 1990s, and many programs have followed since then.

Current Developments

IRT is still being extended with new types of models and procedures. Particularly fruitful areas of expansion are

those leading toward the integration of IRT with multi-level modeling, covariance structure analysis, and cognitive modeling.

This expansion results in models that are far more complex than our current models and, in principle, more difficult to treat statistically. However, these new models appear to lend themselves naturally to the application of Bayesian parameter estimation and model validation using Monte Carlo Markov chain (MCMC) sampling from the posterior distributions of their parameters. Unlike the early history of IRT, the introduction of these new models can be therefore immediately followed by empirical applications that highlight their features.

Jevons, William Stanley

Harro Maas

University of Amsterdam, Amsterdam, The Netherlands

Glossary

a priori method A combination of inductive and deductive inquiry proposed and defended by John Stuart Mill. Mill considered the method of special relevance for political economy. The method basically combined introspection with the deduction of tendency laws.

alii exterendum Literally: to be threshed out by others. Motto of the Statistical Society of London, which expressed its research restriction to data-gathering only, preferably in tabular form. It meant to exclude politics and opinion from its research, in favor of “objective” numerical information.

analogical reasoning Using analogies with known phenomena on the basis of alleged similarities in properties or relationships to explain the unknown.

complexity An event is complex if it is the result of multiple causes. Jevons assumed that by taking averages, erratic causes cancel out, leaving a simple causal relationship.

distinction of mind and matter A widely held distinction in Victorian England, which legitimated different modes of inquiry for the natural and mental (moral) sciences.

disturbing causes Causes that interfere with tendency laws.

index number A (weighted) ratio comparing the values of one or a basket of items to a base value of these items.

introspection A mode of inquiry reserved for the mental sciences in which the truth of the first principles is established by a reasoned inquiry of one’s own mind.

inverse deductive method Making inferences from data to simple general laws by framing hypotheses.

method of graphs In the course of the 19th century, graphs came to be seen as important aids in uncovering (causal) explanations in functional form. The use of graphs with this purpose is referred to as the graphical method or the method of graphs.

method of means A mode of correcting for errors in measurement by averaging.

tendency laws The notion of tendency laws was widely held among 19th century political economists. It signified laws that were true irrespective of disturbing causes that obfuscated their observation in practice.

The Victorian polymath William Stanley Jevons (1835–1882) revolutionized measurement practices in political economy and statistics. Rather than treating political economy and statistics as separate disciplines, Jevons integrated both. Using his training in and knowledge of the natural sciences, especially chemistry and meteorology, Jevons made functional form relevant to economic theory and numbers relevant to empirical evidence. The general statement of his scientific method is found in *The Principles of Science* (1874), the structure of which is heavily dependent on his formal logical system. From Jevons’ time onward, it became increasingly acceptable to think of economics as a natural science in all ways.

Introduction

William Stanley Jevons (1835–1882) is widely acknowledged as one of the Victorian political economists who greatly contributed to the transformation of political economy on a theoretical and empirical plane. This article concentrates on Jevons’ innovative measurement strategies in economics, although it will be seen that these cannot be separated from his approach to theory. Jevons’ measurement strategies stemmed to a large extent from then-current research strategies in the natural sciences (most notably astronomy and meteorology). They transgressed the then-prevailing distinction between the deductive approach of political economists and the inductive approach of what then went for statistics. Jevons revolutionized measurement in economics on the assumption that the universe, the natural and the social, was governed by mechanical laws; mechanical analogies were of major importance in Jevons’ work. Jevons summarized his strategies of measurement in *The Principles*

of *Science* (1874), as he had practiced them in his major statistical studies in the 1860s.

After a short introduction to Jevons' life and work, this article lays out Jevons' general views on measurement in the (social) sciences in relation to the prevailing and institutionalized opinions on economic methodology. It also examines how Jevons put his views into practice in his empirical studies in economics.

Jevons' Life and Work

William Stanley Jevons was born into a well-to-do middle-class family of iron traders in Liverpool in 1835. His father, Thomas Jevons, was a man of some ability with Utilitarian sympathies, who is said to have invented the first floating iron ship. Jevons' mother, Mary-Ann Roscoe, was the daughter of William Roscoe, an important Liverpool banker and art connoisseur, who rediscovered and ardently collected neglected Italian and Flemish masters.

The Jevons and Roscoe families were Unitarians. Closely related to the Huttons and the Martineaus, among others, they constituted part of the intellectual Unitarian circles in Lancashire who were important in promoting the natural sciences. Middle-class Unitarians greatly contributed to the establishment of Mechanics' Institutes designed for the education of the higher working class in the principles of the natural sciences and in the formation of the various literary, philosophical, and statistical societies. The advancement of society was the goal, the progress of science the means.

It was therefore not surprising that education, especially in the natural sciences, was considered of utmost importance by Jevons' parents, though he also became well acquainted with various aspects of culture, especially music, via his mother. When Jevons was 11 years old, he attended Liverpool Mechanics' Institute High School and then, after an interlude of 2 years at a grammar school, he was sent first to University College London School, to enter the College 1 year later, in 1851. For Unitarians and other dissenters from the Anglican Church, University College, London, was one of the few possibilities for receiving a higher education.

Jevons progressed well at the college, especially in chemistry and experimental philosophy, in which he won gold medals. However, he derived most enjoyment from the teachings of one of the permanent influences of his later life, the first Professor of Mathematics at University College, Augustus De Morgan.

Jevons received his education despite the enormous distress suffered by the family, first by the death of his mother when Jevons was only 10, and then, shortly after, by the bankruptcy of his father's iron-trading business in 1848 in the aftermath of the great railway crisis of 1847. This forced the family to move to Manchester. The

family's financial difficulties were instrumental in Stanley sailing off to Australia in 1854 before having finished his college education, to take up a position as a gold assayer at the newly established mint in Sydney.

His work in Sydney left Jevons with ample spare time to pursue his scientific interests. In this period, Jevons at first turned to meteorological issues. The best overview of Jevons' studies in meteorology is provided by Nicholls. Jevons was the first to systematically collect data on the Australian weather. He also made some ingenious experiments on the formation of clouds that were taken up in later years by Lord Rayleigh in quite a different context—in the study of heat diffusion. Jevons published on these subjects in Australian and English journals for natural philosophy, most notably the *London, Dublin, and Edinburgh Philosophical Journal*. Jevons actively participated in the scientific societies of Sydney as well. When he returned to England in 1859, the editors of the *Sydney Magazine of Science and Art* remarked in its columns that "Australia is about to lose this laborious and unassuming yet most promising natural philosopher."

It is generally held that Jevons' decision to return to England was prompted by a sharp shift in interest to political economy. The railway controversy in New South Wales (on which Jevons commented in the newspapers), his reading of Dionysius Lardner's *Railway Economy* (1850), and a growing interest in Bentham's *felicific calculus* gathered from lectures and secondary sources are all mentioned as more or less important influences on this shift in Jevons' scientific orientation. By 1858, Jevons undisputedly considered the study of the social sciences, most notably political economy, the most "cogent business." Jevons returned to London in 1859 to take up his studies in political economy.

Having returned to University College, London, Jevons worked in a frenzy in a variety of fields. He not only studied the standard Mill–Ricardian theories of political economy, but he embarked on ambitious statistical studies and studies in the emerging field of formal logic as well. His approach to formal logic was in line with that of George Boole rather than Augustus De Morgan. Clearly inspired by Babbage's calculating engines project, Jevons became interested in the construction of a logical machine, showing mechanically the virtues of the new systems of logic. Jevons' studies in formal logic are less known today, though some of them were highly successful in his own days. His *Primer of Logic* (1876) even went through 40 (!) reprints.

Jevons felt a growing uneasiness with the deductive Mill–Ricardian approach to political economy, but his new ideas found a skeptical hearing. His first airing of his new approach to the field, the *Notice of a General Mathematical Theory of Political Economy*, read in his absence in October at Section F of the British Association for the Advancement of Science (BAAS) in 1862, was

“received without a word of interest or belief.” Even worse, the *Philosophical Journal*, which until then had received his studies quite favorably, refused the manuscript for publication. Initially, Jevons also failed to get the statisticians of his day, like William Newmarch, interested in his equally innovative use of diagrams to display economic data. These diagrams were inspired by William Playfair’s *Commercial and Political Atlas* and part of an equally ambitious *Statistical Atlas* project that Jevons never completed.

His study on the influence of the gold discoveries in Australia and California on the value of gold, introducing index numbers in economics, was received much more favorably. One year later, in 1864, Jevons was elected as a member of the Statistical Society of London and could write that he was generally considered a “competent statistician.” His definitive breakthrough as a statistician was *The Coal Question* (1865), examining the consequences of the expected decline of commercially extractable coal on British prosperity. In 1865, Jevons had a part-time professorship in logic, moral philosophy, and political economy at Queens College, Liverpool, which he combined with a tutorship at Owens College, Manchester. *The Coal Question* was certainly instrumental in bringing him the Cobden Chair in logic and political economy at Owens College, a post he exchanged in 1876 for a professorship in political economy at University College, London. He resigned in 1881 in order to devote his time to reading and study, especially to his planned large work on economics.

In 1871, Jevons published his seminal work *The Theory of Political Economy*. Jevons was prompted to a rapid publication because of the publication of Fleeming Jenkin’s graphical representation of supply and demand in 1870. Jevons’ book introduced the calculus in economics and was one of the starting points of so-called neoclassical economic theory. Value came to be based on utility rather than labor. Economic agents, workers, manufacturers, consumers, and landowners were all considered to base their decisions on the same form of deliberation at the margin, in Jevons’ words: on the “final degree of utility.” The generalized notion of maximizing a goal function (utility or profits) under given constraints has come to be widely applied in sociology, political science, and ethics as well. Jevons’ *magnum opus* is *The Principles of Science* (1874), synthesizing much of the Victorian literature on scientific method and showing a thorough knowledge of scientific practice as well. This book has been of considerable influence on early logical positivism, especially on Otto Neurath, and was republished in the 1950s by Ernest Nagel. It was also an important source of inspiration for the statistician Karl Pearson.

The publications dating after the *Theory* and the *Principles* are generally considered to be of minor importance. His sunspot studies of the 1870s, which attempted to establish a causal nexus between solar activity and

commercial crises, though not as absurd as they are sometimes described, are usually thought of as a failure and as having contributed to the bad name associated with the analytical use of statistics at the turn of the 19th century. Jevons worked on an encompassing *Principles of Economics*, the manuscript of which was published by Henry Higgs in 1905. From what can be judged from this unfinished material, the end result would not have been too promising. In the second half of the 1870s, Jevons wrote four vehement articles against John Stuart Mill, which did not have the effect he must have hoped for. Quite to the contrary, they isolated him from political economists such as John Elliot Cairnes, Henry Sidgwick, and Alfred Marshall, who were, in method or content, devoted to Mill’s work. Jevons also worked on a second edition of the *Theory*, containing the first bibliography of all the mathematical precursors in economics whom Jevons had been able to trace. In *The State in Relation to Labour* (1882) and the posthumous collection of essays on social reform (1883), Jevons turned more explicitly to the social and political issues of the day, issues that were never far from his mind. These essays undeniably lack the sharpness and innovative force of his early statistical studies and of his *Theory*. In all its bluntness, there is something to be said for Keynes’ horrifying remark that when Jevons so untimely drowned in 1882, leaving his wife and three young children, “his work was done.” An extensive bibliography of Jevons’ work can be found in the 1992 article by White and Inoue, which is reprinted in Inoue’s 2002 collection of reviews and obituaries of Jevons’ work.

Relation of Political Economy to Statistics

To understand how Jevons’ measurement strategies changed the outlook of political economy, it is helpful to sketch the background of the division of labor between political economy and statistics that is characteristic of the largest part of the 19th century in England. Within the scope of this article, it is impossible to do full justice to the variety of positions that are to be found. Jevons steered through a deductive and an inductive approach to economics. These approaches may be affiliated with the names of John Stuart Mill and William Whewell.

Mill’s Defense of Ricardian Deductivism

The dominant view on economic method for 19th century England had been formulated by John Stuart Mill in two key publications that served as a vindication of Ricardian deductive economics. The first is *On the Definition of Political Economy; and on the Method of*

Investigation Proper to It (1836, 1844); the second is his monumental *Logic* (1843). It was generally considered one of the great advantages of the *Logic* that it contained an explicit treatment of the methods of the “moral or mental sciences,” including political economy. John Stuart Mill staked out political economy from the other moral sciences in that it was capable of attaining the same certainty as obtained in “the most demonstrative parts of physics” ([1836] 1967). This he did by limiting the scope of political economy to the study of just three motives of action (the desire for wealth, the striving for luxury, and the aversion of labor) confronted with Malthus’ law of population growth and Ricardo’s law of diminishing marginal returns on land. The certainty of this so-called *a priori* method of the political economists was secured by reliance on introspection. Introspection guaranteed the general and universal truth of the first principles of political economy and by consequence of all deductions derived from them. The many disturbing causes operating in practice were responsible for the fact that the laws or tendencies of political economy could seldom be observed. By distinguishing between the *science* and the *art* of economics, Mill relegated to the practical politician the task to draw policy inferences from the tendency laws of political economy in a complex social reality.

Mill’s position was not inconsistent with the need felt among political economists for statistical facts (as had been emphasized by McCulloch and, of course, Thomas Tooke). The common strategy was, however, to explain the individual fact, rather than show how these facts bear on the theory itself. This “curious separation between abstract theory and empirical work” found general support among political economists, even though debate has been opened up as to what extent Mill subscribed to his own methodological views in his practical economic writing. In correspondence with Adolphe Quetelet, Nassau Senior even went so far as to claim that he did “not consider the truths of political economy” to depend on “statistical facts.” This separation of theory and data is largely responsible for the division of labor between political economists and statisticians, or “statists” as they were called in the early 19th century.

Whewell’s Inductivist Criticism of Ricardian Economics

The sharp split between political economy and statistics was anathema to a group of scientists in which William Whewell is considered to be of central importance. This group included, among others, the political economist Richard Jones and the polymath Charles Babbage. Thomas Malthus was also sympathetic to their cause. Even granting the somewhat different status of political economy, and the moral sciences in general, Whewell emphasized that political economy could not evade the

tedious path followed by the natural sciences to become genuinely scientific. Whewell was aware that institutional support was of utmost importance in promoting an inductive approach to political economy.

Section F of the BAAS and the Statistical Society of London

In 1833, the group around Whewell managed to persuade the BAAS to allow the establishment of a new section, the so-called Section F, devoted to political economy and statistics. This new section should explicitly restrict its research to facts that could be expressed in numbers and that promised to indicate general laws. This was to exclude the intrusion of opinion into the domain of science, something that was especially feared by the members of the powerful Section A (mathematics and physics). As the offspring of the establishment of Section F, the Statistical Society of London was founded in 1834, involving the same group of inductivists.

The logo of the Statistical Society (selected by Charles Babbage)—a loosely bound sheaf of wheat with the words *Aliis Exterendum* (to be threshed out by others)—precisely expressed the aim of restricting research to objective information only, that is, to quantitative data, preferably stated in tabular form and excluding all references to opinions. In practice, this limitation of statistical research to naive Baconian data-gathering proved impossible. Many of the members of statistical societies were practical businessmen with hardly any knowledge, or interest, in science. Indeed, not only for the Statistical Society of London, but for other statistical societies as well (such as its main competitor, the Manchester Statistical Society), political goals determined heavily how use was made of the data gathered. The intrusion of politics into statistical research made Whewell, at the end of the 1850s, so unhappy with the turn and the tone of statistical research in Great Britain that he attempted to abolish the Section F that he had helped to found.

The insecure status of statistical research in the early 19th century served to enforce the alleged superiority of deductive Ricardian political economy. John Elliot Cairnes’ eloquently written 1857 lectures on the “character and logical method of political economy” summarized the prevailing opinion that “for the ultimate truths of economic science we are independent of this inductive process, having the direct proof afforded by our own senses and consciousness.”

Jevons Cutting through the Distinction of Political Economy and Statistics

Jevons made it his lifelong task to combat this division of labor between political economy and statistics, which in

his view had detrimental consequences on both sides. Much in line with Whewell's inductivist methodology, he made it his aim to install political economy on a "truly scientific" basis, using statistics for this purpose. In his aforementioned lectures, Cairnes claimed that many of the principles of political economy "from their nature" did not "admit of being weighed and measured like the elements and forces of the natural world" and of consequence were "not susceptible of arithmetical or mathematical expression." Considering Jevons' empirical and theoretical work in economics, one obtains the impression that it is planned as a word-for-word refutation of the "uninquiring and unhoping spirit" embodied in Cairnes' words.

Even some of the topics of Jevons' inquiries seem to have been given from the examples Cairnes chose: the relationship of man's physiology to the phenomena of the mind, the so-called King-Davenant price quantity table of corn, and the influence of the Australian and Californian gold discoveries on the value of gold. For all these cases, Cairnes argued that because political economy was not an exact, quantitative science, it was "impracticable" to strive for the "precision which is attainable in physical science." Cairnes added that if political economy were treated similarly to physics, it would become a "wholly different study" from that known so far. But this was just what Jevons aimed at. Before examining these three examples in turn, a more general account of Jevons' views on scientific method will be given.

Jevons' Views on Scientific Method

The Uniformity of Scientific Method

Jevons laid out his views on scientific method in *The Principles of Science* (1874), that is, after his major empirical and theoretical work in economics had seen the light. Jevons did not devote separate attention to the method of the social sciences, including political economy, as his great predecessor John Stuart Mill had done. From the foregoing, it should not come as a surprise that Jevons did not do so. Jevons did not accept the categorical distinction between the sciences of mind and nature as defended by Mill and Cairnes and its implications for scientific method. In the introduction to the *Principles*, Jevons stated, by contrast, that "the application of Scientific Method cannot be restricted to the sphere of lifeless objects. We must sooner or later have strict sciences of those mental and social phenomena, which, if comparison be possible, are of more interest to us than purely material phenomena."

Complexity of the Social Sciences

The only apparent difference between the natural and the mental or moral sciences seemed to consist in the complexity of mental and social phenomena. But complexity was, for Jevons, as much a problem for the natural sciences as for the social sciences. Like astronomers infer their mathematical laws from observations, so do political economists from their statistics. Neither of them was an experimental science, but this did not entail, for Jevons, that complexity prohibited the use of mathematics in the study of society any more than it did in astronomy. Jevons referred to Airy's *Theory of the Tides* as an instance where it had been shown to be possible to obtain numerical exactness in a branch of science that formerly had been considered intractable because of its complexity. Jevons considered mastering complexity to be the genuine problem of induction and this problem was no different for natural and social scientists.

Induction: The Inverse Process of Deduction

In the *Principles of Science* (1874), Jevons used his logical machine to elucidate and circumvent the problem of induction. Not incidentally, an image of the machine was printed opposite to the title page of the book. Jevons explained how deductively an avalanche of conclusions could be drawn on the basis of only a limited set of premises. The scientist was depicted as having only nature's conclusions, but not its premises—its laws—at hand. The problem for the scientist was how to infer back to the simple premises producing the observed complexity of nature. Jevons' solution was to equate induction with what he called the "inverse deductive method." This was a reasoned process of searching for the simplest premises from which the observed conclusions could be derived. The logical machine embodied essentially the same process of striking out contradictory conclusions that Jevons used in this reasoning process. The conclusions of the machine, which was referred to as the "logical piano" and which was of only limited capacity, could be read from the display at the front (see Fig. 1).

Jevons' description of the inverse deductive method suggested to Peirce the notion of "abduction" as a mode of drawing inferences, as becomes clear from the small exchange of letters between the young Peirce and Jevons. In the empirical sciences (all of which Jevons considered as quantitative sciences), this reasoned process could proceed only on the basis of a limited set of observations. The inverse deductive method—induction—thus became "imperfect." The premises were hypotheses about the laws of nature: mathematical, not logical, formulae. The problem of induction was how such reasoned guesses were to be made. Analogical reasoning, the method of

Figure 1 Jevons' logical machine. Courtesy of the Museum of the History of Science, Oxford, UK, Inventory No. 18,230 with permission.

means, and graphical methods were all methods that could be used to tackle this problem. In highlighting the importance of these methods for the quantitative sciences, Jevons followed William Whewell's *Philosophy of the Inductive Sciences*. The goal of these methods was to find "rational laws," that is, mathematical functions explaining the relationship between cause and effect over the whole range of possible observations, not only for the range of observations made.

Reasoning by Analogies

Reasoning by analogies was widely practiced by 19th century natural scientists. Faraday, Lord Kelvin, and Maxwell are perhaps the most prominent and it formed a natural part of Jevons' educational background as well. In the *Principles*, Jevons highlights Faraday's use of analogical reasoning as an example to be followed. Jevons' favorite analogies stemmed from mechanics. The great advantage of mechanical analogies is that they carry their mathematics with them or at least suggest that mathematical formulae may be formulated, if not now, then in the future.

In his experiments on cloud formation, Jevons constructed an elaborate analogy between the formation

of clouds and the formation of precipitates in liquids. If it can be shown, so Jevons' argument goes, that precipitates are formed by principles of hydrodynamics only, then by analogy the same holds for the formation of clouds.

Jevons constructed his analogies on the strong conviction that nature is ultimately ruled by mechanistic and deterministic laws. The aforementioned experiments on cloud formation are a case in point. His studies on the cyclical behavior of trade cycles, which are discussed in more detail below, is an even more dramatic example.

The Role of Probability

The hypothetical character of the formulae arrived at made science essentially probabilistic. This did not mean that nature itself is probabilistic—quite the contrary. Jevons' framing of the problem of induction in terms of his logical machine made sense only on the assumption that the universe is governed by deterministic laws, like the conclusions of the logical machine follow mechanically from the underlying set of premises. Referring to Laplace as his authority, Jevons considered it due to one's ignorance, to the principled impossibility of predicting the outcome when all causes are not known, that one needs to reason probabilistically: "*Probability belongs wholly to the mind.*" Limited knowledge and limited data made probability arguments unavoidable in arguing for the existence of laws and regularities in nature. Jevons presented many such arguments in a rather offhanded way to illustrate how regularity in observations gives reason to assume the existence of a causal mechanism, even though the possibility of "fortuitous coincidences" could never be excluded.

Apart from the general acknowledgment that all knowledge is uncertain and hypothetical, it remained unclear how exactly to apply probabilistic reasoning to empirical events in a rigorous way, as is also clear from the scarce examples of probabilistic reasoning in Jevons' statistical studies. In England, this was reserved for the mathematically more talented Edgeworth, Yule, Galton, and Pearson.

Averages and Means

As in the natural sciences, the exactness of political economy depended on the quality of the data, the quality of the measuring instruments, and the abilities of the scientists to search for regularities in a sea of numbers. Two related strategies were of special help. The first was the reliance on averages, rather than raw data. By taking averages, errors in measurement could be corrected for. Jevons' confidence in averaging practices can partly be traced to his great acquaintance with the balance, which he considered one of the most perfect measuring instruments.

Averaging practices were also useful in attempting to circumvent the problem of multiple causation. On the

assumption that disturbing causes cancel out one another on average, Jevons considered obtaining data that were “more true” than the individual data themselves. With regard to political economy, Jevons even went so far as to say that the only way of turning it into a science was by averaging out the “whims of the individual.” In his emphasis on averages and means, Jevons was clearly influenced by Adolphe Quetelet, whom he considered the “true founder of the social sciences.”

The Method of Graphs

The second method of correction for errors was the graphical method. Like Whewell, Jevons considered the use of graphs an important aid in the discovery of a causal relationship between two variables. Indeed, Whewell’s description of the method of graphs fits perfectly with Jevons. Whewell referred to Sir John Herschel’s use of the method of curves in his *Investigation of the Orbits of Double Stars* (1833), drawn “with a bold but careful hand,” as a fine example of how to “discover the laws of change and succession.” Reliance on such methods enabled the scientist to “obtain data which are *more true than the individual facts themselves*.” Jevons’ predilection for the graphical method in threshing out causal relations can be gathered from the use he made of it, in his published as well as in his unpublished work, and in the repeated discussions he devoted to their use. Visually, graphs are certainly the most spectacular innovation Jevons brought to economics.

Jevons’ Measurement Strategies in Economics

To see how Jevons put his general views into practice, three examples of Jevons’ work will be examined in some detail. It will be attempted to bring out how Jevons combined economic theory and statistics to genuinely turn political economy into a science. The distinction between Jevons’ deductive, theoretical work and his statistical studies in this regard has been historically overemphasized and, perhaps, biased by the great influence that John Stuart Mill has had on discussions on economic method.

Jevons’ Experiments on Work and Fatigue

Developments within physiology, in part related to the emerging theory of thermodynamics, seriously undermined the existing classification of the sciences in those of mind and matter. There is a burgeoning literature on these topics.

Jevons, like many other natural scientists, was clearly influenced by these developments, which he considered to bear on the fundamentals of economic theory, most notably his theory of labor. Jevons was most impressed by the book of a lawyer, Richard Jennings, *Natural Elements of Political Economy* (1855), which in a highly contrived and confused style founded the principles of political economy in man’s physiology. In his *Theory of Political Economy*, Jevons praised Jennings’ suggestion to “exhibit the results of the principles of human nature . . . by the different methods of Algebra and Fluxions” as “a clear statement of the views which I have also adopted.”

In a short 1870 article in *Nature*, Jevons attempted to integrate physiological research with political economy. Referring to Coulomb and Babbage, Jevons conducted three experiments that aimed to give insight into the “chemical and physiological conditions” of work and might be of help in “defining the mathematical relations upon which the science of economics is grounded.” It is highly probable that Jevons got the idea for these particular experiments from Richard Jennings’ 1855 *Natural Elements of Political Economy*.

Jevons conducted these experiments on himself. Notwithstanding this questionable set-up, the experiments shed light on how Jevons adopted methods from the natural sciences in political economy. Repeating the experiments several times (so that, in all, 456 experiments were performed), Jevons computed mean values for the outcomes. From the results, Jevons was able to derive a numerical formula for only one type of experiment, a formula that he distrusted on the grounds that it fitted the experimental outcomes “embarrassingly close.” Jevons added that he would have been comforted if he had been able to explain the result “on mechanical principles.” In subsequent issues of *Nature*, the physicist Samuel Houghton came to Jevons’ aid. Houghton argued that by proper comparison of the work done by the human arm with a “compound pendulum,” it was possible to derive formulae fitting the experimental outcomes quite closely.

Jevons was extremely pleased with Houghton’s results and referred to them on two important occasions: in the *Theory of Political Economy* (1871) and in the *Principles of Science* (1874). In the first instance, Jevons emphasized that experiments like those he had conducted might be of help in empirically substantiating his theory of labor, in which the disutility of labor was traded off against the utility of the wage received. In the *Principles*, Jevons referred to Houghton’s finding as a happy instance where an empirical mathematical relation had been explained on mechanical grounds, thus extending the range of its validity.

Jevons’ study in work and fatigue aimed to link the experimental method with theory formation in economics. It also shows how mechanical analogies were of

help in transforming experimental results into Jevons' ultimate standard of scientificity; rational laws in functional form.

The King Davenant Price Quantity "Law"

Another importance instance linking economic data with theory is Jevons' discussion of the so-called King Davenant table of prices and quantities of wheat. Jevons used this table in the *Theory of Political Economy* to demonstrate how a mathematical function might be inferred from statistical data as positive evidence for his theory of the final (marginal) degree of utility—"the all-important element in Economics."

Jevons' choice of this table was not incidental. It was discussed in Whewell (1830), Tooke (1838), and Cairnes (1857), among others, and played an important role in arguments at the time for and against the possibility of mathematizing economics. In contrast with Cairnes and Tooke, Jevons argued that the table could be rendered mathematically and gave numerical support for his theory of utility. Jevons was fully aware of the many obstacles, but did not consider them prohibitive (see Table I).

Jevons first made a conjecture about the functional form of the relation and solved for the parameter values. The formula Jevons considered was

$$p = \frac{a}{(x - b)^2}.$$

Stephen Stigler uncovered the method of computation of a and b that Jevons most likely followed. First, Jevons computed the extreme values to pin down the slope of the line. He then used the value of b thus obtained to compute a by taking the simple arithmetic mean. This mode of computing was common practice in astronomy, dating back to the 17th century. Otherwise than has been assumed, Jevons used neither least-squares nor any other probability-based method.

If it had been Jevons' sole aim to arrive at the best fit, his choice for the general form of the equation is far from logical. Whewell had already found that the data

could be exactly fitted by a cubic. The exact fit is $p = 25 - 62\frac{1}{3}x + 55x^2 - 16\frac{2}{3}x^3$. "An astute numerical scientist" like Jevons would certainly have stumbled on this equation. It was, however, not Jevons' purpose to find the best fit. In line with his exposition of the graphical method, Jevons argued that a function or curve was not meant to intersect all individual observations. A polynomial to fit the data could always be found. Jevons was aware, however, that data are loaded with errors in measurement. Even though a polynomial may give an indication of the "rational function," theoretical considerations must be brought into play to decide on the form of the function. In the case at hand, the function loosely embodies considerations stemming from Jevons' theory of utility, thus providing an explanation of the data, not just a rendering in mathematical form.

Jevons' Gold Study (1863)

The foregoing two examples show how Jevons attempted to introduce methods from the natural sciences in political economy, such as the use of experiments, the graphical method, and the reliance on mean values rather than individual data. Exemplary for Jevons' major innovations in statistics is his study of the fall of the value of gold.

At the start of the 1860s, the influence of the gold discoveries in California and Australia on the value of gold was a subject of heated debate. The common explanatory strategy was to attribute the changes in observations on prices to the gold discoveries, achieved by eliminating all other possible causes successively. This explanatory strategy has recently been happily compared by Hoover and Dowell with Mill's so-called method of residues. As might be expected, there was thus no conclusive way to decide on the influence of gold on prices. Jevons broke with this explanatory strategy and in doing so introduced a wealth of new tools for research in economics: index numbers, graphs, and ratio charts.

Instead of focusing on individual prices, Jevons simplified the problem dramatically by considering it as a balancing problem. Since all goods were traded against gold, Jevons compared the change in the market conditions of gold (the gold influx) against the change in the market conditions of all other goods. Jevons went on to argue that if a change in this balance was observed, it was far more likely that the cause of the change was on the side of gold than on the side of goods, all other changes on the side of goods most probably canceling one another out. Thus, shifting from an analogy with a mechanical balance to probabilistic reasoning, Jevons argued for a causal claim as well as a measurement strategy.

Instead of considering all price changes in isolation, all prices should be lumped together. If an average rise in prices could then be observed against a base year or period, the percentage change gave an indication of the

Table I Jevons' Rendering of the King Davenant Price Quantity Table of Corn

<i>Changes in Quantity of</i>	
<i>Corn</i>	<i>Price</i>

0.5	5.5

fall in the value of gold *as well as* a confirmation of the probable cause: the gold discoveries. This setup made index numbers relevant for economic research. Index numbers had been known since at least the turn of the 18th century and had even been used by a prominent statistician, William Newmarch, in the early 1850s. Most statisticians had refused their use, however, because they considered index numbers to provide delusory information. A major obstacle to their use was the problem of weighting.

Jevons made notice of the problem, but he left its solution “amid the obscurities of economic science in general.” Jevons similarly mentioned and then passed over the obvious problem that his way of framing the inquiry ignored the interdependencies of price changes of goods. In a different context, Jevons remarked that “all the measurements with which we perform our measurements are faulty.” This remark equally applies here. Even though the computation of an index number was surrounded by difficulties, it could be seen as a first approximation to solving these difficulties. Indeed, had scientists

waited until their instruments and data had been perfect, Jevons argued, “we should have still been in the age of science which terminated at the time of Galileo.”

Jevons chose the unweighted geometric mean as the price index. The argument for the choice was that in the case of ratio changes, the geometric mean is the natural choice. He computed the geometric mean for a set of 39 commodities and subsequently checked the outcome against a considerably enlarged set of 118 commodities. From these computations, Jevons safely concluded an increase of the geometric mean “*by about 9½ percent.*” Jevons drew two ratio charts, one picturing the general course of the price level throughout time and the other spectacularly plotting the ratios of the prices of the individual goods in 1862 against the base period (see Fig. 2).

Jevons’ accomplishment was stunning, especially considering the standards of statistical inquiry of his days. Jevons convincingly transgressed the self-chosen limitations set to statistical inquiry to data-gathering only,

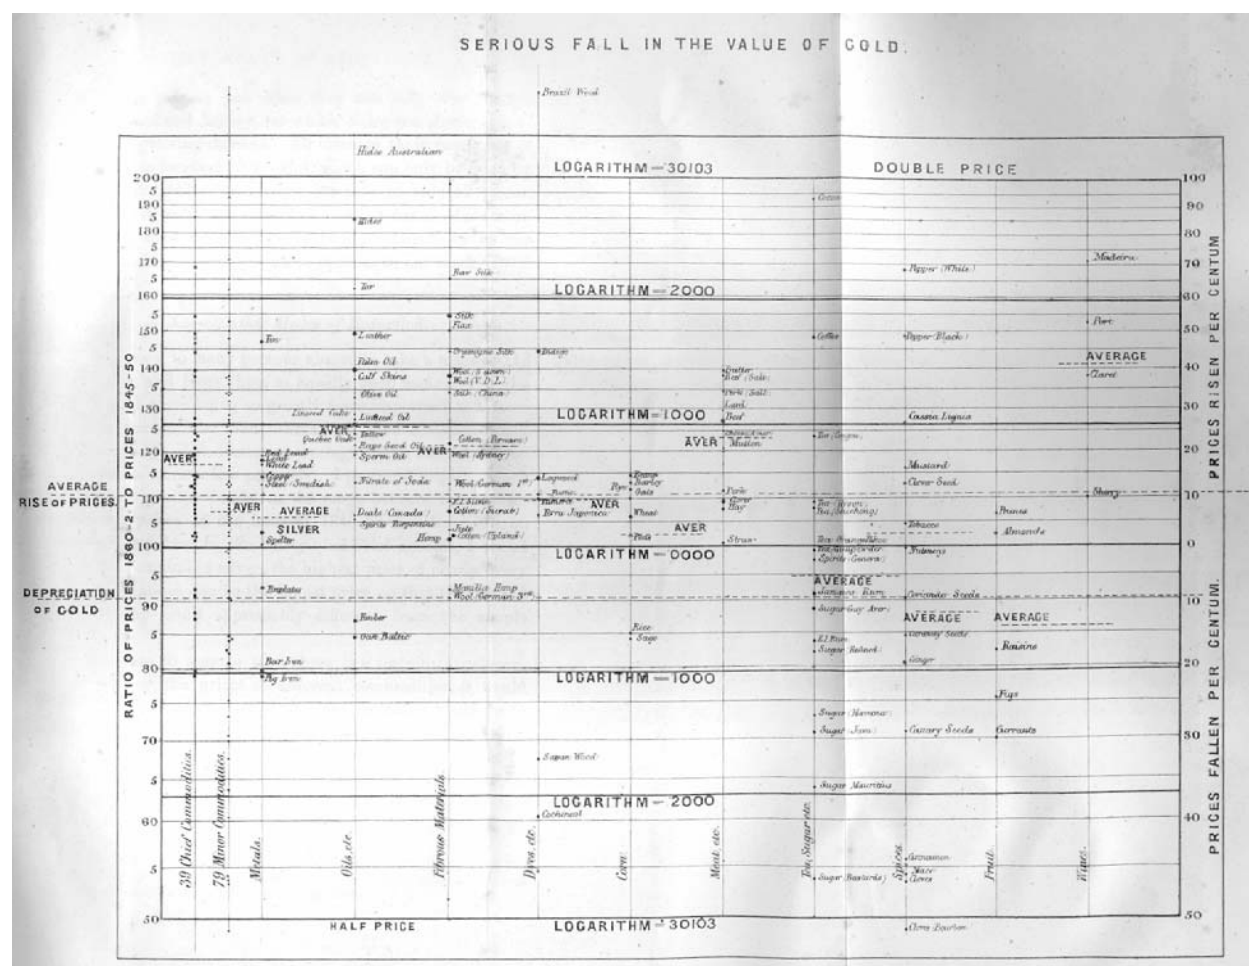

Figure 2 Ratio chart displaying the average individual prices of Jevons’ extended sample of commodities from 1860 to 1862 against their average values in the base period (from 1845 to 1850).

preferably in tabular form and leaving it to the political economists to thresh out conclusions. Here, the data were put to work to obtain quantitative causal inferences and instruments were designed and used to make this possible; index numbers, graphs, and ratio charts.

John Elliot Cairnes immediately acknowledged Jevons' accomplishment and referred most favorably to Jevons' study in a letter to the *Times*. The more so, since Cairnes essentially argued for the same position: that the gold influx had led to a fall in the value of gold. The correspondence between Jevons and Cairnes on the subject is revealing, however. In it, both Jevons and Cairnes

show their awareness that they came to their results via "entirely distinct methods of inquiry."

Other Statistical Work

Jevons' other statistical studies concerned mainly cyclical fluctuations in the economy, the currency system, and the issue of women working in factories. It is generally held that most of his statistical work was the offspring of his abandoned *Statistical Atlas* project of the early 1860s. Some of this work, like his study in the seasonal variations of the money supply, was as thorough and innovative as

PLATE XI

COMMERCIAL FLUCTUATIONS.

Divergence of the Bank of England Accounts from their Average condition after Elimination of the Quarterly Variation.

Figure 3 Jevons' diagram (reduced) showing the divergence of the accounts of the Bank of England from their average values after elimination of quarterly variations. Reading from the top, the diagram shows notes in circulation, private securities, private deposits, bullion and coin, reserves, and public deposits respectively. Courtesy Palgrave/Macmillan Press.

his gold study. Jevons skillfully used simple averaging over weekly, quarterly, and yearly periods, to average out for different periodic variations. One of his diagrams, after elimination of quarterly variations in a number of economic variables, is given here (see Fig. 3).

Jevons was less successful in his attempt to explain commercial fluctuations from cyclical failures of the harvest. Jevons conjectured that failures in harvests might be caused by the cyclical activity of the sun, a cycle for which sunspots gave an indication. Jevons based this idea on the “well-known principle of mechanics that the effects of a periodically varying cause are themselves periodic.” Jevons was never able to substantiate this conjecture appropriately. One of the difficulties was the establishment of the appropriate coincidence in periodicity between the activity of the sun (measured by sunspot activity) and commercial cycles. Once Jevons had managed to more or less synchronize both cycles, the causal chain of events linking both involved massive reactions of British trade on failures in the Indian harvests from at least 1700 onward, a causal link that was considered inconceivable by contemporary commentators. A fine

example of Jevons’ attempt to synchronize the periodicity of sunspot activity and commercial cycles is given in Fig. 4.

His involvement in the issue of women working in factories turned out to be equally unsatisfying. When put to task on the subject, Jevons generously admitted that his plea for the abolishment of women’s work in case there were children was not backed by his statistics. He remained convinced, however, of his conclusions.

Jevons: Humboldtian Scientist

In a brilliant essay, Susan Faye Cannon argued that “if you find a 19th century scientist mapping or graphing his data, chances are good you have found a Humboldtian.” The Humboldtian scientist combines the use of these techniques with a vivid interest in scientific instruments and he does not restrict all these methods and tools to the laboratory, but applies them to the complex variety of real phenomena, whether they belong to the physical, biological, or human world. Without insisting on the label Humboldtian scientist, it is of use in pinpointing a type of scientist highly interested in precise and accurate measurements, not for their own sake, but to derive general laws from them, preferably in mathematical form. Such a scientist does not fit with the image of naive Baconianism. Rather, hypotheses are formed in a loose way from the data, making use of the tools and instruments indicated, with the aim of arriving at general explanations.

Jevons fits this image. And it may well be argued that perhaps the founder of the application of statistics to the social sciences, Adolphe Quetelet, fits the image as well. There was no walk in the country on which Jevons did not take his barometer and thermometer with him to determine the height of mountains and to make meteorological observations. Even when remembering an elder brother, Roscoe Jevons, who turned insane at the age of 18, Jevons thinks first of the wooden balance with which they were able to make fairly precise measurements.

Jevons clearly was not scared off by nature’s complexity. He ingeniously made use of an inverted world map to compare the climate of Australia with that of North Africa. He consciously used averaging techniques to bring out the general course of the Australian climate from the data collected. His experiments on clouds not only tried to reproduce the existing classification of forms of clouds, but searched for a unifying mechanism explaining their formation as well. His experiments on work and fatigue, aiming to shed light on the “physical groundwork” of political economy, and his introduction of index numbers to thresh out a causal relation between the influx of gold and price changes are other cases in point.

Figure 4 Jevons’ diagram showing fluctuations in sunspot activity (represented by Wolf’s numbers) and fluctuations in commercial activity (represented by the prices of corn at Delhi). Time is depicted on the horizontal axis. Jevons did not provide a description of what exactly is stated on the vertical axis. From “The Solar–Commercial Cycle” (1882) and reprinted from Black (1972–1981), 7, 112, with permission.

In retrospect, all this may be considered more or less successful, as many of the scientific endeavors of the 19th century are now considered to be stupefyingly off the mark. But they show the opposite of the “uninquiring and unhoping spirit” that Jevons so much criticized in his later battles with political economists and statisticians. Quoting Herschel, he considered all sciences in the end capable of quantification and—depending on the quality of the data gathered and the measuring instruments used—capable of finding the laws governing the universe, the natural and the social. Slightly exaggerating, one might say that Jevons opened up the “age of measurement” in economics, as the period from Jevons onward has been called.

Glossary

bootstrapping The use of a model derived from a judgment, in place of the judge.

choice Generally, the act of selecting among options. In research, however, the term is often differentiated from the act of putting a specific value on options, as in pricing or matching.

judgment The process of evaluating evidence, modifying beliefs based on the evidence, and stating or otherwise acting on those beliefs. The measurement of judgment involves observing these statements or acts.

matching A method for assessing value using a “fill-in” form in which one or more variables of options are left blank, and the respondent fills in the blanks so that the options are equal in value.

subjective probability The degree of belief that a proposition or set of propositions is true.

utility This term is used in two senses. First, it is often used to describe the benefit yielded by an action or course of action (someone who chooses A over B is therefore presumed to believe they will get more benefit from A than B). Second, it is a measure that reflects or summarizes choice. The outcome of utility measurement is often assumed to say something about the first kind of utility.

Central to the social sciences is some version of belief–desire psychology: We perform act X because we want Y, and believe that by doing X we will obtain Y. Ideally, acts can be divided into two sorts—judgments (or acts that reflect beliefs) and choices (or acts that reflect preferences). Beliefs and preferences can be distinguished in the following way: beliefs can be compared against a standard of accuracy, whereas preferences cannot. In reality, no act is a pure judgment or choice, but the goal of measurement is to distill these beliefs and preferences in

as pure a form as possible. This article focuses on four key aspects of measurement in judgment and choice. These have been chosen both because they are among the most important and because they provide a broad picture of the range of measurement methods used by decision scientists, and the problems that arise in their use.

The Lens Model

The lens model is a general framework for measuring judgment and assessing its validity. It was first described by Egon Brunswik in the context of perception and was later extended to clinical judgment by Kenneth Hammond and colleagues. In principle, the lens model can accommodate all relationships between judgments, outcomes, and the data on which those judgments are based. In many, and perhaps even most, practical cases, some of the information necessary for such a complete analysis is missing, but the lens model summarizes ideal conditions of analysis that can inform research under less ideal ones.

Imagine a doctor assessing a patient’s health. The doctor observes some attributes, such as blood pressure, heart rate, and temperature, and from them makes a judgment about the patient’s health. The patient, moreover, has a true health status that may differ from the doctor’s judgment. We can formally conceptualize problems like this using the framework depicted in Fig. 1, which shows why this is called the “lens” model. A judgment is made based on observable predictor variables ($\mathbf{x} = \{x_1, x_2, \dots, x_n\}$). For each specific set of predictors a judgment y_s is made, and there is a corresponding objective outcome y_o . That is, the doctor estimates the health of the patient and the patient actually has a specific health status. From knowledge of the judgments, the outcomes, and the predictors, we can construct a statistical model of the judge

Figure 1 Relationships between components of the lens model.

and of the environment. These models are typically (but need not be) constructed using multiple linear regression. Figure 1 shows the important measurements that can be made, given many sets of judgments, outcomes, and predictors. These are summarized as follows:

- r_A : The accuracy or achievement of the judge, or the correlation between outcomes and judgments.
- $\hat{y}_J(\mathbf{x})$ and $\hat{y}_O(\mathbf{x})$: The predictions from a model mapping predictor variables onto predicted values.
- R_J and R_O : The correlation between judgments and outcomes and the predictions of their respective models ($R_J = R_{y_J \hat{y}_J}$, $R_O = R_{y_O \hat{y}_O}$). R_J is sometimes labeled “cognitive control,” because it reflects how consistently judges use the available information.
- G : The correlation between the predictions from the two models, or $R_{\hat{y}_J \hat{y}_O}$. This can be called modeled knowledge.
- C : The correlation between the residuals from the two models. This can be called unmodeled knowledge, because it means that the judgments contain useful information that is not incorporated in the model.
- R_B : The relationship between the outcomes and the predictions of the judgment model (the subscript B is for bootstrapping; see later).

The lens model equation decomposes accuracy into components attributable to how information is used by the judge, how useful the information is, and the predictability of the environment:

$$r_A = GR_O R_J + C \sqrt{(1 - R_O)(1 - R_J)}.$$

The second term in the right-hand side is the unmodeled component of judgment. The modeled component is thus the product of modeled knowledge \times task predictability \times cognitive control. Several methodological issues must be addressed when applying the lens model.

First, r_A must be assessed using a representative research design, meaning that the predictors and outcomes used to assess the judges are a representative sample of the environment in question. Second, because predictors are partially redundant (i.e., they are inter-correlated), there can be many equally reliable models relating judgments and outcomes to the predictor variables. Third, models of the judge and of the environment should always be cross-validated on a holdout sample, or at least subjected to statistical tests of shrinkage.

A number of generalizations about human judgment have come from studies conducted within the lens theory framework. First, the linear regression model usually provides an excellent fit to judgment, even when there are significant nonlinearities in the environment. Second, the best-fitting model also contains a lot of unsystematic error, meaning that people are inconsistent. Third, people draw on relatively few cues, usually no more than three and often less. Finally, what people say their judgment policies are often differs from what statistical models show. The latter finding is important for those wishing to study judgment—we cannot simply ask people what they are doing, we must actually observe them doing it.

The term “bootstrapping” is used to describe the use of a statistical model of a judge to stand in for the judge. These models virtually always outperform real judges. It appears that people are pretty good (but not great) at working out a tacit model of how data should be combined, but their judgments contain a lot of error that can mask this relationship. Moreover, judges are almost never as good as the best-fitting linear model; indeed, it has been a matter of great concern to researchers why actuarial models that outperform “clinical” (or unaided) judgment do not play a greater role in real-world diagnosis.

Probability Judgment

From the perspective of decision making, the most important judgment is of the likelihood of events, or their subjective probability. The nature of probability remains controversial, and this controversy has seeped into research on probability assessment. However, it is generally assumed that a subjective probability is a degree of belief (DOB) in a statement or set of statements.

Statements of DOB can be elicited in the form of verbal reports, meaning the use of everyday language such as “very likely” and “probable.” People like giving probabilities in this form, but the subjective meanings of the terms they use vary so much that they provide a poor guide to action. Likelihood ratings are a more formalized version of verbal reports. Here a standard set of terms having a clear ordering in terms of probability is used to form response categories. An example is the 4-point scale “very likely,” “likely,” “unlikely,” and “very unlikely.” Such a scale is useful when

all that matters is the rank of likelihood judgments. But there is no correct level of accuracy associated with each rating. Moreover, even for the same person, the terms will not have the same meaning in different contexts; the term “very likely” will denote a very different numerical probability when it refers to rain tomorrow, compared to a supernova of the sun within the next decade.

Most research into DOB assessment is based on numerical assessments. This is done using two classes of methods. When estimating quantities, such as “next year’s sales projection,” an interval-probability method is used. The typical method is the elicitation of a confidence interval in which the respondent provides an interval that he/she believes has an $X\%$ chance of containing the true value, as in “there is a 95% chance that next year’s sales will be between £3 and £4 million.” A related method is the fractile method, whereby the respondent reports fractile values for the quantity. For instance, they might be asked to specify three values such that there is a 5, 50, and 95% chance that the true value is no more than the corresponding value.

When assessing the likelihood of propositions (i.e., “Shakespeare wrote *Doctor Faustus*”), probability judgments are used; these are responses that can be directly transformed into a number on the 0–1 scale, where 0 means there is no chance of a statement being true, 1 means it is certain to be true, and intermediate values reflect proportionate degrees of uncertainty. The methods used are manifold, with the most common being statements of percentage likelihood or probability, and other methods being the use of a probability wheel (whereby the area on the wheel is adjusted to correspond to the probability of being correct), relative frequency estimates (e.g., “for 100 cases about which I was this sure, I would expect about 60 to be correct”), and odds judgments (e.g., “I would assign it odds of 3 to 1,” meaning it has a chance of being correct three out of four times).

The important measurement issues in subjective probability judgment concern accuracy. This is usually indexed by calibration and discrimination (see Table I for more details). Calibration refers to the difference between the proportion of correct statements given a specific numerical judgment and the value of that judgment. For instance, do we find that of those patients given a 95% chance of surviving an operation that 95% do indeed survive? Discrimination refers to the ability to distinguish between cases. For instance, is the probability different (whether higher or lower) for a group given a 95% chance of survival and a group given a 5% chance of survival? Perfect calibration is found when the judged probability equals the observed probability, and perfect discrimination is found when judgment categories all have either 0 or 100% true statements. Signal detection theory uses the analogous terms bias (c) and sensitivity (d') to denote, respectively, calibration and discrimination.

Most research into DOB has focused on calibration. Fig. 2, which plots subjective probabilities (p) against objective probabilities or the proportion correct (\bar{x}), summarizes the stylized outcomes of dozens, if not hundreds, of experiments. First, people are generally overconfident, meaning their probability judgments are too high. Second, overconfidence declines as the task becomes easier. Some, although not all, overconfidence is caused by researchers often (inadvertently) choosing trick questions that are likely to be answered incorrectly (e.g., “Who invented the telescope, Galileo or Leeuwenhook?”).

As with any judgment task, participants can be motivated to give responses differing from their true beliefs for strategic reasons. They might, for instance, give lots of high-confidence responses because they want to be seen as confident, or may give lots of 50% responses because they do not want to commit. One way to ensure that respondents give their true probability judgments is by paying them according to a strictly proper scoring rule, which assigns payoffs to subjective probabilities such that the maximum reward comes from reporting one’s best probability estimate. The most widely used approach is based on the quadratic score (often called the Brier score):

$$s = \frac{1}{n} \sum_{i=1}^n (p_i - x_i)^2,$$

where p_i is the stated probability that the event will occur; $x_i = 1$ if the event occurs and 0 otherwise. If we let ψ_i be the subject’s true belief about the probability of an outcome, the expected value of this score is

$$E(s) = \psi_i(1 - p)^2 + (1 - \psi_i)p^2.$$

This is minimized when $\psi_i = p_i$, so a good incentive scheme is one that pays or punishes by an amount equal to $a - bs$, where b is a positive amount of reward and s is the quadratic score. This payoff function is maximized when $\psi_i = p_i$.

Valuation

Central to the study of preference and choice is the measurement of the value of things. There are two straightforward and widely used methods of finding out how much something is worth to somebody: we can ask them to put a price on it, or we can ask them to choose between it and something else.

Four pricing methods are illustrated in Fig. 3. If you already own an object, you can state how much you would require to give it up (willingness to accept; WTA) or you can state how much you would pay to prevent having to give it up (equivalent loss; EL); if you do not own an object, you can state how much you would pay to obtain

Table I Components of Judgment Skill: Decomposition of the Quadratic Score

The quadratic score can be decomposed into three components, each of which reflects a different aspect of the decision maker's skill:

$$s = \bar{x}(1 - \bar{x}) + \frac{1}{n} \sum_{j=1}^t n_j (p_j - \bar{x}_j)^2 - \frac{1}{n} \sum_{j=1}^t n_j (\bar{x}_j - \bar{x})^2,$$

where \bar{x} is the proportion correct, p_j is a specific probability judgment (e.g., $p = 0.55$), n_j is the number of times this judgment is used, and \bar{x}_j is the proportion of items assigned this probability that are correct. The first term on the right-hand side, the variance of the observed outcomes, is called "knowledge" when used for tasks in which a respondent states their belief and then assigns a probability to it. The second component, "calibration," indicates the squared deviation of the average confidence judgment from the average proportion correct. Calibration ranges from 0 to 1. It does not discriminate between over- and underconfidence.

Perfect calibration could be achieved by giving the average proportion correct for each probability judgment ($p = \bar{x}$), but this would make the individual judgments all but useless. The third component in the decomposition, called "resolution" or "discrimination", indicates whether the judge gives different probability judgments for tasks differing in their average outcome (analogous to r_A in the lens model). Resolution does not depend on what the judgments are, but only on the fact that the different values of \bar{x}_j differ. A judge who gave probabilities of 1 whenever they were incorrect, and 0.5 when they were correct would have perfect resolution. The maximum value of resolution is the knowledge score, so many scholars suggest that a normalized discrimination index (NDI) be used, where $\text{NDI} = \text{resolution}/\text{knowledge}$.

**Figure 2** Calibration plot showing overconfidence and the hard–easy effect.

		Good	
		Gain	Lose
Money	Gain	Equivalent gain (EG); you own neither, but you can receive one or the other	Willingness to accept (WTA); you are the owner, but you will give up ownership in exchange for a gain
	Lose	Willingness to pay (WTP); you are not the owner; but you will acquire ownership in exchange for a loss	Equivalent loss (EL); you own both, but you must give up one or the other

Figure 3 Four ways of eliciting a price.

it (willingness to pay; WTP) or you can state how much you would be willing to accept in place of obtaining the object (equivalent gain; EG). These methods are all widely used in valuation studies. In studies of intertemporal choice, EL and EG are almost the norm (e.g., "how much in 6 months would be the same to you as receiving £100 now" is an example of EG); in studies of consumer choice, WTP is natural ("how much would you pay for this toaster?"); in contingent valuation, WTP and WTA are widely used ("how much would you need to be paid to permit this river to be polluted?" or "how much would you pay to prevent it from happening?").

Economic theory states that, under most circumstances, all methods of pricing should yield the same price, but this is far from true. One of the most celebrated findings in choice research is what Daniel Kahneman, Jack Knetsch, and Richard Thaler called the "endowment effect," which means that WTA is typically far greater than WTP. This is true for commonplace consumer goods such as pens and coffee mugs, and for more momentous goods as well. To illustrate, one study found that if the risk of injury from a household cleaner is increased from 10 to 15 injuries per 10,000, most consumers will not buy the good at any price; but they would only pay, on average, \$0.65 more to decrease the risk from 15 to 10 injuries per 10,000. The major reason for the WTA/WTP discrepancy appears to be that people are systematically loss averse, meaning they treat a gain of x as being not as good as a loss of x is bad. When stating their WTP, therefore, they are trading off a loss of money against a gain of some good, and so loss aversion leads them to put more weight on the money. For WTA, the situation is reversed, and the loss of a good is traded against the gain of money. Other pricing methods fall in between, and Bateman and associates provide strong evidence that the pattern is $\text{WTP} < \text{EL} \leq \text{EG} < \text{WTA}$.

Pricing is a specific example of a general method of preference measurement called matching. In general, one option is fully specified and another has some missing information. For example, respondents are asked what value of x would make the following options equivalent:

- (A): A 3-week trip to Australia at a cost to you of \$2000, or
- (B): A x -week trip to Australia at a cost to you of \$3000.

Another method is choice, whereby respondents are presented with two or more options and they choose the one they prefer. The experimenter would fill in a value for x , and ask “which would you prefer, A or B?” The comparison between choice and matching is most important from the perspective of preference measurement, because it has yielded evidence of widespread preference reversals, meaning that under one measurement technique people prefer A to B, but under another they prefer B to A. Preference reversals were first shown by Paul Slovic and Sarah Lichtenstein in the domain of gambles. When people choose between gambles, when one choice offers a high probability of winning a small amount (P-bet; e.g., a 0.8 chance of \$10) and the other offers a low probability of winning a high amount (\$-bet; e.g., a 0.1 chance of \$80), they tend to prefer the P-bet. On the other hand, they will put a higher price on the \$-bet. This appears to be one expression of a general phenomenon called the “compatibility effect”: when stating one’s preferences (or making judgments in general), dimensions that are more compatible with the response mode get more decision weight. For the gamble example, when pricing a gamble, the money dimension gets more weight because it is compatible with (i.e., easy to translate into) price.

Utility Measurement

Central to the study of choice is the concept of utility, which is, very roughly speaking, an index or measure of the benefit provided by an option. Utility is an inherently subjective concept, although it has been shown that given a small number of consistency or coherence conditions (the axioms of John von Neumann and Oskar Morgenstern), a cardinal utility function can be derived from gambles. Most utility measurement methods are based on the assumption that people are expected utility maximizers, where the expected utility of a prospect is given by the sum of the products of the probability of outcomes multiplied by their utilities [$EU = \sum p_i u(x_i)$], meaning that they will always choose the prospect having the highest expected utility. Of the many utility measurement methods available, the following discussion focuses primarily on three that are solidly rooted in the axioms of utility theory. These are the certainty equivalent

(CE), probability equivalent (PE), and gamble-trade-off methods.

The CE and PE methods are used to fit a utility function between a minimum utility level and a maximum utility level, which are given arbitrary values, usually 0 and 1. Imagine a set of possible outcomes, $\{s, x_1, x_2, \dots, x_n, l\}$, where s and l are, respectively, the smallest and largest outcome, and all x_i take on intermediate values. The CE and PE methods work by offering the decision maker a choice between x_i for sure, and a gamble between s and l :

We start by assigning utility values to s and l . Because utility is measured on an interval scale (unique up to a linear transformation), these values are arbitrary as long as $u(l) > u(s)$, and for computational reasons it is best to choose $u(s) = 0$ and $u(l) = 1$. In the PE method, the value of p is varied until the decision maker is indifferent between the gamble and the sure thing, meaning that $u(x_i) = (1 - p)u(s) + pu(l) = p$. For different values of x_i , the same process is repeated until all possible values of x_i have been assigned their utility value. The CE method proceeds similarly, except now the value of p is fixed and the value of x_i is varied until indifference is reached. The interpretation of the numbers is the same as before. With the PE method, x_i is specified and $u(x_i)$ is derived; with the CE method, $u(x_i)$ is specified and x_i is derived. Both methods have shortcomings. A major one is the assumption that people maximize expectations, meaning that the decision weight they put on probabilities is equal to the probabilities. It is well known that this is not true, and that the true probability weighting function is more like the one illustrated in Fig. 4, first proposed by Kahneman and Tversky, which plots psychological weights $\pi(p)$ against probabilities. The function gives too much weight to small probabilities, and too little weight to intermediate ones; moreover, there is a rapid increase (even a discontinuity) when going from $p = 0$ to $p > 0$ and from $p < 1$ to $p = 1$. To account for such problems, utility assessment procedures that “cancel out” the effects of probability weighting have been developed. Most notable of these is the gamble-trade-off method proposed by Peter Wakker.

In the gamble-trade-off model, participants begin by equating a pair of gambles, as illustrated in Fig. 5. One gamble offers a p chance of l' and a $(1 - p)$ chance of

Figure 4 Psychological decision weights associated with different probability values.

Figure 5 The gamble-trade-off method for utility measurement.

x_0 (less than l'); the other offers a p chance of s' ($< l'$; note that s' and l' probably will not be the largest and smallest possible values) and a $(1 - p)$ chance of an unspecified x_1 . Once x_1 is specified, it replaces x_0 in the next gamble and x_2 is obtained in the same way. The process continues until the range of values x_0 to x_n covers the range over which a utility function is needed. The logic is that the difference in utility between all consecutive values of x is equal, regardless of how the decision maker weights probabilities. That is, for all x_i and x_{i-1} ,

$$\begin{aligned} \pi(p)u(l') + \pi(1 - p)u(x_{i-1}) &= \pi(p)u(s') \\ &\quad + \pi(1 - p)u(x_i), \\ \therefore u(x_i) - u(x_{i-1}) &= [\pi(p)/\pi(1 - p)] \\ &\quad \times [u(l') - u(s')], \end{aligned}$$

where the right-hand side in the second expression is a constant. In this way, a number of values of x can be produced that are equally spaced in utility, and a utility function can be derived as shown in Fig. 6. The shape of the utility function reflects risk attitude: concave (downward) functions mean risk aversion, and convex functions mean risk seeking. That is, a concave function,

Figure 6 Utility function derived from the gamble-trade-off method. Note that the illustrated function is concave, but the utility function can take any shape.

such as the one in Fig. 6, means someone will turn down a fair gamble (i.e., with expected value of 0) in favor of a sure thing; a convex function means they will accept it. There is controversy over how utility functions derived in this way can be interpreted. The usual economic interpretation is that there is a global function defined over states of wealth, and the measured utility function constitutes only a small slice of it. Yet the concavity usually observed in this slice is, as Matthew Rabin has demonstrated, incompatible with any reasonable global utility function. More realistic is a utility function, as first proposed by Harry Markowitz and developed by Kahneman and Tversky, having a “kink” at one’s current state of wealth, with convexity for losses and concavity for gains. The methods just described, therefore, are best interpreted as telling us about the local utility function, just above or below this kink.

Another issue concerns how utilities can be combined. Suppose, for instance, you find that £100 is worth 0.6 on a scale, and a diamond ring is worth 0.2. It is not possible to conclude that £100 and a diamond ring have a utility of 0.8; the utility analysis permits us to conclude no more than we knew without it: the ring-plus-£100 is worth no less than the ring or the £100 alone. There are two reasons for this. First, utility is measured only up to a linear transformation. Second, because of complementarity and substitution effects, the utility of each part of a bundle cannot be combined in a linear fashion. To find the utility of the money and the ring requires subjecting the entire bundle to a utility analysis.

The Problem of Response Variance

Measures of judgment and choice should conform to “description invariance” and “procedure invariance”: different representations of the same problem, and different ways of measuring responses, should yield compatible

judgments and choices. In fact, as already mentioned, this precondition is far from being met. The judgments and choices people make are highly dependent on irrelevant task features, and so researchers must always ask whether the results they obtain represent the decision maker's beliefs or preferences. The problem is so acute that many researchers have suggested that measured judgments and preferences are often "constructed" in response to the task, rather than "reported." Consequently, a word of caution is offered to researchers and consumers of research: always ask how much judgments and choices reflect true beliefs or preferences, and how much they reflect how the task was described and the responses elicited.

Glossary

empiricism The view that all knowledge is based on or derived from sensory experience.

factor analysis A mathematical technique used to determine the minimum number of factors required to explain an observed pattern of correlations.

induction The method by which a general statement, suggesting a regular association between two or more variables, is derived from a series of empirical observations.

interpretivism A perspective or method that emphasizes understanding of intentional human conduct.

ontology A branch of philosophy dealing with the nature of existence or reality.

paradigm A number of theories that depend partly on the shared metaphysical beliefs of the scientific community (Kuhn).

positivism A strict empiricism that recognizes as valid only knowledge claims based on experience.

realism The assertion that the objects in the world have an existence independent of our conception of them.

refutation An approach opposed to verification, claiming that the scientific process begins when observations clash with existing theories (Popper).

relativism A doctrine that claims that the conceptions of good and evil are relative rather than absolute.

This article describes attempts to create knowledge through the process of social measurement. The main approaches in the philosophy of science are presented and the processes through which quantitative measurement instruments are developed to test hypotheses, and how they generate new questions and create new knowledge, are reviewed. Qualitative attempts to study phenomena, the investigation of which cannot be carried out by standardized quantitative measures, are described. Intelligence quotient (IQ) tests, emotional intelligence tests

(developed in response to the inadequacy of the IQ tests to predict success in real-life situations), the F scale (based on the authoritarian personality theory), and the Big Five (a measure to map the various dimensions of personality, which started by attempts to find words that refer to characteristics of behavior) exemplify the contribution of quantitative measures to knowledge creation; Frieilich's anthropological study about the Mohawk men who worked as building molders in New York of the 1960s, as well as various explorative attempts to study the life of gay couples, are described to exemplify qualitative ways of knowledge creation, when quantitative measures are inappropriate.

Introduction: Knowledge and Science

The word "science" has its origins in the Latin verb *scire*, meaning "to know." We can "know" through tenacity, authority, faith, intuition, or science. The major purpose of science is to develop laws and theories to explain, predict, understand, and control phenomena. The scientific method is distinct in its notion of intersubjective certification, but all observation is potentially contaminated, whether by theories or by worldview or by past experiences. Scientific knowledge is tentative and subject to revision on the basis of new evidence. Science cannot provide certainty, but it is the most objective mode of pursuing knowledge. It is generally believed that the goal of the pursuit of knowledge is the discovery of truth, which may either take shape in the mind of the observer or is to be approached only through the evidence of the senses. Two additional views of science are the consensual, according to which the goal of science is a consensus of rational opinion over the widest possible

field, and the dissension, according to which scientific research is much more controversy laden.

An enormous amount of knowledge resides in the ability to notice and interpret phenomena. Knowledge can be stable or flexible, shared by all or residing in special individuals, taking the form of general rules learned by rote or treating new situations in an imaginative way. What a person sees depends both on what is observed and on what previous visual/conceptual experience has taught a person to see. Every description of observable events has what might be called “objective” and “subjective” sides, i.e., “fits” are recognized in a particular situation, but the process of fitting to a situation modifies it.

From Logical Positivism to Scientific Realism

The concepts discussed so far are related to the evolution of scientific thought from logical positivism to postpositivism and scientific realism. For many years, “positivism,” a strict empiricism that recognizes as valid only knowledge claims based on experience, has dominated discussions of scientific method. During the 1920s, positivism emerged as a full-fledged philosophy of science in the form of logical positivism. Developed by the Vienna Circle, a group of scientists and philosophers, logical positivism accepted as its central doctrine Wittgenstein’s verification theory of meaning, which holds that statements are meaningful only if they can be empirically verified, and inductive inference can never be justified on purely logical grounds. A more moderate version of positivism is known as logical empiricism, which became the “received view” in the philosophy of science. The concept of verification was replaced with the idea of gradually increasing confirmation. Verification is considered a complete and definitive establishment of truth. Universal statements can never be verified, but may be confirmed by the accumulation of successful empirical tests. Logical empiricists believe that all knowledge begins with observations, which lead to generalizations. Science and knowledge are believed to occur inductively from data to theory. A finite number of observations are believed to lead to the logical conclusion that a universal statement is “probably true,” tentative, and in need of permanent proof. Observations are always subject to measurement error, and theory depends on observation.

Unlike the positivists, Karl Popper (1902–1994) accepted the fact that observation always presupposes the existence of expectations; hence, the scientific process should begin when observations clash with existing theories, which are subjected to rigorous empirical refutation tests. Contrary to Popper’s refutation rule, Thomas Kuhn’s (1922–1996) model emphasizes the conceptual

frameworks that guide research activities. Kuhn’s paradigm includes a number of theories that depend partly on the shared metaphysical beliefs of the scientific community. Given its advocacy of relativism, Kuhn’s *Structure of Scientific Revolutions* became one of the most carefully analyzed works in the philosophy of sciences. Larry Laudan (1952–), on the other hand, sees science operating within a conceptual framework that he calls research tradition, which consists of a number of specific theories, along with a set of metaphysical and conceptual assumptions that are shared by those scientists who adhere to the tradition. The “truth” or “falsity” of a theory is therefore irrelevant as an appraisal criterion.

Critical relativism is a multifaceted philosophy of science, arguing that knowledge production in the social sciences is impacted by the broader cultural milieu and there is no “scientific method,” but disciplinary knowledge claims are viewed as contingent on the particular beliefs of its practitioners. It rejects the basic premise of the positivistic approaches that there is a single knowable reality and accepts different ways of exploring natural phenomena, each with its own advantages and liabilities.

Classical realism believes that the world exists independently of its being perceived and that the role of science is to use its method to improve our perceptual measurement processes, separate illusion from reality, and thereby generate the most accurate possible description and understanding of the world. The claim that a scientific proposition seems true does not mean that it is certain, but rather that the world is as the proposition says it is.

Objectivity, Standardization, and Behavior Sampling

In the positivist approach, as a whole, measurements are developed to test hypotheses. However, often the existence of a measurement instrument is an impetus to the generation of new questions, and the creation of new knowledge. Anastasi (1908–), one of the best known psychologists in the field of testing, tells us that psychological tests are tools that can be instruments of good or harm, depending on how they are used. She defines a test as an “objective” and “standardized” measure of a sample of behavior. This definition focuses our attention on three elements: (1) objectivity, which tells us that most aspects of a test are based on objective criteria, such as how the test is scored and how the score is interpreted, and are not a function of the subjective decision of a particular examiner; (2) standardization, so that no matter who administers, scores, and interprets the test, there is uniformity of procedure; and (3) a sample of (a person’s) behavior, desirably a representative sample, from which we can

draw inferences and hypotheses. A test is not a psychological X ray, nor does it necessarily reveal hidden conflicts and forbidden wishes.

Measurement Instruments as an Impetus of New Questions

As far as knowledge creation is concerned, the effect of measurement on the objects being observed is of major importance. Even in the hard sciences, wherein knowledge is usually considered an objective, reproducible truth derived through the scientific method, measurement affects results in the most physical sense. To gain any knowledge of a system requires interaction with it. When something is seen, it is because quanta of light hit the object and are reflected to the eyes (or to an instrument). This is not an issue as long as the objects are macroscopic, because then the interaction is vanishingly small relative to the object. However, when the objects are on atomic scale, the interaction energy is on the order of the object energy. This is the physical reason for the famous Heisenberg Uncertainty Principle, which fundamentally affects quantum mechanics, the basis of physics. Observation and measurement always involve interaction with the observed object. Because of quantization, this interaction cannot be made infinitely small. Therefore, for atomic-scale objects, the interaction is similar in size to measured quantities, leading to inability to measure everything with infinite precision.

The Case of Intelligence Quotient Tests

When Alfred Binet (1859–1911) began research on the measurement of intelligence, he did not realize the Pandora's box that he was going to open. With the creation of the Binet scale (later modified by W. Stern and renamed the intelligence quotient), human beings were given a quantitative, objective method of gauging "intelligence." Originally, Binet intended his test to be a rough guide for identifying mildly retarded and learning-disabled children, with the hope of administering these children special training to improve their mental capacity. Scientists such as Goddard, Terman, Yerkes, and countless others saw this new test as a means of identifying inferior individuals who needed to be regulated and, most importantly, prevented from reproducing. Many of these scientists used their data to create a hereditarian theory of IQ that relied primarily on within- and between-group heredity. In other words, they would identify an estimate of heritability within a single population and then say that this similarity within the group also explains the common differences between groups. It was these assumptions that created a major problem: human beings

now had quantitative scientific data to support racism and discrimination. The demons were out of the box.

The Case of Emotional Quotient Tests

Another question raised with respect to IQ tests relates to their inadequacy to measure success in real-life situations; assessing this has contributed to the creation of new knowledge. When psychologists began to write and think about intelligence, they focused on cognitive aspects, such as memory and problem solving. However, there were researchers who recognized early on that the noncognitive aspects were also important. As early as 1943, Wechsler (1896–1981) was proposing that the non-intellective abilities are essential for predicting a person's ability to succeed in life. Robert Thorndike (1943–), to take another example, was writing about "social intelligence" in the late 1930s. The work of these early pioneers was largely forgotten or overlooked until 1983, when Howard Gardner began to write about "multiple intelligence." Gardner proposed that "intrapersonal" and "interpersonal" intelligences are as important as the type of intelligence typically measured by IQ and related tests. In 1990, Peter Salovey and John Mayer coined the term "emotional intelligence," defining it as "a form of social intelligence that involves the ability to monitor one's own and others' feelings and emotions, to discriminate among them, and to use this information to guide one's thinking and action." Salovey and Mayer also initiated a research program intended to develop valid measures of emotional intelligence and to explore its significance. In 1995, Daniel Goleman became aware of Salovey and Mayer's work, and this eventually led to his book, *Emotional Intelligence*. To be a scientist, probably an IQ of 120 or so is needed simply to get a doctorate and a job. But it is more important to be able to persist in the face of difficulty and to get along well with colleagues and subordinates than it is to have an extra 10 or 15 points of IQ. The same is true in many other occupations. In doing the research for his first book, Goleman became familiar with a wealth of research pointing to the importance of social and emotional abilities for personal success. Some of this research came from personality and social psychology, and some came from the burgeoning field of neuropsychology. Research now emerging suggests that emotional intelligence, and particularly the new measures that have been developed to assess it, is in fact a distinct entity.

The Case of the F Scale

The problems resulting from Anastasi's demand for objectivity may be exemplified by the authoritarian personality theory and the various scales to measure authoritarianism and related variables. The study of authoritarianism, an example of an inductive empirical

personality research, has grown out of the deductive psychoanalytic theory. It began with an attempt to find the personality variables related to anti-Semitism, continued with defining anti-Semitism as a part of ethnocentricity (prejudices against ethnic minorities in general), and ended up with considering ethnocentricity as a general fascistic tendency, the origin of which is a personality structure called the “authoritarian personality.” Authoritarian individuals were perceived as having a strong primitive id, a weak ego, and a rigid superego, which is based on a fear of punishment rather than on a true internalization of morality. This personality structure is behaviorally expressed by authoritarian aggression, obedience, projectivity, and other traits, according to which the F(ascism) scale was developed. As was the case with the IQ tests, the F scale was politically, methodologically, and theoretically criticized. It was argued that it represents an ideological bias of politically leftist researchers, hence focusing only on authoritarianism of the political right, associated with fascism, and ignoring the existence of left-wing authoritarianism, associated with communism. An immediate attempt to develop a measure unrelated to political attitudes resulted in the development of the Dogmatism scale. Here it can be seen how the effects of believed flaws in a measurement instrument result in an attempt to correct it and create new knowledge. Methodologically, it was argued that the F scale is not valid, because all its items are phrased in the same direction; hence it cannot be known whether an agreement with a certain statement is a valid evidence of authoritarianism or rather expresses a general tendency to agree with every statement in general (a response-set bias). Intensive research efforts were invested in the attempts to test this claim and in the development of an alternative biased scale. Theoretically, it was argued that the whole research method of authoritarianism is wrong. First, a relation between authoritarian attitudes and behavior does not necessarily exist, and second, each one of the different personality characteristics has to be measured separately to prove the alleged relations among them, rather than starting with a scale that presupposes that such relations do exist. The effect of this alleged flaw of the F scale resulted in the development of separate measures of the different variables that are supposedly characteristic of the authoritarian personality, thus promoting the creation of new knowledge. A series of studies investigating authoritarianism in court, authoritarianism and repression, and authoritarianism and obedience to instructions enlightened the issue of validity, which becomes complicated given the complexity of the concept of authoritarianism. The sources of authoritarianism among children, as well as the interaction between authoritarianism and various situations and its effect on intragroup preferences, are two

additional fields that exemplify how developing the F scale and its related variables contributed to the creation of new knowledge. Finally, it is important not to ignore the possibility that the study of authoritarianism has been influenced by different sociopolitical climates; from the 1930s till nowadays, both researchers and the groups they study have been affected by sociopolitical realities.

The Case of the Big Five

Personality can be defined as the distinctive and characteristic patterns of thought, emotion, and behavior that define an individual's personal style of interaction with the physical and social environment. When people are asked in daily life to describe a personality, the response is likely framed in terms of personality traits, e.g., adjectives such as “intelligent,” “extroverted,” “conscientious,” and so forth. One way to begin the task of deriving a comprehensive but manageable number of traits is to consult a dictionary. The assumption is that through linguistic evolution, the language will encode most, if not all, of the important distinctions among individuals that make a difference in everyday life. Allport and Odbert actually undertook this task by going through the unabridged dictionary. They found approximately 18,000 words that refer to characteristics of behavior—nearly 5% of the English lexicon. Next, the list was reduced to about 4500 terms by eliminating obscure words and synonyms, and this shortened list was then organized into psychologically meaningful subsets. Subsequent researchers have used such trait terms to obtain personality ratings of an individual. Peers who know the individual well are asked to rate him/her on a scale of each trait. For example, a rater might be asked to rate the person on the trait of friendliness using a 7-point scale that ranges from “not at all friendly” to “very friendly.” Individuals can also be asked to rate themselves on the scales. For example, Raymond Cattell (1905–) first condensed the Allport–Odbert list to less than 200 terms and then obtained both peer and self-ratings. He then used the method of factor analysis to determine how many underlying personality factors could account for the pattern of correlations among the trait ratings. His analysis yielded 16 factors. A similar procedure was used by the British psychologist Hans Eysenck (1916–1997) to arrive at two personality factors, introversion/extroversion, a dimension first identified by the psychoanalyst Carl Jung (1875–1961) that refers to the degree to which a person's basic orientation is turned inward toward the self or outward toward the external world, and emotional instability/stability, which Eysenck calls neuroticism, defined as a dimension of emotionality, with moody/anxious, temperamental, and maladjusted individuals at the neurotic or unstable end and calm, well-adjusted individuals at

the other. Nowadays many trait researchers agree that five trait dimensions (the “Big Five”) may provide the best compromise. There is still disagreement about how best to name and interpret the factors, but one reasonable way to summarize them is with the acronym OCEAN: openness to experience, conscientiousness, extroversion, agreeableness, and neuroticism. Many personality psychologists consider the discovery and validation of the Big Five to be one of the major breakthroughs of contemporary personality psychology. Thus, the 18,000 words found by Allport and Odbert in 1936 were reduced to five major factors that express a personality. Moreover, the introversion/extroversion dimension, suggested by Jung on purely deductive theoretical basis, is one of the current Big Five factors, which are the result of thorough inductive empirical testing, as was the case with the authoritarian personality theory and the F scale. Have the Big Five created new knowledge? Interestingly enough, the same two researchers who validated the Big Five have just recently edited and published an almost 500-page volume of research, connecting the Big Five to personality disorders, which are the most frequently recognized psychopathologies today. Thus, the Big Five seems to be not merely a valid instrument to characterize personality, but has a diagnostic value in the realm of psychopathology. And, if it is possible to characterize individuals who suffer from different personality disorders by the Big Five, how does this relate to the other diagnostics? Is it possible to predict that authoritarian individuals, to take only one example, would have low scores on the openness-to-experience factor? How would authoritarians, whose superego is supposed to be weak, score on the conscientiousness factor? How about the emotional intelligence of authoritarians, who are supposed to be rigid and dogmatic? Does it seem reasonable to predict that emotionally intelligent individuals would have high scores on the extroversion and openness-to-experience factors? Finally, how would psychologists score on these and other measures? Only future research will tell.

Alternatives to Quantitative Research

A perennial debate in the philosophy of social sciences is whether they should strive to emulate natural science methods, or whether understanding social phenomena is something essentially different from explanation in the natural sciences. The naturalists say that the social sciences should be like the natural sciences, whereas the interpretivists assert the contrary. Interpretivism can be roughly divided into two conceptual parts: a positive program for how to do social science and a set of arguments for why any attempt to implement natural science methods in the social sciences is doomed to failure.

Some have argued that the social sciences cannot explain events by causes because they cannot capture all the complex contributing factors, because there is no material constitution to social facts (such as marriage or money), or because human reason is necessarily involved. But if science has the goal of providing the means for explanation, prediction, and intervention, then social science must also be able to do this in order to be considered science. Causal relations are the basis of this type of reasoning. When the function of an artifact or practice is identified (the function of the Hindu taboo on eating cattle is to provide traction animals for farming; the function of Potlatch is to redistribute food, etc.), what is explained? Carl Gustav Hempel (1905–1997) argued that functions cannot explain why the functional item is present (why the Hindu's have the taboo, or why the Kwakiutl have the Potlatch). But identifying functions is ubiquitous in social science (as is the case in biology), and functions seem to be playing an explanatory role. Philosophers have taken up the challenge to analyze how and what function ascription explains. The role of laws as essential to explanation has been defended by Hempel and formalized in his deductive–nomological model of explanation, arguing that, if they are necessary in physical science, then they must be necessary also in social science. The problem then arises that there appear to be no laws in social science, hence these explanations are impossible.

Another relevant issue in the context of qualitative methods is the Individualism–Holism debate, which is often dated back to Emil Durkheim's formulation of the holistic position and Weber's definition of the individualist position. Today the discussion of the two positions is typically divided into three different issues:

1. The ontological issue: Are there any irreducible social phenomena?
2. The explanatory issue: Are there any explanations that are irreducible to the individual level?
3. The semantic issue: Are there social concepts that cannot be defined by reference to individuals only?

Schön's approach about reflection-in-action and reflection-on-action is a process that reshapes what we are working on, while we are working on it. If something is not working correctly, then we “reflect” (a conscious activity) in the action-present. A critical aspect is the questioning of the assumptional nature of knowing-in-action, which is often left unexplained or unmentioned when we describe what we do, but is revealed in skillful performance. Reflecting-in-action is generally called forth when a surprise appears in the process of accomplishing the task. That surprise causes us to question how the surprise occurred, given our usual thinking process. As we work on a project, many of the “surprises”

we will encounter will appear because the knowing-in-action, on which we draw, is largely skills that we perhaps developed in other fields. Thus, the surprises occur because our old model does not work without modification for the new task. We reflect-in-action and find out what is different and how we can change our thinking to address this new task. We reflect-on-action, thinking back on what we have done in order to discover how our knowing-in-action may have contributed to an unexpected outcome. How do we reflect-on-action? First, we choose a critical incident, which could be something that we believe we finally did correctly after much ado, or something that even in the end we believe we did not do very well. Then, we think about the components of that incident from two different time frames. For example, if it is something with which we struggled and were proud of the accomplishment in the end, we will try to find that “light bulb” that helped us make sense of it and try to find out what was it like before that time and what was it like after that time. Next, we discuss the thinking process that either existed, or needed to exist, between the two time frames. What was not right in the knowing-in-action? We see if we can find specific examples to link in this discussion and draw on our resources (book, articles, etc.) that help explain the incident. Finally, we wrap it all up: What have we learned so next time our knowing-in-action (or at least our reflection-in-action) will be different and will reflect our new understanding?

In addition to these issues, we should also be aware of certain social phenomena for which either the quantitative methods or random sampling are inapplicable.

Mohawk Heroes in Structural Steel

During the 1950s, New York residents could occasionally read in the newspapers about a unique phenomenon, the Indians from the Mohawk tribe who worked as structural steel molders on high-rise buildings. The members of the Mohawk were described as “brave” and “physically stable.” Why were so many Indians of the Mohawk tribe molders? It was argued that, for some reason, the Mohawk Indians do not suffer from acrophobia. Morris Frieilich tried to understand the reasons for this lack of acrophobia among the Mohawks by investigating the Caughnawaga reserve, which was considered the home of the Mohawk Indians. During the participant observations, Frieilich carried a small notebook and a pencil, trying not to be obtrusive, and recorded the names of the people with whom he was talking, the topics of the conversations, the time, unusual events, and statistical data that he might have otherwise forgotten, such as salary, age, frequency of travels to the reserve, and the like. He revealed that the life of the Mohawk Indian is focused in the role of the

fearless hero who uses every opportunity to demonstrate disdain for the security, laws, authorities, and social conventions of other groups. According to the Mohawk culture, being a man equals being a warrior. In the original Mohawk society, Mohawk Indians were involved in battles of small groups, and the social role of the warrior was prestigious and socially rewarded. “The game of the warrior” during the 1950s equated to the danger of being a high-rise molder, expressing the continuity of the ancient Mohawk social structure. The warrior-molder formula was developed because of the similarity between the two modes of life and because being a “real” warrior was no longer possible; the modern parallel was the molder, who carried out dangerous tasks in a group of young men with an older leader (the supervisor).

In terms of social measurement, Frieilich’s research methods, compared to quantitative methods, are much more prone to subjectivity, personal interpretation, and bias as a result of his contacts with the study participants. His participant observations have not met Anastasi’s requirements of objectivity, standardization, and the representativeness of the behaviors being sampled. However, applying quantitative systematic methods not only was impossible, but would have never yielded the findings discovered by Frieilich. Unlike the quantitative approach, adopted by social scientists from life and hard sciences, qualitative researchers do not have any hypotheses to be tested in their studies. The question whether Frieilich “measured” the phenomena at hand remains open. There is no doubt, though, that he created knowledge.

Knowledge Creation without Measurement: Gay and Lesbian Couples

Gays and lesbians are a minority in the population in every society. One of the arguments used by mental health professionals who consider homosexuality a mental disorder is that homosexual individuals are usually incapable of establishing solid, lasting relationships. Yet little is known about gay and lesbian relationships. How many gays and lesbians live as couples? What is the average duration of a relationship? How many open vs. monogamous relationships are there among gay and lesbian couples? Research into gay couples is relatively new, and gay people remain a largely invisible segment of the population. Problems in obtaining study participants who reflect the diversity of this group continue to plague studies of homosexual relationships; some of the published research on same-sex couples is based on small samples, and many studies are only anecdotal. Statistics about the percentages of singles, married, and divorced men and women in different age groups is well-documented among heterosexuals, but a similar

database has not been established for the gay community. What can be asked, however, putting aside aspirations to generalize the results, is how (rather than how many) gay and lesbian couples live.

Americans live in a society where strong feelings against homosexuals are expressed openly and in almost every context. Legal, religious, and social institutions are constructed with a significant bias toward heterosexual marriage and, implicitly or explicitly, against homosexual partnerships. David McWhirter and Andrew Mattison have noted many of the ways that internalized social fears and prejudices toward homosexuals can create havoc within gay partnerships, and several other authors have discussed the role these social attitudes play in the relationships of gay couples. McWhirter and Mattison undertook an extensive investigation of 156 gay couples in order to ascertain patterns of change as the couples aged. They were dissatisfied with attempts to impose heterosexual models of the family life cycle on gay couples. Their interpretation of the data led to a developmental theory of male couples composed of six stages: blending, nesting, maintaining, building, releasing, and renewing. Loosely based on the age of the relationship, the model has been broadly used to describe the development of gay male couples.

Douglas Carl cautioned that gay men who come out of the closet as adults may become sexually involved with several men or may rapidly move in with someone they are dating, only to break up within a year. Carl equated this phenomenon to adolescents going steady, only without the restraints typical of the younger age. For most gay men, this period of unbridled sexuality subsides with time. Carl also noted that many gay couples join across racial, cultural, or socioeconomic lines. He speculated that this occurs because a smaller pool exists from which to choose partners in the gay community. Nonetheless, these couples will face many of the same strains that cross-cultural marriages experience. McWhirter and Mattison stated that limerence (intense sexual attraction that usually accompanies the early stages of intimate relationships) usually begins to decline after the first year or two of the relationship, and at the same time there is greater interest in "nesting" urges. This developmental change in the relationship is sometimes misinterpreted as loss of love or as ambivalence about remaining committed.

In conclusion, male couples have been shown to face unique challenges. However, many men feel that their love for one another is worth every sacrifice. Because the recognition of gay-couple relationships is relatively new in society and gays are a sometimes invisible segment of the population, hypotheses have not been developed on the basis of previous knowledge nor has a quantitative approach been applied; even so, knowledge of these groups of people has been created.

Conclusion

The question as to whether social sciences are "scientific," as life sciences or hard sciences are, continues to bother some social scientists (particularly those who deal with the philosophy of science). Those who doubt the "scientificness" of social sciences claim that social researchers, those individuals who study human behavior, cannot be objective enough because of the lack of the necessary distance or detachment between the researcher and those being investigated. There are social scientists and philosophers of science who think that human behavior should be measured like any natural phenomenon, and that what exists is only what can be observed and quantitatively measured. According to this view, the social scientist is supposed to be objective, and although the issue investigated could be subjectively selected, its scientific measurement should be value free. Measures that exemplify this positivist approach provide examples that demonstrate how the development of measurement instruments results in the generation of new questions and knowledge. Flaws in measurement instruments, and their correction, have an effect on the creation of knowledge (e.g., the development of emotional intelligence measures as a result of the inadequacy of IQ tests to predict success in real-life situations).

An opposite view argues that human behavior should be investigated only qualitatively, and that the efforts to measure it quantitatively leave important elements out of the picture. Moreover, there are phenomena that cannot be quantitatively measured because of various reasons. Attempts to investigate such phenomena qualitatively contribute to the creation of new knowledge. In some instances, as in anthropology, this contribution remains qualitative; in other cases, qualitative measurements can be a basis for formulating hypotheses that can be tested by quantitative measures.

Knowledge Work

Robert D. Austin

Harvard Business School, Boston, Massachusetts, USA

Glossary

agency theory A theory that addresses the dynamics of an agency relationship, with particular emphasis on the alignment (or lack thereof) of incentives between principal and agent, and on the use of measurement coupled with payments to adjust incentives.

agent Someone who does work on behalf of another, a principal, in exchange for payment.

attributability The degree to which a measurement can be attributed to some causal object—an individual, a group, or a process.

evaluability The degree to which the normative adequacy of a measurement can be judged.

measurability The degree to which important aspects of the observed work yield to cognitively simple and relatively compact quantification.

observability The degree to which activities involved in work are easy to see, understand, and evaluate.

precision The degree to which a change in a measure indicates change in the underlying quantity of interest rather than random disturbance.

principal Someone who pays another, an agent, to do work.

reliability The degree to which a measurement indicator retains, over time, its integrity as a representation of an underlying quantity of interest.

sensitivity The degree to which a change in an underlying quantity of interest tends to change a measurement indicator.

separability The degree to which the outcomes or effects of the work of one individual or group can be differentiated from the outcomes or effects of the work of another individual or group.

Knowledge work is work in which important value-creating transformations occur in the realm of ideas or

in which substantial amounts of productive activity is intellectual rather than physical; as Drucker put it in 1959, “work that is based on the mind rather than on the hand.”

It is now widely accepted that organizations’ abilities to create, communicate, retain, and use knowledge are critical to their success. In high-technology sectors of industrialized economies, rapid growth has underscored the economic importance of knowledge work and created entirely new occupational categories—network manager, software engineer, and biotech researcher, to name but a few. These knowledge workers produce economic value primarily by manipulating thoughts, ideas, and symbols. Their work has distinctive characteristics that affect our ability to measure it. Specifically, knowledge work is difficult to observe because its materials and products are intangible and complex. Its processes are highly interdependent, which leads to difficulties in attributing outcomes to specific people or causal factors. Because the work is often highly specialized, it is difficult to evaluate; often managers (and other observers) of knowledge workers cannot do what they do and are not qualified to judge the work outcomes, especially interim work products. In addition, innovation—by definition, doing or making something different—is *the* key to value creation in much knowledge work; this fact presents challenges in that previously established forms of measurement may not adequately capture what is novel and important in such work.

Categories of Difficulty in Measuring Knowledge Work

There are three categories of difficulty in measuring knowledge work. First, knowledge work is less observable than physical work. The activities involved in loading coal

into a rail car are easier to see, understand, and evaluate than the activities involved in progressing toward a successful database design. Although the problem of observability has long been known and studied, it takes on new depth when the activity being measured is intangible thought-stuff.

Second, the motivation of knowledge workers is more reliably intrinsic than it is for many physical workers. Knowledge work is often idiosyncratic and oriented toward creative activities and problem solving; hence, it is interesting for workers. Physical work is more often repetitive and oriented toward compliance and, hence, less interesting. The possibility that strong intrinsic motivation can be relied on to direct workers' activities requires rethinking research based on less optimistic assumptions about human motivation (such as economic agency theory) and suggests additional dimensions of measurement relevant to work outcomes.

Third, it is the nature of knowledge work that a high degree of individual capability in the worker is often the critical factor in achieving successful outcomes rather than, as with much physical work, his or her consistent compliance with a plan or efficient participation in an externally programmed system. An excellent technical support person is excellent not because of his or her performance on well-known and well-understood tasks but rather because he or she is good at the exploration, knowledge creation, and analysis needed to perform excellently in solving unprecedented problems or in other vaguely defined tasks. In knowledge work, talent, skill, and knowledge (TASK) differentials matter a great deal; performance is often more about what a worker can do than about the level of effort he or she exerts. Levels of talent and skill interact strongly with performance and therefore must also be measured.

Although problems in the second and third categories are important, the focus here is on the first category, problems of observability. This is because problems of motivation and TASK differentials often manifest themselves in terms of observability.

How Economists Approach Work Observation Difficulties

Problems of discerning performance in social phenomena have been much studied. Economic agency theories, recent and direct attempts to address issues of observability, are notable for their growing prominence in research and practical contexts; they are, for example, employed in debates about how business executives should be paid. The foundational agency model was introduced in 1973 by Ross and refined in 1979 by Holmstrom; all subsequent models have been variations on this

Ross-Holmstrom (R-H) model. Although such models ultimately fail to capture the full complexities of the problem of measuring knowledge work, they are a useful starting point in considering this subject because they distill observability problems into their simplest, most fundamental elements.

The R-H model depicts an organization in highly simplified form: two individuals and the contractual relationship between them. A principal has control over resources and hires an agent to transform resources into output with money value. The principal tries to maximize profit—the difference between the value of the agent's output and the payment required to induce effort from the agent. The agent's motivations are also self-interested and simple—he or she wants to maximize his or her income while minimizing effort and avoiding risk. The interests of the two are therefore opposed. The principal wants to extract as much effort as possible from the agent while paying him or her as little as possible. The agent wants to do as little work and bear as little risk as possible while being paid as much as possible.

The principal cannot directly observe the agent's work. This assumption is justified by noting that (1) often it is not feasible for a manager to watch an employee at every moment, and doing so would in any case obviate the efficiencies sought in hiring the agent; and (2) often workers are hired for specialized abilities that the principal does not possess and has only limited ability to understand and evaluate. Because the principal cannot observe how much effort the agent is exerting, the principal cannot compensate the agent on the basis of how hard he or she works (his or her level of effort). The principal does have available, however, a signal of the agent's effort level, although that is complicated by a random component (representing factors that are beyond the agent's control; e.g., rainstorms that depress a salesperson's performance in a given week). The signal's random component has distributional properties such that unfavorable signal outcomes become less likely when the agent's effort level increases. Hence, the signal is statistically, although not directly, indicative of the agent's effort level and can serve as a measure of performance. There is also an assumption, often implicit, that higher levels of effort by the agent will make more valuable work outputs more likely.

An optimal compensation schedule based on the signal of agent effort can be derived from this theoretical setup. The schedule maximizes expected profits for the principal and expected utility for the agent, subject to a constraint that ensures that the agent expects enough reward to remove him or her from the labor market. The consideration of the properties of this schedule produces the following conclusions.

1. The agent demands additional compensation for bearing the risk associated with the probabilistic signal

of his or her performance; thus, measuring and rewarding performance is more costly for the principal than if effort could be observed directly because of the agent's risk aversion.

2. The outcome is Pareto inferior to the outcome that would result if direct observation of effort were possible; that is, the principal and agent would be collectively better off, and neither would be worse off, if effort were directly observable; hence, there is economic value lost due to observation difficulties.

3. The optimal compensation contract includes a variable component that increases with the signal (the measure of performance).

This last conclusion is offered both as an explanation and an endorsement of increasing-in-output payment schedules (such as sales commission systems).

Banker and Datar have broadened this discussion of observability to include problems of precision and sensitivity of the performance measure, which may complicate the discernment of the agent's underlying effort levels and prevent the creation of effective compensation schemes. Precision, roughly defined, is the degree to which movement in the signal indicates movement in the underlying quantity of interest (e.g., effort) rather than random disturbance. A very low precision signal is not useful because too many of its changes are due to random noise. Sensitivity, roughly defined, is the degree to which a change in an underlying quantity of interest (e.g., effort) tends to change a measurement indicator. A measure that is very low in sensitivity is not useful because even large movements in the underlying quantity of interest result in small, difficult-to-discern movements in the signal. The fields of statistical process and quality control address related issues involved in separating signal from noise in repetitive and stable industrial processes.

How Behavioral Scientists Approach Work Observation Difficulties

In contrast with the rigorous theorizing of agency economics, behavioral science has tended to study observability via detailed, often field-based, empirical examinations. Early work focused on pathological phenomena. In 1963, Blau conducted research on government bureaucracies and found that well-intentioned measurement programs were consistently dysfunctional. In one study, agents at an employment office reacted to a system that measured job-applicant interviews by shifting most of their efforts to interviewing, away from locating new job opportunities; fewer job placements resulted, even though that was the organization's *raison d'être*. Office

managers then enhanced the system to include eight measures, some of them ratios, such as "percentage of interviews that resulted in job referrals." At first the enhancements seemed to work, but Blau's replication of the study revealed that earlier dysfunctional behaviors had been replaced by more sophisticated dysfunction. Agents "engaged in outright falsification . . . by destroying at the end of the day those interview slips that indicated that no referrals to jobs had taken place." Further attempts to fix this system by adding many more measures were also ineffective; employees always adapted and dysfunction resulted.

As described by Blau, the pattern of dysfunction that resulted from observability problems had three unfortunate characteristics. First, dysfunction seemed inherent in the attempt to measure these administrative organizational activities; regardless of the incentive effect designers of a measurement system intended—regardless even of whether they meant to create any incentive effect at all—unintended incentive effects appeared. Second, dysfunction was persistent; it resisted efforts to eradicate it by adjusting the measurement technology. Finally, dysfunction was hidden from the designers and users of the measurement system, often until some catastrophic failure occurred; the question "how do you know your system is not dysfunctional?" could not readily be answered. In 1956, Ridgway summarized the findings of several studies that reported similar dysfunctional patterns by concluding, "quantitative performance measurements—whether single, multiple, or composite . . . have undesirable consequences for overall organizational performance."

This persistent dysfunctional pattern has often been explained as resulting from incompleteness in measures. A measurement system suffers from incompleteness when measures do not capture all critical dimensions of productive work. (A dimension of activity is critical when no value can be produced without devoting effort to it.)

The R-H model offers no explanation for the pattern of dysfunction that results from incompleteness in measures because it assumes implicitly that measures are complete. In fact, the increasing-in-measured-output payment schedules that seem implicated in the pattern of dysfunction identified by Blau (and others) seem to be specifically recommended by the R-H model. The two streams of research were at odds on this point.

Economists have since modified their models to address the problem of incompleteness and consequent dysfunction. In 1991, Holmstrom and Milgrom modeled a situation in which the agent allocates effort across tasks, some of which are measurable and some of which are not. They show that if one of the unmeasurable tasks is critical to value creation and rewards increase with measurements on measurable tasks, then dysfunction will result. If the agent is willing to do valuable work without measurement-linked rewards, then letting him work for

a flat fee is the best you can do with incomplete measures. Milgrom and Roberts concede that this result “imposes a serious constraint on the incentive compensation formulas that can be used in practice.” Holmstrom and Milgrom have argued that the measurability of specific effort dimensions may be a determining factor in work efficiency, organization, and organizational structure.

Knowledge Work and Observability

As Holmstrom and Milgrom have shown, if the problem of completeness remains unsolved, then solutions to the problem of unobservable effort that tie variable payments to signal outcomes (e.g., output measures) are dysfunctional. Furthermore, because knowledge work tends to be oriented toward innovation and problem solving, it may benefit from efforts on dimensions that were unanticipated. Knowledge work is multidimensional, and the criticalness of dimensions often evolves dynamically. To put this another, less formal way: in work that is about smartness, how smart someone works (i.e., how cleverly one allocates effort across tasks) is necessarily of great importance. For these reasons (and others), the problem of completeness is especially prominent when the work being performed is knowledge work.

Prescriptive works on the subject of organizational measurement often include recommendations that measures be as complete as possible. One popular treatment, for example, urges that organizational scorecards be balanced by including nonfinancial as well as financial measures, in categories that more exhaustively cover what really matters to a business. Although balance might not be precisely the same thing as completeness, the evoked intuition is often the same. Although recommendations of balance or completeness may be a step in the direction of improved practice, it remains important to understand when completeness can be achieved and in which work settings.

Observability issues that arise in physical settings have typically been framed in terms of asymmetry in information about workers’ hidden acts (usually effort allocations). Knowledge work generates more pronounced asymmetries, based not only on information asymmetries but also on talent, skill, or knowledge asymmetries between a manager and those he or she manages. A manager who has the same information as a worker can still lack the expertise needed to understand, attribute, evaluate, and act on what he or she observes. Hence, observability problems that afflict knowledge work may be particularly severe and persistent.

Knowledge asymmetries and resulting observability problems cannot necessarily be designed away.

Prescriptive treatments of organizational measurement often focus almost exclusively on the measurement technology—on “choosing the right measures”—as if observability were entirely dependent on the shrewdness of measurement system designers. In fact, observability problems derive ultimately from the characteristics of the specific organizational setting that are the site of a productive act—not just from the design of the measurement technology.

Persistent observability problems common in knowledge-work settings can be decomposed into three categories. Difficulties in any of these categories can suffice to undermine performance measurement objectives.

1. Measurability is the degree to which important aspects of the observed work yield to cognitively simple and relatively compact quantification. If we cannot measure what we care about in a way that is meaningful, with acceptable confidence in the validity of the measure, then measurement becomes more difficult. In such situations, less direct proxy measures are often sought, which creates potential for problems in the other two categories. For example, the quality of work during software development is notoriously difficult to measure. Counts of defects in the final product, a common measure, are at best only suggestive of quality as a customer defines it, which is in terms of suitability for the customer’s evolving intended purpose.

2. Attributability is the degree to which a measurement can be attributed to some causal object—an individual, a group, or a process. Measuring something without knowing (or at least confidently hypothesizing) its relationship to a causal action or object is not very useful. Moreover, the ability to measure a thing does not assure that the thing can be easily or usefully attributed to an actionable underlying cause. Often, there are important interdependencies in knowledge work; it is rarely easy, even after the fact, to say who contributed what to the value in the final product.

3. Evaluability is the degree to which the normative adequacy of a measurement can be judged. Measuring and attributing without knowing whether the measurement reflects favorably on the object of attribution is not very useful. Standards and benchmarks assist with evaluability issues. But the ability to measure and attribute a thing does not assure that the thing can be easily or usefully evaluated. Much knowledge work results in products that are distinctive and, in general, the greater the distinctiveness, the lower the evaluability.

Prescriptive treatments and economic models have often assumed away these problems, especially the second and third. The R-H model, for example, deals in a limited way with measurability in that the agent’s effort expenditure cannot be directly observed. Because there is only one agent, however, there are no issues of attributability.

Evaluability is assumed, in that signal and work outputs are usefully related and effort allocation occurs along a single dimension. More effort is good; less effort is bad.

The situation is usually considerably less simple or convenient in knowledge-work settings. Because much of the work is intangible and conceptually complex, measurability problems are common. Proxy measures are not obvious, and usually there are questions about the attributability of a chosen proxy measure. The collaborative and interdependent nature of much knowledge work makes it difficult to draw lines of causality, especially when progress is evolutionary and proceeds at an uneven pace. Determining who or what was responsible for a favorable or unfavorable outcome can be difficult if not impossible for an idiosyncratic, evolving, or poorly understood work process. These same difficulties complicate evaluability. Activities and outputs may be unprecedented. No obvious standard of evaluation may exist. Comparison with what was done last time may not be meaningful because of changes in process and the work environment since then.

Measurability issues necessitate the use of proxy measures in place of true measures—measures of what the organization truly values. Once proxy measures are introduced, questions about their relationship to true measures arise. Attributability concerns complicate attempts to establish persistent relationships between proxy and true measures, leaving workers latitude to engage in dysfunctional behaviors. Problems of evaluability hinder the detection of dysfunctional behaviors as the pattern unfolds.

Several characteristics of organizational situations that have often been observed to complicate work measurement create particularly difficult problems for knowledge-work measurement. Measures of knowledge work are more likely to be incomplete due to these factors.

- **Context insensitivity.** Because measurement designers may lack vital knowledge about the work, contextual variables that have independent effects on proxy measures may remain unknown. Even if they are known, they may be ignored because of the conceptual complexity involved in measuring them. Ways of affecting proxy measures that are known to workers but not to measurers create potential for incompleteness and dysfunction.

- **Separability.** Because of knowledge asymmetries and the collaborative nature of some knowledge work, measurement users may have difficulty separating the work of one individual or group from that of another because the work is (or seems) so interdependent. Consequently, workers may have the ability to move proxy measures in what seems like a favorable direction by shifting work difficulties onto other workers. Needless to say, a system that rewards such behavior does not foster cooperation among workers and may result in undesired outcomes from the overall collaborative activity.

- **Reliability.** For knowledge work that is rapidly changing, attribution and evaluation may become difficult because comparisons of a process from repetition to repetition are not obviously valid. The degree to which measures succumb to problems of context insensitivity and inseparability may change from repetition to repetition. Empirically discovered correlations between measured quantities and underlying phenomena may not persist. If the measurement process is a statistical one, the problem manifests itself as a fundamental incoherence in the population definition.

- ***Ex post* causal ambiguity.** Knowledge asymmetries provide latitude for variation in *ex post* interpretation of events. If a complex computer error shuts down a production facility, for example, there may be only two or three people who truly understand what has happened. The parties involved may take advantage of this fact by lobbying for specific interpretations of measurements and events. This practice has a destabilizing effect on efforts to establish underlying causal attributions.

In established or more physical measurement settings there is often a consensus on the causal models that underlie measurement. In many knowledge-work settings, no such consensus exists. Moreover, the extent to which such a consensus is realizable may be limited by the rapidly changing nature of knowledge work.

Measuring Knowledge Work in Research

Many of the difficulties that afflict managers as they attempt to measure the performance of knowledge workers also carry over to researchers as they attempt to understand the same work. Researchers have attempted to overcome the observability difficulties inherent in knowledge work in a number of ways.

Simon and others conducted comprehensive investigations in 1979 into the nature of human problem solving by using talk-aloud protocols, in which research subjects verbalized their thoughts while attempting to solve a problem. Although these experiments have led to insights into human cognition, they provide limited assistance in quantifying important aspects of knowledge work; most such studies were not conducted in real work settings, and observations often did not yield compact quantification. Also, human problem solving, although a significant component of knowledge work, by no means exhausts value-producing activities. For example, many creative activities involved in knowledge work may not be usefully conceptualizable as problem-solving activities.

In 2002, Amabile *et al.* pioneered empirical methods for examining creative activities by engineers through

several means that vary in their obtrusiveness, including close examination of their daily work products, coding of subjective records kept by workers (such as diaries), and direct observation of work processes. In the tradition of Blau, ethnographers have continued to apply their methods to achieving an understanding that takes into account the rich contexts and deep expertise levels that exist in knowledge-work settings. Austin and Devin have suggested in 2003 a formalized approach to analyzing differences in subsequent versions of knowledge-work outputs (e.g., software) as a means to gaining insight into work processes. Ways of gaining empirical insights into the nature and essential characteristics of knowledge work are evolving; this is likely to continue in the near future.

Laboratory Experiments in Social Science

Murray Webster, Jr.

University of North Carolina, Charlotte, North Carolina, USA

Glossary

condition (Theoretical) Abstract and historical fact or given, e.g., “task-focused group,” “motivated actors,” “full knowledge of payoffs.” (Experimental) State of a theoretical condition under examination, e.g., “Condition 1, higher status for self than other.”

design Abstract features of a situation intended for an experiment. E.g., “The design included four conditions, differing by status position of the focal actor, in which all actors were task-focused.” Cf. operation.

operation Specific structural fact and action during an experiment. “Design” refers to abstract criteria; “operations” refers to observable facts. E.g., “The operational measure of satisfaction was marking above the midpoint on the questionnaire item.”

phase Temporal part of an experiment, often tied to independent and dependent variables. E.g., “Independent variables regarding the task and each subject’s status position were introduced in phase 1; dependent measures of behavior were recorded in phase 2.”

variable Structural fact and action taking different values during an experiment. Independent variables are controlled by an experimenter to create the experimental design; dependent variables are uncontrolled and are measured to test predictions.

Experiments entail creating and manipulating independent variables, and, following those operations, measuring the dependent variables. The temporal ordering distinguishes experiments from other methods. For instance, in surveys, responses (dependent variables) are analyzed by statistically controlling the independent variable(s) *after* data collection. Laboratories are physical locations for data collection. In most cases, a laboratory’s design allows optimal conditions for accurately measuring changes in dependent variables, often including arrangements to

improve visibility and technology to present information and record behavior and other responses.

Role of Experiments in Social Sciences

Contemporary social science methods are diverse, including unstructured, structured, and participant observation; surveys of attitudes or behavior; content analysis of written or photographic material; analyses of archived data; and different kinds of experiments. Experimental types include those conducted in the field (e.g., large-scale drug trials), in contained natural settings (e.g., new classroom techniques, employee incentive programs), and in a laboratory. Data collection thus uses observational, survey, or experimental methods and data from each type can be subjected to various analytic methods. Surveys and experiments lend themselves to inferential statistics, whereas observational methods lend themselves to qualitative analytic techniques. However, qualitative analyses of some experimental data, such as postsession interviews, may be important and inferential statistics are appropriate for some kinds of observational data, such as records of repeated events.

An experiment is a simplified constructed reality in which an investigator controls the level of an independent variable(s) before measuring a dependent variable(s). Attempting to reduce or eliminate extraneous factors, deliberately creating different levels of independent variables, and then measuring effects permits strong inferences, though not proof, of causal relationships. Laboratory experiments developed first in the natural sciences (see [Table 1](#)), becoming the standard research method whenever they can be used (astronomy and meteorology, for instance, also use other methods). Social

Table I Some Historical Uses of Experiments in Social Sciences

Psychology has the oldest tradition of experimental methods in the social sciences. Around 1900 in Russia, Ivan Petrovich Pavlov, trained as a physiologist specializing in the digestive system, naturally turned to an experimental laboratory for his famous studies of the relationship between time of bell ringing and saliva production. U.S. psychologists Edward L. Thorndike at Harvard University and J. B. Watson at Johns Hopkins University developed laboratory methods for their studies, and experimental methods have become standard in many areas of psychology.

In social psychology Solomon Asch studied conformity and Muzafer Sherif studied norm formation and transmission in laboratories. Soon afterward, Leon Festinger and his many colleagues and students investigated social comparison and cognitive dissonance. Both editions of *The Handbook of Social Psychology* contain didactic chapters on experimental methods.

In economics, Chamberlin introduced laboratory studies of markets in the 1940s, Siegel and Fouraker analyzed games, and von Neumann and Morgenstern pioneered the study of rational choices. Davis and Holt, and Kagel and Roth, provide comprehensive overviews of experimental economics.

In political science, many experimental studies were stimulated by Thomas Schelling's theory of negotiation strategies. Axelrod studied cooperation experimentally using rational choice and other approaches.

In sociology, Robert Freed Bales studied discussion groups in his Harvard University laboratory beginning in the 1940s, and Joseph Berger, a research assistant for Bales, helped to found a continuing tradition of experimental research at Stanford University.

science borrowed and adapted laboratory methods and there has been dramatic growth in the use of this method, although other methods, primarily surveys, are still more common.

Sometimes people wonder whether results would differ if an experiment were repeated with a different subject population. Results would differ, though that fact may well be irrelevant to the researcher's real interest. For instance, Swedish, Japanese, and Argentine citizens might well exhibit different rates of overall influence in

a laboratory conformity experiment, but so what? It does not matter whether Argentines or Swedes accept influence in contrived situations. One might want to know how they act in everyday settings, but the laboratory is hardly an everyday setting. Laboratory resources are too valuable to waste on whimsical explorations of "What would happen if . . . ?"

However, demographic characteristics of a population, such as gender, nationality, or skin color, may operationalize theoretical factors, in which case laboratory

results are informative. For instance, one might use gender as an instance of the theoretical construct “status characteristic,” or one might want to know the extent to which fairness norms are important in experimental participants’ social systems. In 1980, Foschi distinguished experimental limitations of culture from theory-testing uses of cultural facts and discussed some theoretical uses of cross-cultural comparisons.

A well-designed experiment tests hypotheses contrasting two or more possible outcomes, derived from a theoretical base. Those may include a theoretically derived hypothesis and a null hypothesis, or contrasting outcomes that would support contrasting theories. The theory is the abstract template for the experimental design. Experimental design means creating an alternate social reality—a theoretically guided virtual reality—that creates independent variables and facilitates measurement of dependent variables. Experiments are somewhat similar to theatrical performances and an experimenter is in some ways similar to a director. In complexity and difficulty, the parallels are obvious. In other ways, however, laboratories are unlike theaters. Participants in an experiment must truly believe that the created situation is real; they must interact, rather than adopting the largely passive role of theatrical patrons. Nuance, individuality, and variable performance are desirable in the theater because they make characters seem more “human” and “interesting.” In an experiment, uniformity and standardization become crucial; variability and measurement variance (within conditions) are unwanted. Subtlety, complexity, and ambiguity often are prized in the theater; in experiments, everything must be obvious and clear. Experiments are often less exciting to watch or act in than theater. Yet “boring” would be irrelevant. The excitement of experiments comes from puzzle-solving and from the challenges of producing the design and assessing theoretical ideas in it.

Designing an effective experiment is difficult and time-consuming. Survey and observational research is heavy on the back end: it may take years before a data set has been fully analyzed and interpreted. Experimental research is heavy on the front end. It may require months, even years, to construct a setting and operations. However, experimental data usually are simple and readily interpretable. The main “work” of laboratory experiments takes place before the data come in. What experimental data show—their theoretical meaning—is often clear as soon as they appear.

Uses of Experiments in Social Science

Appropriately used, laboratory experiments are the best method to develop and test many kinds of theories.

However, not every research question is appropriate for experimentation. For instance:

- Experiments are not useful when a theory’s constructs cannot readily be created. For instance, theories of the cultural antecedents of modern attitudes or of the relation of family structure to educational attainment are not easily translated into operations permitting experimental assessment.

- Experiments are not useful for analyzing existing data and secondary analyses of experimental data seldom are as useful as those for which an experiment was designed. Meta-analyses of comparable experiments, however, can be very useful.

- Experiments are not useful for characterizing populations. Social science experiments, like chemistry experiments, are highly unusual situations, unlikely ever to appear in natural settings. Except for what experimental data show regarding a theory, the data themselves are uninteresting.

- Experiments usually are not useful absent a testable theory. Without an explicit theoretical question, there are no guides as to which features of the experiment, or which outcomes, are significant. Any analysis is open to infinite alternate interpretations, with no way to choose among them. In other words, one might “see what happens,” but one will have no idea why, under what conditions that effect appears, or whether it ever will recur. Without a guiding theory, too many experiments are needed to make any real progress. Thomas Edison, it is said, tried out 997 materials to find a suitable filament for light bulbs, but his efforts were unusually well funded. Theoretically driven experiments might have achieved the result more quickly.

However, when appropriate—which means when used to test derivations from a theory—experiments can be enormously useful.

- Experiments generally offer the most convincing evidence in favor of theoretical explanations. No other kind of data matches that from experiments for being directly relevant to the ideas under test and no other data suggest causality as conclusively as experiments do.
- Experiments, being deliberately constructed observational settings, can offer unobstructed measurements. For example, Bales-type discussion groups typically work in laboratories with one-way mirrors, videotapes and sound tapes, computerized voice analyses, and a variety of paper and pencil recording mechanisms that offer optimal data collection. Comparable groups in natural settings—juries, committees, sports teams, etc.—entail many observational difficulties and compromises. Furthermore, such natural groups always include

unmeasured amounts of personal history, biases, other agendas, and the like that a researcher is unaware of. The best control for unknown factors is random assignment to experimental conditions, which is virtually impossible in naturally occurring groups.

- Related to the above point, experiments permit a high degree of isolation of processes that may be confounded with other processes in a natural setting. For instance, in a laboratory it is possible to study, say, influence caused by gender differences independent of many other factors that are—for this purpose—irrelevant, such as liking, romantic attraction, or appearance.
- Experiments permit studying unusual or rare situations that, nevertheless, may be highly informative for some theory. For instance, many experimental studies of status processes induce almost continuous disagreements among work partners, something that seldom if ever occurs among real work groups, because influence is a proven useful laboratory measure of status effects.

Experiments are artificial and that is the great strength of this kind of research. Well-designed experiments include *all* and *only* those features of a situation that are most informative for the ideas under test. Experiments readily permit random assignment of individuals to experimental conditions. They permit optimal measurement, often using unusual technology and other techniques. Experiments do not *directly* tell about the natural world, where several social processes tend to occur together and where measurement may be difficult or impossible. Experiments are ideal for showing how specified elements of social structure and social process affect one another and isolating conditions under which the effects appear.

At one time, social science experiments sometimes were criticized for being artificial. That criticism never arises in developed sciences where experiments are the dominant empirical method. What happens in a chemistry laboratory bears little resemblance to chemical reactions in nature—the laboratory situation is simpler, it may involve elements and compounds that do not exist in nature, and it simplifies the complexity of a natural environment. Chemistry experiments are artificial. They are valuable for what they tell about theoretical questions under investigation. The theories, after laboratory confirmation, may be applied outside a laboratory, but application is different from theory development and theory testing.

Elements of Experimental Design

Effective experimental design begins with a list of a new experiment's essential abstract features. As noted

above, a theory is the template for experimental design. Experimental design begins with the theory's scope conditions—telling classes of situations to which the theory claims to apply—and antecedent and initial conditions describing specific instances for testing the theory's predictions. Fully stated hypotheses have the form "Given SC_1 and SC_2 and AC_1 , if X_1 and X_2 , then Y ." Here, scope and antecedent conditions are given as SC 's and AC 's whose values are constant across experimental conditions, " X 's" are independent variables whose values are controlled to test hypotheses, and " Y 's" are dependent variables that will be measured as data.

Individuals will be assigned to experimental conditions at random, to control for the variety of unwanted sources of variance: history, prior experiences, etc. Next, an experimenter turns to devising operational measures of predicted outcomes. For instance, bargaining experiments may be developed to test a rational choice theory of behavior that claims as a scope condition to apply to all individuals who want to maximize winnings. An experiment testing derivations from such a theory would need a provision to motivate participants, such as highly desirable winnings; money would be appropriate here, whereas game points might not be. Whether behavior conformed to predictions might be measured as each participant's winnings or some other appropriate instance of the predicted outcomes.

Sometimes investigators are surprised to realize that information that they thought was obvious in a design got overlooked by a number of participants. For instance, if it is crucial for participants to know the gender of a real or simulated interactant, that information must be presented clearly and emphatically. Gender, like all other conditions, must be created fully rather than minimally. If one's partner is to be a male, a picture creates the condition more powerfully than a verbal description. A male wearing obviously gender-typed clothing and saying he has gender-typed hobbies produces a more uniform effect than leaving the gender characteristic partly undefined. A good rule of thumb for experimental instructions is to repeat every significant fact *three* times. For some, the repetition is excessive, but spurious variance is reduced to the extent that everyone shares the same information within an experimental condition. Pretesting is essential (see below) to ensure that none of the instructions are reactive, for instance, that the repetition is not unduly annoying and therefore excessive.

Once an experimental design incorporates scope, antecedent, and initial conditions, attention turns to dependent variables and their measurement. The first question is what consequences the investigator has predicted from combinations of circumstances; that is, what would constitute predictive success in this situation? Often a theory predicts several different sorts of consequences and an investigator will select one or a few of them as most

informative or most practical to measure. Selecting among alternatives is partly a matter of taste and partly governed by ease, cost, measurement, and other practical considerations. In selecting dependent measures, it is wise to keep these concerns in mind:

- Is a measure unambiguous and clearly related to the predictions? For instance, in bargaining experiments, the value of winnings makes a better measure than participants' subjective satisfaction because measuring winnings is straightforward, whereas measuring subjective states requires inferential leaps.
- Is an experimental situation clear and simple? Complex situations may be harder for participants to understand, thus increasing unwanted variance in the data. Even worse, complex situations may trigger other processes, not of interest at the moment, that affect the dependent variables. For instance, participants might, in addition to winnings, be concerned with self-presentation ("Do I seem like a nice person?"), equity ("Am I treating the other person unfairly?"), or hostility ("I'm going to show that guy I don't like him, even if it costs me a few points!"). Competing processes may obscure the effects of theoretical processes under test.

Example: An Experimental Investigation of Gender and Performance Scores

A laboratory experiment by Martha Foschi and her students illustrates many features of good design. Researchers investigated consequences of status (instantiated by gender) and performance assessment (whether a particular score was "good," "average," etc.) in task groups.

The theoretical foundation for this work is the family of theories of status generalization. Those theories take as scope conditions that individuals are task-focused and collectively oriented, and within those conditions, they seek to explain behavioral inequality, such as influence from the structure of status relations in the group and evaluative information provided to interactants. The main outcome is performance expectation states, a theoretical construct operationally measured by resistance to influence in cases of disagreement.

Foschi *et al.* took the following questions (among others) for research:

- (1) In status-homogenous (e.g., same sex, age, skin color) dyads, do individuals form expectations consistent with evaluative feedback during interaction?
- (2) Do women and men form different levels of self-expectations, given the same structure of status relations and evaluative feedback?

- (3) How do self-expectations affect the standards that individuals develop to assign someone high or low ability?

Participants were 156 Canadian college student volunteers who served in same-gender dyads, with 39 dyads of each gender. To create the scope conditions, the researchers told participants that they were working on a team task, judging pairs of abstract patterns to tell which of each pair contained more white area. They also told them that the team with the best score at the end of the project would receive a cash bonus.

The experiment had two phases, corresponding to inducing independent variables (phase 1) and measuring dependent variables (phase 2). It had six conditions. Because within a dyad, members were equated on age, gender, and educational level, they began as status equals. In two conditions, individuals received no evaluative information as they worked on the task. In other conditions, participants were told that they received either high scores (15 correct out of 20) or low scores (9 out of 20), and in some conditions, high or low scores were also announced for their partners. Thus, phase 1 instantiates scope conditions (task focus, collective orientation) and antecedent and initial conditions (status equality, evaluative information).

Phase 2 measured performance expectations behaviorally and ability standards subjectively. For a behavioral measure of expectations, participants work on a set of two-stage problems, exchanging "initial choices" and making private "final decisions." Experimenters control feedback from partners such that the partner's initial choices appear to disagree with the participant's. The proportion of times a person resolves disagreements in favor of self measures her or his relative performance expectations. For standards, Foschi *et al.* distributed questionnaires asking how many trials participants would require for a convincing assessment of ability level and the percentage of correct answers required to infer either high or low ability for a person. Responses give subjective assessments of standards used by people in different conditions of the experiment.

Foschi *et al.*, of course, were crucially interested in results of this experiment, but this article does not focus on the hypotheses, which were confirmed. Instead, it emphasizes the translation processes that take investigators from abstract considerations, such as task focus and evaluative feedback, to concrete manifestations in the experiment and then back again from proportion of influence rejection and marks on questionnaires to interpretations in terms of expectation states and ability standards. Theories and interpretations of results use abstractions; experiment use substantive, concrete instances of them.

The task of instantiating abstract ideas requires imagination and role-taking. Participants do not know the

abstract theoretical ideas under test; they understand their situation as a concrete instance. Creating independent variables experimentally entails finding ways to instantiate them in concrete features of a situation. Here, creating self-expectations (as required for the third research question above) meant administering a plausible test of ability and returning believable “scores” to the participants. Similarly, dependent variables must be created operationally. In this case, rejection of influence has proven a good way to assess relative performance expectations and questionnaires are widely accepted as means to understand respondents’ subjective experiences. Both measures have been widely used in other experimental settings, increasing confidence in their adequacy.

Foschi and associates employed two other crucial kinds of assessments of the design: manipulation checks and postsession interviews. Various checks are employed to assess whether participants understood the situation as the experimenter intended. For instance, researchers asked participants how many correct answers they and their partners received in phase 1. Those given high or low scores (15 or 9) all recalled exactly those scores. Furthermore, the researchers asked them to rate those performances on scales from Poor (1) to Excellent (6) and found the mean scale points ordered as they should be: 4.73 for those told 15/20, 3.45 for those given no feedback, and 2.34 for those told 9/20. Postsession interviews provide additional information about beliefs and motivations. They also allow an experimenter to inquire about any surprising behavior or other occurrences during an experimental session and allow participants to ask about any aspects of interest to them. Foschi *et al.*’s participants all recalled perfectly that they and their partners were of the same gender, age, and education. The postsession interview provides another opportunity to ask about task focus and undesirable possibilities, such as suspicion that the disagreements did not truly originate with a participant’s partner. Investigators fully debriefed the participants, explaining all aspects of the study to them and answering any questions they might have.

Assessing Experimental Design and Operations

Effective design is not subtle, and effective instructions are deliberately repetitious. Working from a list of things that participants need to know, investigators design an experiment to make those points emphatically, to make them salient and memorable. Clarity and uniformity are essential.

Effective experimental design requires great attention to detail and creative imagination, but it never is possible to anticipate the effects of every design detail. Therefore,

assessment is essential; experimenters must use available measures of success or create new measures to tell whether they have created all intended features of the situation. Pretests, checks, and postsession interviews are the main ways to monitor success.

Pretesting “tries out” a design to assess whether it functions as required. At the pretest stage, it is important to gather as much information as possible about possible problems and to be open to possible unanticipated interpretations by participants. Pretesting may involve extensive questionnaires, interviewing, and other means to obtain information on aspects of experimental operations. Once pretesting shows a design to be satisfactory, the experiment may be stripped of those assessment measures to save time and to focus on theory testing.

Checks assess at each experimental session how successfully various conditions were created. It is important not to take for granted that some feature that seems obvious to the investigator also will be apparent to every experimental participant. For instance, if it is crucial for a participant to know a real or simulated interactant’s age or gender, not only should the design stress those points, but the design should allow for assessing whether participants notice, understand, believe, and remember crucial facts.

Postsession interviews generally have three goals: (1) additional manipulation checks and follow-up on any idiosyncratic behavior or other occurrences relevant to the independent or dependent variables or scope conditions; (2) explaining any deception in the experiment, as well as the reasons for it; and (3) inviting participants to inquire further about any aspects of their experience that they wish to explore. As with other aspects of experimental design, the postsession interview requires considerable thought and pretesting so that it yields the information an investigator needs, as well as protecting and enhancing the welfare of participants.

Some Contemporary Issues in Laboratory Experimentation

New Technology: Television and Computers in the Laboratory

Networked personal computers are ideal for many operations of laboratory experimentation. They carry communication, either actual or controlled, among experimenters and participants; they can present all manner of information, such as independent variables; they also can administer questionnaires and tests; and they collect and store data. When integrated with closed-circuit live and taped video, they improve both the ease with which experiments are conducted and the quality of

presentation. Among the advantages from technology are the following:

- Ease of presentation, reducing fatigue among experimenters and interviewers.
- Uniformity of stimuli, reducing variability of administration that can show up as random variance in data.
- Error-free data, better than human experimenters could record. This advantage is particularly significant because errors in data recording are particularly difficult, sometimes impossible, to identify afterward.

Technology also brings new challenges, among them:

- It may be less involving than live administration, if participants treat videotaped presentations as “entertainment” and do not give them their full attention.
- Clear, fully explained, unambiguous instructions and procedures become crucial because participants cannot ask questions during an automated experiment and experimenters generally cannot intervene if they seem puzzled or act inappropriately on some experimental task.
- For programmatic research, it is valuable to ascertain how data from experiments using new technology compare to data from older designs. This can be especially important when an investigator wants to compare results of conditions from different experiments or when performing meta-analyses.

Data Inclusion: Whether to Retain a Participant in the Sample for Analysis

In a perfect world, every experiment would perfectly instantiate the scope conditions and independent variables, and the dependent variables would perfectly reflect all and only the theoretical concepts of interest. In the real world, that happy state is not likely. Some participants will not pay attention, or will misunderstand, information related to crucial antecedent conditions. Some will disbelieve some things they are told. Others will respond to internal factors (unshakeable prior beliefs, extreme tiredness, recreational or prescription drugs) rather than to social factors in behavior affecting the dependent variable. If scope or antecedent conditions have not been created for a particular participant, then her or his behavior is irrelevant for the theory under test. Success at creating experimental conditions must be assessed for every participant so that the investigator can decide whether that person's data should be included in the sample for analysis. There is no point in analyzing data (“Y”) from someone whose experience does not instantiate (“If X”) in an hypothesis of the form “If X, then Y.” Assessing, through manipulation checks and interview, whether someone's experience did place her or him in the kind

of situation required is always a matter of judgment and in most cases the decision is not clear-cut. A participant may say she paid attention most of the time, for instance, and the interviewer must then decide whether, on balance, she was “in” the desired situation often enough to retain her data. Practice, attention, and empathy help, but even with the best efforts some errors will take place. That is why good design requires $n > 1$ for conditions!

Every investigator will from time to time develop a feeling that “Something just is not right, but I can't put my finger on what that is.” This cannot be a reason to exclude. Someone whose behavior “is not right” might well be someone whose behavior does not conform to the investigator's theory. This is theoretical disconfirmation; it is not failure of experimental design. When, then, should data be excluded?

Three useful rules of thumb on exclusion of data are as follows:

(1) If it appears that, say, more than ~20% of participants' data should be excluded, probably the experimental design should still be considered at the pretest stage. Most social science experiments are not so complicated that more than 20% will need to be excluded, once design flaws have been corrected.

(2) An investigator *never* uses the dependent variable measures to decide exclusions. This could easily shade into excluding disconfirming data but retaining confirming data—a practice better suited to psychics than to scientists.

(3) Exclusion is properly done by reference to pre-determined rules and standards. In other words, if someone's data are to be excluded, it requires justification by a rule established before that person entered the laboratory. Such rules include successful creation of all scope, antecedent, and initial conditions, though it will be important to give operational indicators of just what “success” means for those. Overall, unless an investigator can cite a specific reason to exclude, the data must be included.

Ethics: Stress, Deception, Informed Consent and Care of Participants

Whereas an investigator properly focuses attention on theoretical and methodological issues, it is important not to forget the larger picture. Laboratory experimentation in the social sciences is partly a humanistic endeavor. It relies on humans who volunteer their time and efforts (either freely or for pay or course credit) and its ultimate purpose is to inform and to benefit other humans. Because of some particularly egregious examples of unethical procedures (in medical, not in social research), U.S. and some other governmental funding agencies have developed standards for protecting human subjects. For

most research, federal agencies rely on Institutional Review Boards (IRBs) delegated to examine each proposal and certify that it does not unduly threaten the welfare of those to be studied. Regulations evolve, and a wise experimenter checks with the local IRB or a federal Web site at the proposal-writing stage.

The main concerns are (1) psychological stress, discomfort, or embarrassment during the session and (2) privacy and security of information afterward.

An experimental laboratory in most cases is an unfamiliar setting and it usually contains several potentially frightening elements: microphones and video cameras directed toward participants, experimenters dressed in lab coats, questionnaires that resemble coursework examinations, etc. Interaction processes in behavioral experiments are other potential stressors, possibly triggering concerns with self-presentation, test anxiety, behaving appropriately, and the like. Finally, many—though not all—social science experiments include deceptive elements, such as the near-continuous disagreements in the Foschi *et al.* experiment outlined above. Two points are crucial here. First, experimenters must think carefully about potential sources of stress, avoiding or minimizing them where possible through design changes and, always, through observing participants during every session to watch for evidence of discomfort. Second, experimenters have a moral obligation to explain fully every deceptive element of a design and reasons for it immediately at the end of the session. It is unacceptable to allow anyone to leave a laboratory with induced misunderstandings or false ideas—including “test scores” and simulated behaviors of others—that may have been created during the group.

Even something as simple as word choice can make a surprising difference. It has been found that substituting “participant” for “subject” and “study” for “experiment,” to cite just two examples, reduces anxiety considerably. Generally, it is helpful to go over all details of every experiment with an eye to reducing unnecessary anxiety-provoking elements.

Unfortunately, informed consent is better suited to medical research than it is to social research. The reason is that most people simply do not know what they will find “too stressful to bear.” Many college sophomores think they could, for instance, shrug off an experiment in which they were told they gave heavy electric shocks to a nice man, even though in an actual experiment where they did that, some participants had nightmares for weeks afterward. Participants do not understand their resilience, and lack thereof, as well as an experimenter and an IRB must. Responsibility clearly is with them, not with participants, to make the experience harmless and beneficial to those who undertake it.

Thorough planning, full explanation, giving all participants chances to express their feelings and reactions to a study, and freely discussing all significant

elements of design (including anything that a participant thinks is significant even if the experimenter does not think it is crucial) are obligations that laboratory experiments entail. With those elements in place, most participants report that they find the experience interesting and beneficial, for they learn about research and, sometimes, about themselves in the process.

In fact, ethical considerations are, in some ways, easier to achieve in laboratory experiments than in other research settings. In experiments, one has the advantage of postsession interviews to detect potential lingering adverse effects and concerns. The research is also explained face to face, allowing greater sensitivity to potential distress and offering participants the chance to ask questions and receive full explanations. Observational settings, in contrast, usually do not readily achieve informed consent and surveys usually are not well explained to participants. That is not to say that those methods are ethically deficient, only to note that experimental methods offer the potential to be conducted in a highly ethical, sensitive, and beneficial manner.

Artificiality, Realism, and Generalization from Results

Laboratory experiments are, by design, artificial settings, in the dictionary sense of being socially constructed. They create unusual situations and ask people to participate as others observe and record what they do. Participants may work on contrived tasks, interacting with fictitious people having unusual characteristics, under conditions that would be impossible to sustain in any natural setting.

Some ask, using the term introduced by Campbell and Stanley in 1966, “What about external validity?” Yet concern with the external validity of experiments often is misguided, because although processes of theoretical interest should occur both in the laboratory and in the natural world, they do not occur in the same way. The laboratory, by design, should be “artificial”; otherwise why go to the trouble to create an experimental setting? “Valid” might incorrectly suggest that without direct generalization from the laboratory to a natural setting, findings are not valid. Laboratory results are valid if they inform about theoretical ideas, not if they accurately reproduce concrete features of some natural setting. A laboratory is as real as any other situation in which participants might find themselves and it certainly is involving for them. Laboratories are different from natural settings and they are simpler than natural settings, but they are certainly valid and real.

As noted earlier, an experiment itself does not *directly* tell about the natural world. Experimental results illuminate a theory. Applying that theory later to a natural

setting makes a better world, perhaps, but by that stage the experimental laboratory work that developed the theory is finished. In 1998, Jonathan Turner explored the benefits to basic science from applying theories for useful purposes. Among them, application forces theorists to confront explicitly what their theories claim will happen and conditions under which those effects should appear.

Reliability, Multiple Measurements, and Programmatic Research

No important information should come from a single observation, for every observation contains (often unknown) amounts of error. This caution applies to dependent variables in an experiment and also to measurements designed to assess success at creating the scope and antecedent conditions of an experimental condition. An experiment in which a dependent variable is measured only once is a much weaker design than one in which multiple measures are collected. For instance, suppose an investigator wanted to study responses to violations of fair distributions of rewards. A design that creates either fair or unfair allocations of rewards among individuals, and then allows a subject to reallocate rewards once, is much weaker than a design permitting multiple reallocations. With repeated opportunities to reallocate, transient sources of error decline in importance. With multiple measures, one might measure reaction to unfairness by the mean amount reallocated. Even better, a design that permits multiple measures of different types will reduce unwanted effects of error variance even further. If one measures several different reactions to unfairness, such as self-reported anger, physiological changes, and attempts to leave the situation in addition to the amount reallocated, data would be less affected by random error than they are with a single type of measurement.

Although most experimenters understand the importance of multiple measures of dependent variables, many experimental designs still depend on single measures. For instance, for an experimental study of bargaining, participants might be asked on a questionnaire how much they cared about winning points in the game: "Winning was my only concern," "I very much wanted to win," "I wanted to win," "So-so," "I somewhat wanted to win," "Winning was not very important," and "Winning was unimportant to me." Then, the experimenter might exclude data from any participant who answered "so-so" or below. That would mean making inclusion decisions on a single data point. A better design would use multiple measures of the scope and antecedent conditions, as Foschi *et al.* did above. Their design employed five bipolar scales to assess task focus and belief that the experimental task was unrelated to other skills that an individual might believe she possessed.

A 2000 paper by Thye provides several ways to assess the impact of error variance in experimental research. Among other useful analyses in that paper, the author points out that even random measurement error can result in either type 1 (falsely concluding that experimental conditions do differ) or type 2 (missing a true difference between conditions) errors. Although problems of systematic measurement error and of type 2 errors from random measurement error are perhaps well recognized, it is useful to remember also that measurement error that is differentially associated with experimental conditions can create differences in data unrelated to the theoretical variables of interest.

Results of any single entire experiment too are subject to unknown amounts of measurement error. Thus, a single study is much less reliable than a replicated study. Furthermore, the more unlike the first study a replication is in terms of concrete details of design, subject pool, cultural background, and measurement operations, the more impressive it is when it obtains similar results. Cohen (1989, p. 262) observed that, "The hypotheses, procedures and measures of an experiment represent only one set of instantiations of the concepts contained in [theoretical] explanations..." Reliable assessment of theories requires programmatic research, sets of sequential experiments, in order to develop cumulative knowledge about the adequacy of theories. Replications, though probably considerably more common than *published* replications, still are not undertaken as often as would be desirable from a measurement or a knowledge-developing perspective. Although there are undoubtedly many reasons for this, including cost, love of novelty, a preference for new or disconfirming evidence, and the enormous variety of theoretical perspectives in many social sciences, the quality of knowledge can be improved markedly by more frequent replication of all research, including that emanating from the laboratory.

The best way to reduce the uncertainty and effort needed to conduct laboratory experiments is to make use of existing designs and measurement techniques wherever possible. There is still an unfortunate reluctance among social scientists to adopt and adapt proven experimental designs, perhaps reflecting a love of novelty or a misplaced view that one is going to revolutionize the field by a single, brilliant experiment. This is a waste of effort. Some designs have proven themselves excellent for studying certain social processes—the Asch conformity experiment and the basic status experiment that Foschi *et al.* adapted are examples. More seriously, refusing to adapt standard techniques makes the results of different experiments difficult to compare and the knowledge produced is not cumulative. A great deal of wasted effort could be avoided if social science experimenters copied their sisters and brothers in the natural sciences and sought to build on existing

experimental designs to develop and assess new theoretical ideas.

The most useful single piece of advice for a beginning experimenter is to look around and see how someone else has studied the phenomenon you are interested in and then adopt and adapt as much of that design as possible. That way you can focus your efforts on the new ideas that you are investigating and you have the best chance of contributing to knowledge in your discipline.

Conclusions

Laboratory experiments in social science require creating artificial settings and asking participants to engage in specific kinds of behaviors that are recorded. In a well-designed experiment, all operations are concrete manifestations of abstract factors in a theory. Experimental research should be readily interpretable by moving from concrete measures produced in a laboratory to abstract theoretical dependent variables and that information should be used to assess the derivations and assist in developing theories.

In addition to thoughtful design, it is important to include provision for monitoring the quality of an experiment. Useful techniques include pretesting and measures during the conduct of an experiment and in a postsession interview. The more aspects of a design that can be assessed in these ways, the stronger the confidence an investigator may place in conclusions drawn from this type of research.

In addition to scientifically adequate design, social science experiments must incorporate ethical concerns for the welfare of participants, during the experiment itself and afterward. Responsibility for ethical concerns properly rests with the investigators; relying on participants to know their limits and to understand the dangers through varieties of informed consent generally abdicates that responsibility and places it on people lacking the experience they would need to protect themselves.

Single measures and single experiments can mislead because of measurement error. Multiple measures should always be used for important variables and replication is essential for important theoretical questions. Programmatic experiments generally result in more reliable information than one-shot studies. They always partially replicate past work (in operations and measures, most typically), and through differences in setting and populations studied, they permit assessing different aspects of the design.

Laboratory experiments are complicated, and effective design presents many challenges. In return for the effort involved, they often return reliable data permitting strong inferences that are useful for theory building.

Laboratory Studies

Donald W. Fiske

University of Chicago, Chicago, Illinois, USA

Susan T. Fiske

Princeton University, Princeton, New Jersey, USA

Glossary

confounding Varying an unintended variable along with the variable of interest, particularly as applied to experimental manipulations of independent variables.

correlational research Studies concerned with the relationships among a set of measured variables; the variables are not directly under the control of the experimenter.

demand characteristics The features of the situation that constrain the participants' behavior by communicating the hypothesis to them.

dependent variable In an experiment, the measured variable presumed to be influenced by the experimental manipulation of the independent variable.

expectancy effects The impact on participants of experimenters communicating their prior beliefs concerning the participants' likely responses.

experiment A study of the effects of randomly assigned independent variables, which are manipulated by the experimenter, on dependent ones, which are measured by the experimenter.

external validity The extent to which an investigator can generalize beyond the immediate data and findings.

independent variable In an experiment, the manipulated variable, levels of which the experimenter randomly assigns to participants; the experiment tests the causal effects of this variable.

internal validity The extent to which an investigator's conclusions hold for the particular participants, measuring procedures, and conditions studied.

method specificity The extent to which a set of data is determined by a particular procedure used to collect it. The term "method" may be applied to a range of procedures.

response rates The percentage of the sampled population that, when contacted, will agree to participate in the

research, or the percentage of participants who complete the researcher's measures.

unobtrusive measures Assessments taken without the participant's awareness.

A laboratory study is an investigation that occurs in a place dedicated to research, its conditions being designed to eliminate, or at least minimize, effects from unwanted influences. Laboratory studies often are experiments, but sometimes are correlational studies, including those that investigate individual or group differences. Laboratory studies have advantages with regard to design, setting, researcher, participants, and measurement; the advantages primarily relate to precision, control, and internal validity. Laboratory studies also have disadvantages with regard to each of these factors, method specificity and external validity being primary among these.

Background: Correlational and Experimental Research

The laboratory has been the site of research investigations for centuries. Researchers can control many conditions in the laboratory and can keep specialized equipment there. Psychology was one of the most recent disciplines to enter the laboratory, only about a century ago; other social sciences, such as economics, are only now expanding their use of the laboratory. This article concerns the quality of laboratory research on behavior, focusing on what affects

the behavior that can be observed in the laboratory or, more precisely, what affects the measurements that can be taken for later statistical analysis. Although many of these factors have similar effects outside of the laboratory, they come into particular focus in the laboratory, where so much can be precisely controlled. This article addresses both the laboratory's advantages and its disadvantages, classifying them by issues of design, setting, researcher, participants, and measurement.

Two primary kinds of research occur in the laboratory: correlational and experimental. (A third kind, descriptive research, estimating the population's levels on variables, as in opinion surveys or the census, rarely occurs in the laboratory.) Correlational research has the goal of assessing the relationships among two or more measured variables; these can include nominal (categorical) variables, such as gender; ordinal (sequential but not ratio-scaled) variables, such as birth order; and continuous variables (either scaled or not), such as age, response time, measured amount of a particular personality trait, or number of correct answers. Correlational research cannot draw strong causal inferences. Experimental research aims to allow valid causal inferences. It requires (1) an independent variable that experimenters can manipulate, assigning participants to different levels of the variable, such as experimental and control groups; (2) the ability to assign participants randomly to the different levels; and (3) the ability to control extraneous variables that might either covary with the independent variable (creating a confound) or create unwanted random variance (error).

Advantages

Whether correlational or experimental, well-conducted laboratory studies excel at internal validity, which is potential precision, control, and confidence that the conceptual variables have been operationalized as intended.

Design

Laboratory studies allow precise design. Because the researcher determines the variables, the series of manipulations and measures can be specified precisely, then administered in the desired sequence, with high response rates and relative attention. Researchers can identify relevant variables and operationalize them deliberately. Because of time and space constraints, laboratory researchers typically are forced to focus on a few critical variables in their designs, whether correlational or experimental. This focus disciplines the questions that researchers ask, often making hypotheses more precise.

Setting

The laboratory setting by definition is isolated from ordinary life; as a place that the researcher can control to a great extent, the laboratory can block or minimize certain stimuli that might interfere with observing the effects of the variables of interest. For example, consider weather conditions as intruders (open windows might create unacceptable variation in noise, wind currents, temperatures, and humidity). In a more general sense, researchers can minimize most forms of stimulation except the experimental variables or critical measures. That is, the laboratory setting can isolate the variables of interest. Participants' reactions can be gauged with a minimum of distraction or input from extraneous variables. Spotlighting manipulations and measures allows them to have maximum potential impact and perhaps the most pure assessment.

The setting is a psychological phenomenon. Its nature depends largely on the particular participant construing it. The point here is that it is not the objective setting that determines the behavior of the participant, but the setting as interpreted by the participant. In order to ascertain how most participants construe the setting, researchers can pilot test their setting, procedures, and variables.

Researcher

The laboratory researcher can easily control characteristics of the researcher who comes in contact with participants. For example, a researcher's appearance, manner, script, and demographic categories can be held constant, varied systematically, or counterbalanced. Of equal importance, the laboratory can control the participating researchers' knowledge of the hypotheses, as well as individual participants' conditions or status on critical measures, any of which could affect the outcome via expectancy effects. The degree and type of interactions between the researcher running the study and the study participants also can be controlled, monitored, and assessed.

Participants

Laboratory research participants frequently are selected for convenience and availability. In studies of adult humans, college students, usually psychology majors, often serve as participants, in order to fulfill a departmental requirement. In studies of children, those whose parents have the time, contacts, interest, and ability are overrepresented. In studies of animals, those bred for the purpose often serve. In all cases, no attempt is made to sample randomly a study population from a larger population of interest. This limits the external validity or generalizability from the laboratory sample to participants in the field.

The compensating factor with laboratory samples is their relative convenience and low cost. Researchers do not have to go out to find the participants in their natural habitat, but instead participants come to them. This may allow research to occur more efficiently.

Measurement

At its best, the laboratory affords precision of measurement. Laboratory researchers can specify the conditions and methods of measurement in fine-grained ways. For example, the laboratory can minimize the problem of bias, error, or disagreement in observer reports by using direct observation (for behaviors amenable to being observed in the laboratory). The laboratory can collect extremely fine-grained physiological measures at the level of single neurons, responses of extremely short duration at the level of milliseconds, and actions in small well-defined units (a blink or a nod).

The psychometric properties of laboratory measures can be well specified. For each of the major variables in a researcher's plan, two attributes of each measuring procedure need to be considered: reliability and validity. Reliability is essentially replicability: the question concerns how well the researchers can reproduce this array of measurements if they change the particular operationalization to which the participants are responding, or if they ask them to respond again at a different time. Validity asks how well researchers are measuring whatever it is that they want to measure. But first, researchers must specify exactly what they want to measure. To measure intelligence, is it just verbal intelligence, or is it active vocabulary, or is it the number of words for which the participant can give good definitions? For the sake of research processes and for ease in communicating with fellow researchers, each major variable should be described precisely. As a research program progresses, key terms should become increasingly clear and better specified.

Disadvantages

The great deficit of laboratory studies is external validity—that is, whether the results observed in that context generalize to other contexts in other laboratories or outside of the laboratory. Much of the problem in external validity can be understood as method specificity: some results may be a product of the method, not the construct the researcher hopes to assess.

Design

Laboratory studies typically are limited in time and space. Thus, on average, they are less likely to be longitudinal

and extended over long periods, either within a single session or across repeated visits to the laboratory. Except for captive laboratory animals, the setting limits the time researchers can interact with their participants. Limits of time and space also constrain the number of variables, whether manipulated variables or measured variables, that can be assessed in a laboratory setting.

Setting

For behavior that occurs in the laboratory, the questions to ask concern what it represents and what it means. Participants may react to the fact of being measured. Reactivity to the setting may cause anxiety, self-consciousness, impression management, or a whole host of unknowable effects. Researchers can deduce the effects of the laboratory setting by replicating the study in a field setting or even in other laboratory settings that systematically vary the potentially contaminating variables, to discover their effect.

Nevertheless, one major disadvantage of the laboratory is verisimilitude. Because the laboratory is an artificial setting controlled by researchers, set aside and isolated for the purposes of research, it may seem removed from everyday life. Researchers distinguish between mundane realism of the setting (how much does it resemble life outside the laboratory) and experimental realism (to what extent are participants involved and spontaneous). Using experimental realism, researchers can demonstrate the possibility of particular patterns of behavior by showing that they can occur, at least in some settings. Sometimes, capability for particular behaviors is all that is needed to meet the goals of the research. It may be important to know, even if in a laboratory setting, that people or animals are capable of particular behaviors. For example, demonstrating that young infants can distinguish groups of objects by number (i.e., they can distinguish twos from threes, and both from fours), regardless of the specific objects, is important, no matter where it is shown to occur.

As noted, one advantage of the laboratory setting is a researcher's ability to isolate the variables (stimuli) of interest, in order to maximize their impact. This control can go too far, in the sense of creating what are called demand characteristics. That is, the setting can be constructed in such a constrained way that other researchers judge that cooperative participants had no choice except to respond in the predicted manner. A subtle criticism, it reflects a judgment that the setting required only one kind of response, in ways beyond the presentation of the stimulus. As Martin Orne observed, participants play a certain role and place themselves under the control of the experimenter, cheerfully performing push-ups for no apparent reason or adding numbers for 5 hours and tearing up the results. Participants think the

“good-subject” role is to help validate the experimenter’s hypothesis, so the participant looks for cues in the environment that will convey the hypothesis, in order to behave accordingly. The set of cues to the experiment’s hypothesis constitutes its demand characteristics. If participants do not behave spontaneously but instead try to confirm the hypothesis, this artifact clearly threatens internal validity.

Researcher

Closely linked to demand characteristics of the setting are the expectancies and authority of the experimenter. Just as the laboratory researcher exquisitely controls the setting, so too does the researcher, if not monitored, control the participant. Stanley Milgram’s famous social psychology study showed that laboratory participants would shock another participant (seemingly to dangerous levels), merely because the researcher in authority told them to do so. Experimenter effects, effects generated unwittingly by experimenters, have been a source of much thought and research for several decades, ever since Robert Rosenthal introduced the concept and a line of research on the topic.

A typical demonstration of the experimenter effect uses a number of participants as experimenters. Half of these are led subtly to believe that the participants will perform a certain way and the other half are given a different expectation. Almost invariably, the participants as a group respond in conformity with the expectation given by their “experimenters.” The actual experimenters were puzzled about how to explain this dependable and replicable finding. The central question concerned how an experimenter’s expectation was transferred to the participants. Two groups of “experimenters” read to their participants exactly the same instructions, except, of course, for the word or words that made the instructions different for the two groups of participants. No one heard any difference in the readings. Finally, a colleague detected a slight difference in the emphasis given a key word. In a carefully designed and executed study by Duncan and Rosenthal, some student instructors were led to expect that the participants they would be working with would tend to make ratings toward the success end of a scale while other student instructors were led to believe that their participants would tend to make ratings toward the failure end of that scale. And that is the way the two groups of participants tipped their judgments. The researchers concluded that the way in which the experimenter reads instructions to participants, even when instructions are read accurately, can significantly determine the participants’ responses to an experimental procedure.

Researchers can influence participants in many subtle ways. As demonstrated by Rosenthal’s program of research, when experimenters know their hypotheses

(which will be the case for all except hired staff), and they know the experimental condition or assessed selection score of the participants, they may inadvertently behave in ways that confirm their own hypotheses.

Participants

External validity constitutes the obvious limit in laboratory studies, and one of the laboratory’s clearest restrictions is generalizability beyond the sample. Volunteer participants are not a random sample even of the departmental subject pool. They certainly are not a representative random sample of their age cohort or of people more generally. Specific biases arise from using volunteers, as Rosenthal and Rosnow have documented, and from using college students, as David Sears has documented.

Measurement

Many of the main problems concerning reactivity and response set result from people constraining their own responses to fit their view of the most socially desirable response. People do not want to look deviant, foolish, or bad, even when their individual responses are confidential and anonymous. People do not even like to make other people look bad, and their ratings often have a clear positivity bias.

Reactivity to the fact of being measured in a laboratory may be handled by the use of unobtrusive measures that participants do not perceive. Or the critical manipulations and measures may be disguised by being embedded among innocuous filler stimuli and items. Participants may not be told the full purpose of the study until afterward, to minimize their reacting to the hypotheses, in a misguided effort to help, hurt, or present themselves in the best possible light. Disguising the fact of measurement, its purpose, its method, and its timing all can minimize problems of reactivity. However, the ethical issues involved must be resolved thoughtfully, in consultation with Institutional Review Boards.

Every method makes a unique kind of contribution to the observation of behavior. The term “method specificity” captures this problem, which is that the measurement method adds unwanted variance to the observation. Campbell and Fiske identified this issue with regard to multiple methods to assess multiple personality traits, demonstrating method effects, independent of trait effects. One solution is to use multiple methods and to estimate method effects. Response sets form a particular class of method effects; they are most relevant to a participant’s responses on a paper and pencil test with multiple response alternatives to each item, and are most often seen in responses to personality measures

Table I Response Sets or Systematic Reactions to Measuring Procedures

<i>Kind of procedure</i>	<i>Response set or systematic reaction</i>	<i>Manifestation</i>
Self-report	Social desirability	Marking the response alternative perceived to give the most favorable impression
Self-report	Acquiescence	Giving “yes” responses, agreeing with the attitude statement
Rating behavior	Halo	Allowing a general impression of the person rated to affect their ratings on specific characteristics
Rating behavior	Leniency	Tendency to rate everyone as above average
Rating behavior	Position set	Tendency to mark an item, especially on a multistep scale, in the same position as the preceding item

of self or others and in responses to attitude measures. A response set contributes unwanted variance to data.

Table I presents a sample of response sets. At the top is the most common and best studied one, social desirability. At the bottom of this list is a fairly uncommon set, position set, which consists of repeating the response just made to the preceding item. Especially when the participant is working toward the end of a test, the repetition of the same response may occur out of frustration, fatigue, or boredom, when the participant does not want to take the trouble to figure out the best response.

When researchers suspect that a response set is contributing unwanted variance to the data, they can record the response alternatives for each item on the measure that would indicate a participant showing that response set, and simply score the measure for the sum of those alternatives. The researchers could statistically control for that response set. And they could then see if the response set score from this test had an appreciable correlation with that from some other test, perhaps a fairly similar test that might be expected to show it. Any response set that

appears in the test-taking world can be construed as a psychological trait. The best known instance of this is social desirability, which has been identified in social discourse and elsewhere. Other response sets may be consistencies in respondents' ways of handling items that they find difficult to answer. Rewriting or removing items may be the best way to reduce the influence of response sets.

Conclusion

The laboratory study excels at internal validity and precision, but it is not designed to foster external validity (generalizability beyond specific methods, participants, settings, and designs). Multiplism, in the form of multiple measures and multiple replications, can ameliorate these problems, but they remain an intrinsic challenge to laboratory research. Research programs do well with methodological pluralism, combining laboratory and field studies.

Glossary

classification The ordering or arrangement of a group of objects into categories based on their physical characteristics, with the objective of producing a thematic representation of those objects (e.g., a map).

hierarchical classification system The ordering or arrangement of classes of objects such that the more detailed classes comprise subsets of the more general classes.

land cover The physical characteristics of the terrestrial surface, most generally described by the dominant, observable vegetation or structures.

land use Human exploitation of biospheric resources in terrestrial ecosystems, either above or below the surface and potentially including groundwater reserves and wildlife.

land use change Temporal shifts in the type or intensity of human exploitation of biospheric resources in terrestrial ecosystems.

land use management The process by which human land use is controlled to attain a specific goal, such as the maximization of resource extraction, minimization of environmental impact, or some combination of both.

legend The classes (e.g., of land use or land cover) drawn from the classification scheme that appear in an accompanying map or data set.

mapping The process by which the actual geographical arrangement of entities of interest (e.g., different land uses) is determined and depicted in a digital or paper product.

minimum mapping unit The size of the smallest feature on a map.

resolution The ability of a sensor (e.g., satellite-borne) to distinguish two closely spaced objects or lines as two, rather than one, object or line; alternately, the smallest object or narrowest detectable line.

Land use mapping encompasses a range of procedures and data sources that are used to determine the spatial arrangement of human activities in terrestrial ecosystems and their change over time. Land use mapping techniques are employed to monitor and help predict the environmental and human health impacts of different land uses.

Introduction

People live on land and thereby make use of the resources land provides. The capabilities and limitations of land from the “use” perspective are therefore fundamental factors modifying the “way of life” locally, regionally, and globally. A particular land use is a result of decisions based on environmental, socioeconomic, and cultural factors. Because these vary over time, land use also changes. Ultimately, individuals make land use decisions regarding specific patches of land. Individual decisions are difficult to predict, yet affect land use patterns and trends over large areas.

Knowledge of current land use is critical for many environmental monitoring activities. At the local level, environmental planning and management are necessarily founded on current land use. Regionally to globally, land use has been recognized as a critical factor mediating between socioeconomic, political, and cultural behaviors and global environmental change, including changes in atmospheric chemistry and climate. Because of the difficulty in predicting land use decisions, a method is needed for acquiring such information. Land use mapping is a tool to meet this need.

What Is Land Use?

In simple terms, land use refers to human activities that are directly related to the land. More specifically, land use encompasses the human exploitation of biospheric resources immediately above or below the surface; bodies of water (shallow lakes, rivers, marshes, and swamps), the near-surface sedimentary layers and associated groundwater reserve, the plant and animal populations, the human settlement pattern, and the physical results of past and present human activity (terracing, water storage or drainage structures, roads, buildings, etc.) are included in assessing resource exploitation. Land use, therefore, is a broadly inclusive term reflecting the terrestrial consequences of the human–land interaction.

Land use may be considered from various perspectives, two of which are discussed here. An “urban” perspective focuses on the use of land in urban areas where most people live, the modification of land through creation of infrastructure, and the capture of detailed information about human actions and their consequences in these settings. A “resource” perspective would place a more balanced emphasis on various land surface components, regardless of human population density or degree of landscape modification. There are valid reasons for each perspective, depending on the intended use of the information. The urban perspective is most useful for urban planning and development purposes. This need is typically met through specially designed mapping or information gathering at the local level. On the other hand, the resource viewpoint refers to the use of all land, and because most landmass is not urbanized, issues relating to agriculture, forested areas, or other ecosystems tend to dominate. From the viewpoint of climate change or of sustainable development of natural resources, the resource perspective is of primary interest.

Present land use indicates that the human “footprint” is undeniably large and continues to expand, with perhaps 40% of terrestrial net productivity and half of the available freshwater resource diverted for human use. High-quality land use mapping data are an important descriptor of the distribution and intensity of human environmental impacts and are required for many other applications as well. These may include models and measurements of carbon cycles or assessments of the extinction risk among endangered species. Land use mapping from this resource perspective forms the basis for the remaining discussion.

Historical and Contemporary Examples of Land Use Mapping

The importance of land use mapping has been recognized since at least the Middle Ages. The medieval

Domesday Book, based on survey data and completed in 1086, summarizes for most of England an array of land use characteristics that remain foci of present-day land use mapping activities, such as extent of agriculture and natural areas that might be used to increase agricultural production. Detailed maps of land use in England were developed in the 18th century using similar survey techniques and questionnaires. The methods employed for these ancient land use inquiries are still in use but have been refined by the addition of new data sources from remote sensing, a technology that reduces the cost, effort, and subjectivity of purely survey-based mapping enterprises. Remote sensing and geographic modeling increase the ability of the surveyor to measure temporal changes in land use. Measurement and mapping of land use across broad and often sparsely populated geographical regions are usually impractical without remote sensing data, even though remote sensing and modeling approaches are most appropriately used to infer land use, not to measure it directly.

Various approaches to determining land use or land use change using geographic information and remote sensing techniques have been developed over broad, often agricultural, areas; the characteristics of such major efforts are summarized in [Table 1](#). Coarse-resolution (e.g., 0.0833 degree cells) land use change models synthesize a wide variety of national statistical data sources and interpolate predicted global patterns of conversion of natural habitats to agriculture from the beginning of the Industrial Revolution. Agricultural land use maps that exist for China depict the extent of major agricultural practices that correlate very well with census-based estimates of the extent of individual agricultural land use practices. In Canada, a national-scale land use map was produced by fusing Census of Agriculture statistics with moderate-resolution imagery in a procedure called “Land Use and Cover with Intensity of Agriculture” (LUCIA). The secondary result of the LUCIA land use mapping initiative has been the production of agricultural pollution data that can be related to aspects of environmental degradation, such as species endangerment. Similar national data now exist for the United States, and the European Union has developed high-resolution land use/land cover data for member countries under the auspices of its Coordination of Information on the Environment (CORINE) program. Remote sensing and ancillary data sources were combined to demonstrate that as much as 83% of global land area is significantly modified by human land use activities. One of the hallmarks of many of the large land use mapping projects has been data availability: the new maps are often available freely in digital format through various Internet access systems, a quantum leap forward from historical land use documentation through laborious censuses and limited distribution.

Table I Examples of Leading Land Use or Land Use Change Data for Various Regions

<i>Data source</i>	<i>Description of data</i>	<i>Resolution</i>	<i>Location/extent</i>
Ramankutty and Foley (1999)	Global land use change data describing land use conversions to and from agriculture	5 minutes	Global agricultural regions
Frolking <i>et al.</i> (1999)	Agricultural land use derived from the Advanced Very High Resolution Radiometer	1 km	China
Kerr and Cihlar (2003)	All types of land use/land cover, but especially detailed within agricultural regions, derived from the vegetation sensor aboard SPOT4 using the LUCIA process	1 km	Canada
Hurt <i>et al.</i> (2001)	All types of land use/land cover but at a very low level of thematic detail (small number of land use/cover classes)	30 minutes	United States
Coordination of Information on the Environment (a European union program; separate sources for each European country)	Hierarchical classification and land use/land cover mapping initiative based on satellite data interpretation (minimum mapping unit is generally 25 hectares)	Variable (about 100 m, but with a minimum mapping unit of 25 ha)	Europe
Sanderson <i>et al.</i> (2002)	Estimates of the extent of human modifications of natural ecosystems	1 km (source data often of coarser resolution)	Global

Land Use/Land Cover Relationship

“Use” and “cover” are two terms commonly associated with land, and they are often considered synonymous. However, this is not the case, and a conceptual difference exists between the two terms. Interestingly, the confusion seems to have emerged as a result of the need for mapping. In this section, the land use/land cover relationship is reviewed and implications for mapping are discussed.

Strictly speaking, land cover refers to the physical characteristics of Earth's surface. The Earth may be observed directly (on the ground) or indirectly (through remote sensing). Land cover typically includes vegetation, bare ground, water, human constructs such as buildings or roads, and mixtures of these. On the other hand, land use is characterized by the arrangements, activities, and inputs people undertake with respect to a certain land cover to produce, change, or maintain it. Because possible uses are to a large degree determined by physical land characteristics, land cover is an important factor in determining or indicating land use; in fact, this relationship is the basis for land use mapping. However, the strength of the relationship between land cover and land use varies.

Land use implies the application of a management strategy or input for the purpose of deriving a product or benefit from an area. The socioeconomic forces shaping land use are also part of its study, but these cannot be

easily mapped. Land use is determined by many factors—natural as well as economic, institutional, cultural, and legal. In general, possible types of land use are limited by biophysical constraints: climate, topography, soils and the geological substrate, availability of water, and the type of vegetation. Frequently, these factors also find consistent expression in land cover. For example, the presence, type, and characteristics of vegetation cover are effective indicators of the biophysical conditions.

Although environmental conditions provide strong constraints on possible land uses, they are not necessarily decisive; some types of land use are, at most, weakly constrained by local biophysical parameters. This is especially true for those land uses that result in new land cover (transportation infrastructure, buildings), in which the biophysical constraints are mitigated by the investment of energy and materials. Furthermore, land cover provides only an approximate guidance as to land use. A forested area may have an agricultural land use if it is also used for grazing. The same area could also be used for recreation, wildlife protection, or resource extraction if the forest is intended for harvest. A single patch of forested land may thus have a combination of different uses. Conversely, different land cover types may have identical land use, such as if both a grassland and a forest are used for recreation. Land use is also influenced by cultural factors. For example, agricultural practices differ from one region to another depending

on the history, local traditions, and the way of life, entirely separately from biophysical constraints.

Land cover can be a cause of, or a constraint on, land use. In the latter case, the relationship between cover and use tends to be strong because the land use in question is implied by the land cover's physical characteristics. When the modification of land cover is less profound (i.e., if the change is not large enough to cause a shift from one cover type to another), the type of land use may be more difficult to infer, and the reliability of the inference tends to be lower. The distinctions will vary with the type of use, geographic region, and time. For example, cropland is relatively easily mapped from remotely sensed data in most cases, provided that the sensor's spatial resolution is adequate. The type and intensity of management are much less evident, although they may be inferred, given knowledge of local practices. Similarly, multiple or mixed land uses, such as agroforestry, are also difficult to distinguish solely from land cover data. Because land use practices change with time, so may the relationship of land use to land cover.

Given the multifaceted nature of land use and the variety of causal factors affecting it, precise mapping of land use over large areas becomes a challenge. Remote sensing methods developed during the past ~60 years permit the mapping of land cover types and their properties, which may be discerned from electromagnetic radiation that is detected by sensors aboard satellites or aircraft. There are no equivalent direct sensing methodologies for land use, and the land cover/land use link is therefore the only conceptual approach to mapping land use over large areas. However, the success of "translating" land cover information into land use depends on several main factors: classification scheme and legend, environmental setting, and both the types and characteristics of remotely sensed data (particularly spectral and spatial). These factors are discussed in subsequent sections.

Land Use Classification and Legends

Classification is an abstract representation of the field conditions, using a particular set of diagnostic criteria; more simply, it is the ordering or arrangement of objects into groups or sets on the basis of their relationships. Classification thus necessarily involves the definition of class boundaries, which should be clear, precise, possibly quantitative, and based on objective criteria. Ideally, a classification should be scale independent (the classes should be applicable at any scale) and source independent (the scheme does not depend on a particular data source). For some purposes, it is desirable to establish a hierarchical classification scheme that permits the identification

of progressively more specific land uses given additional mapping resources and/or data sources. For example, a hierarchical classification of a particular region with three "tiers" might proceed as follows: agricultural land → cropland and pasture → permanent pasture lands.

A legend is the application of a particular classification in a specific geographic area using a defined mapping scale and a specific data set. Thus, a legend may contain only a subset of the possible classes, and its content depends on the mapping scale as well as on the data source and the mapping methodology. The transition from an abstract classification to a particular legend requires assessment of the minimum mapping unit (MMU).

In the past, two approaches have been employed for mapping land use over large areas. Both are founded on the relationship between land use and land cover, and they differ primarily in the definition or selection of an appropriate land use classification and of the associated legend. In 1976, Anderson and colleagues described a land use classification scheme that combines aspects of land cover and land use and that is designed for use with remotely sensed data. A more recent proposal by Cihlar and Jansen involves a stepwise approach in which the land use classification and associated legend are defined separately from those for land cover. The 1976 scheme, which has also formed the template for land cover classifications, has been used extensively in the United States and to a lesser degree elsewhere. The conceptual advantage of the second approach is its flexibility and the transparency in the definition and application of land use categories. The two approaches are referred to in the following discussions as "parallel" and "sequential," respectively.

Parallel Strategy

The United States Geological Survey sponsored an early, and particularly influential, land use mapping program. The classification system developed for this project was hierarchical, with relatively coarse land use classes being progressively subdivided into more detailed uses. For example, a first-tier land use is "agriculture," which can be subdivided into a number of second-tier uses, such as "cropland and pasture" and "confined feeding operations." These uses may then be further subdivided to include progressively more detailed classification items. The overall classification system was designed to represent those parts of the United States that are of highest relevance for natural resource use (i.e., a resource perspective). The initial classification contained little thematic detail for urban areas, but was designed to permit detailed descriptions of land use even in these areas.

In the 1976 approach, land use is determined based on land cover as the principal surrogate. However, it assumes that other information is also available and would be used, e.g., the image interpreter's customary references to

pattern, geographic location, or knowledge of local practices. The classification is formulated in land use terms when possible, but the mapping is conducted by considering primarily land cover features recorded by the remotely sensed data. The first two tiers of the hierarchical system were fully defined as follows:

-
- 1 Urban and built-up land
 - 11 Residential
 - 12 Commercial and services
 - 13 Industrial
 - 14 Transportation, communications, utilities
 - 15 Industrial and commercial complexes
 - 16 Mixed urban or built-up land
 - 17 Other urban or built-up land
 - 2 Agricultural land
 - 21 Cropland and pasture
 - 22 Orchards, groves, vineyards, nurseries, and ornamental horticultural areas
 - 23 Confined feeding operations
 - 24 Other agricultural land
 - 3 Rangeland
 - 31 Herbaceous rangeland
 - 32 Shrub and brush rangeland
 - 33 Mixed rangeland
 - 4 Forest land
 - 41 Deciduous forest land
 - 42 Evergreen forest land
 - 43 Mixed forest land
 - 5 Water
 - 51 Streams and canals
 - 52 Lakes
 - 53 Reservoirs
 - 54 Bays and estuaries
 - 6 Wetlands
 - 61 Forested wetland
 - 62 Nonforested wetland
 - 7 Barren land
 - 71 Dry salt flats
 - 72 Beaches
 - 73 Sandy areas other than beaches
 - 74 Bare exposed rock
 - 75 Strip mines, quarries, and gravel pits
 - 76 Transitional areas
 - 77 Mixed barren land
 - 8 Tundra
 - 81 Shrub and brush tundra
 - 82 Herbaceous tundra
 - 83 Bare ground tundra
 - 84 Wet tundra
 - 85 Mixed tundra
 - 9 Perennial snow or ice
 - 91 Perennial snowfields
 - 92 Glaciers
-

The conclusion from the 1976 approach was that level I land use data (categories 1 through 9) could be gathered from the Landsat Multi-Spectral Scanner (resolution, 80 m) or more detailed sources; Anderson's group indicated that level II classification required high-altitude photos. The Landsat Thematic Mapper (resolution, 30 m; these data were not available when Anderson's group designed their land use classification system) or other, more detailed satellite remote sensing data sources may now be used to replace or supplement aerial photography. In principle, the result of this approach is a land use map that extracts all discernible information from the available data sources.

Sequential Strategy

This is a new approach that divides land use and land cover mapping into separate, distinct steps. The rationale is threefold: land use and land cover are fundamentally different, i.e., land cover maps are easier to prepare and exist in many cases with a land cover-specific legend, and land cover is an important determinant of land use. The sequential approach accommodates any land cover classification scheme and mapping legend, but it does assume that such a legend has been chosen. For the geographic domain of interest, it then analyzes the relationships between this legend and the envisioned land use classification. Four relationships may exist between the polygon boundaries outlining individual mapping units for land cover and land use categories: (1) one-to-one, in which the boundaries of land cover polygons and land use polygons coincide, (2) many-to-one, (3) one-to-many, but constant across the mapping domain, and (4) one-to-many, varying across the domain. For a particular area, the existence of these relationships needs to be established from field observations or another source (e.g., expert knowledge). For the first two situations (one-to-one and many-to-one), land use maps may be derived from land cover alone. For the one-to-many cases, three increasingly costly options exist: modify land use legend (and, if feasible, land cover legend), provide additional data or information (e.g., elevation), and collect more field observations. It is possible that all three solutions need to be employed, but these can then be restricted to the specific land cover types, thus keeping the mapping costs down.

The advantages of the sequential strategy are that the land cover and land use are conceptually separated, the potential confusions between the two are known, and that it may be applied to existing land cover maps. When applied to a new area for which no land cover map exists and with appropriate source data, the sequential approach could result in a map very similar to that of Anderson's group (depending on the amount of supplementary data); it may thus be viewed as a generalization of the earlier methodology. This strategy has not yet been extensively

tested but provides a sound theoretical basis for land use mapping.

Land Use from Remote Sensing and Ancillary Data

Remotely sensed data from satellites or aircraft are the main data source used for land use mapping. Remote sensing techniques are able to provide synoptic, spatially, and spectrally consistent, frequently updated measurements of land surface characteristics. Passive optical measurements (using the sun as the source of electromagnetic radiation) in the visible (0.4 to 0.7 μm) and the infrared (0.7 to $\sim 2.5 \mu\text{m}$) parts of the electromagnetic spectrum provide the most information and are therefore used most frequently. Physically, these measurements capture the solar radiation reflected in the individual spectral bands that are delimited by spectral filters. The bands and filters are carefully selected to maximize the contrasts between various surface targets while being affected as little as possible by atmospheric conditions.

The radiation reflected by the surface is captured by sensors carried aboard aircraft or satellites. Until the 1980s, the aerial photographic camera was the leading sensor type. Following technological developments during and after the World War II, this technique provided much flexibility in the type of film and mapping scales used, from black and white panchromatic to color infrared films and mapping scales ranging from 1:1000 to $>1:100,000$ (the mapping scale can be precisely controlled by choosing the camera lens focal length and the aircraft flying height). The data are analog in format, thus requiring analysis by experienced photointerpreters, but aerial photographs are usually maintained in regional and national archives. The art of photointerpretation also developed during and after World War II. Compared to digital methods (see later), an important advantage of visual interpretation methods is the ability to use effectively various clues in the image in addition to tone; these include pattern, shadows, size and shape (in two or three dimensions), and context. Land use change may also be measured effectively because of the relatively long data record: aerial photographs for some regions are available as far back as the 1930s or even earlier.

Publicly available satellite data suitable for land cover and land use mapping have been archived since 1972. Following the launch of Landsat and its Multi-Spectral Scanner (MSS), with a resolution of 80 m, optical satellite data have been acquired continuously; spatial resolution has increased to the current range of between ~ 5 and 30 m. Although the data have not been systematically and completely retained around the world, extensive archives are nevertheless available, and are sufficient for repeated land cover/land use mapping of large areas. Major archives are maintained by the space agencies that launched

the respective satellites, and by individual countries that operate satellite receiving stations through agreements. For example, Canada has comprehensive coverage of its territory provided by satellite programs of the United States (the Landsat MSS and Thematic Mapper since 1972, and the National Oceanic and Atmospheric Administration since 1989) and France (Système Probatoire pour l'Observation de la Terre since 1986). Compared to aerial photography, satellite data have the advantages of radiometric calibration (thus permitting analysis by computers), generally much more frequent coverage, spatial consistency, and retrospective availability (mapping of previous conditions is feasible even if not planned at the time), among others. Aerial photographs, on the other hand, compared to satellite imagery, are generally available from earlier time periods.

Regardless of the sensor and data type, land use mapping requires that raw data be converted into information, a process termed information extraction. Strictly speaking, the information that can be directly extracted refers to land cover type or other target characteristics (e.g., percent vegetation cover). This is because the reflected electromagnetic radiation carries an imprint of physical or chemical properties of the target. The science and art of mapping land cover from remote sensing data have been well established for aerial photography and studied extensively for satellite data. To extract land use information, the additional step of establishing the relationship between land cover and land use is required (see the preceding discussion of parallel and sequential strategies).

From the viewpoint of land use information, a major difference between analog aerial photography and digital satellite images is in the ability to use context at the information extraction stage. This includes not only the direct clues embedded in the image, such as spatial patterns, but also—and especially—the expert knowledge and understanding of land use practices, local conditions, the peculiarities of land use/land cover relationships, and the ease with which additional information from other sources can be brought to bear on the preparation of the land use map. Although, in principle, many of these inputs could also be included in digital analysis, such a process is more complex and difficult. On the other hand, intermediate solutions employing both digital analysis and external knowledge are feasible, but their effectiveness will depend on the degree to which systematic relationships exist between land use and land cover. This aspect becomes less important as the mapping scale becomes less detailed.

Issues in Land Use Mapping

As evident from the discussions so far, there is no simple formula for land use mapping that will apply to all

situations. As with most mapping methodologies, the success will depend on the type and level of detail in the desired information, the available data that may be used to extract that information, and the compromises in the mapping process, for which both the map producer and the user must be prepared. There are three areas where flexibility exists: scale influences, supplementary data use, and accuracy assessment.

Scale Influences on Land Use Mapping

Land use mapping requires consideration of different aspects of scale and resolution. First, the minimum mapping unit, defined as the smallest area a mapped feature can occupy on the land use map, should be determined. In general, as the MMU becomes smaller, the spatial resolution of the input data must increase, concomitant with the increasing likelihood of errors. The needs of the users of a land use map affect the MMU substantially. For example, a land use map might be developed to identify the spatial distribution of meadow habitats for wildlife conservation purposes. If the users are interested primarily in large animal conservation, meadows that are less than 0.5 hectares may not need to be mapped. Therefore, there will be significant interplay between the MMU and the spatial resolution of the data used for the mapping task. Landsat Thematic Mapper (TM) data, a commonly employed source, consists of pixels that are 30×30 m, or 900 m^2 (0.09 hectares) in size. Consequently, the smallest possible MMU of a land use map that draws primarily on Landsat TM data is a single pixel of 0.09 hectares, but a more practical MMU (one that was less error prone) would be several pixels. Supplementary data should be sought wherever practicable because they may improve, or at least maintain, the accuracy of the land use map while simultaneously allowing for a reduction in the MMU. Commonly used land use mapping ancillary data sources include agricultural or population statistics, but other sources, such as high-resolution imagery, may also be helpful. Specific supplementary data needs, as with the MMU, will be influenced strongly by the needs of land use map users and by the map legend.

The extent over which land use is to be mapped exerts considerable influence on mapping methodologies. Many local land use mapping efforts may be performed entirely through direct survey of the land. These do not require a great deal of conceptual refinement beyond the need to design a suitable sampling strategy for cases where the survey is not exhaustive. Across broad regions, thematically detailed land use characteristics may be mapped at coarse, and usually variable, resolution using census questionnaires, but this technique is most useful for populated areas. Land that has no permanent, or easily contacted, human population is still often subject to human-based

land uses, such as resource extraction or wildlife conservation.

Supplementary Data

Several modern land use mapping efforts have used supplemental data from censuses and surveys to derive land use classes at the final stage of standard image classification procedures. Supplemental data (e.g., those derived from questionnaires or field samples) used in this way “train” the classification procedure to discern the effect of prevailing land use in the spectral signal of the land surface. Combinations of remotely sensed and census data have been used to create land use maps in many places, including Europe, United States, Canada, and China. The spatial resolution of such land use maps can be as high as the satellite sensor resolution (most commonly 1 km across such large regions) or, depending on the specific methods used and quality of census data, can be a compromise between the spatial resolutions of the remotely sensed and census data. The accuracy of the resulting maps depends on the tightness of the land cover/land use relationships (refer to the previous discussion of sequential strategy).

Accuracy Assessment of Land Use Maps

Validation of land use and land cover maps can be difficult because supplemental data are frequently needed to help distinguish land use from land cover (which can be derived from remote sensing data alone). The supplemental data, such as from an agricultural census or survey, may be the only source of information over large areas that can be employed to characterize land use. In the absence of independent information on land uses within an area, as well as their spatial distribution (e.g., from field surveys), the approach to validation is likely to be restricted to measurements of consistency between the completed land use map and the supplemental or ancillary data sets that permitted the land use map to be derived from remote sensing data. For example, the extent of a particular land use can be compared between the completed land use map and summary statistics provided at a county level by an ancillary data source, such as a census of agriculture. It is worth noting that, given the 1976 criterion of the Anderson group, that land uses should be represented by a particular cover type whenever possible, it may be possible to derive use from cover without extensive reliance on ancillary data sources. In that case, alternative estimates of land use, perhaps derived from supplemental data sources, could provide truly independent estimates of land use that could be used for validation purposes.

When spatially explicit land use data that are independent of the land use map are available, standard

Table II Construction of an Error or Confusion Matrix^a

Mapped land use pixels	Ground truth land use pixels ^b			Total
	I	II	III	
I	25	5	9	39
II	7	21	5	33
III	8	2	30	40
Number of ground truth pixels	40	28	44	112

^a In this example, matrix construction enables the land use map producer to estimate rates of commission and omission errors for each land use class; there are three land use classes, labeled I–III.

^b From ancillary data sources.

classification accuracy assessment is possible. This method requires the production of a confusion (or error) matrix. Confusion matrices allow the analyst to compare the results of the mapping procedure to ancillary data describing known characteristics of the area under consideration, often referred to as ground truth, and to identify magnitudes and types of mapping error (Table II). There are two error categories. First, errors of omission (which can be assessed to estimate so-called user's accuracy) occur when pixels that are identified by the ground truth data set are misclassified. Second, errors of commission (also known as "user's accuracy") occur when a particular mapped class belongs to a different class, as identified by the ground truth data.

In Table II, the producer's accuracy for land use type I is $25/(25 + 7 + 8) = 62.5\%$, so the error of omission is 37.5% for this land use class (i.e., 15 pixels that are actually of land use class I were mapped as different land uses). However, of greater interest is the user's accuracy, which is $25/(25 + 5 + 9) = 64.1\%$, so the error of commission is 35.9% (i.e., of the 39 pixels in the map that should have been labeled as land use class I, 25 were correctly labeled). Overall, in this example, the land use map is 64.1% accurate with respect to land use class I, but only 60% of the ground truth pixels with class I have been correctly mapped. The user's accuracy (which is the complement to the rate at which errors of commission occur) is the more important of the two statistics because it directly measures the accuracy of the final land use map with respect to the classes that are included.

Two questions need to be addressed regarding the accuracy of a particular land use map. First, what is the required accuracy? There is no agreed-upon accuracy value, but Anderson's group suggested in 1976 that land use and land cover maps at high spatial resolutions should have a classification accuracy of at least 85% and should have equivalent classification accuracies between individual legend items. Second, what level of confidence in the final accuracy value does the user need? Obviously,

this will depend on the users' needs and the degree to which the accuracy may be traded against the resources required. In reality, both questions translate into mapping costs. Costs in the preparation of the map are inevitable (although they may be modulated by trade-offs regarding the legend and the input data type), but the accuracy assessment costs are, in principle, optional, and, furthermore, are highly variable, depending on the approach chosen to establish the map accuracy. In practice, accuracy assessment of derived land cover or land use maps often suffers due to the significant resources required to obtain reliable accuracy estimates. This is significant because once a map is produced, it tends to be used regardless of its accuracy (if the latter remains unknown), particularly if such a map is the only map and the information is needed urgently.

Conclusion

Land use, which is the product of human interactions with the land, is crucial for environmental monitoring purposes. The importance of land use stems in part from its tendency to "feed back" on the human enterprise by modifying human health, agricultural productivity, or the capacity for resource extraction from an area. Beyond such straightforward measures of the importance of land use as a characteristic of the environment, human/land interaction affects the natural environment's capacity to provide ecosystem goods and services; the goods and services, in turn, enable the conventional economy to exist and to support functioning natural ecosystems. There is virtually no major aspect of human activity that can be considered to be truly independent of the human/land interaction. The task of managing land use to minimize negative economic, health, and environmental feedbacks is a rapidly evolving process that relies on accurate information concerning the variety and spatial distribution of particular land uses. Land use mapping is a key technique for meeting these requirements.

Language Acquisition

Allyssa McCabe

University of Massachusetts, Lowell, Lowell, Massachusetts, USA

Glossary

competence The internalized knowledge of language, especially rules and structures. Competence contrasts with performance and is assumed to surpass it.

elicitation The prompting or stimulation of children's production of language.

mean length of utterance (MLU) A measure used to assess early syntactic development; the average length of a child's utterances calculated in morphemes.

morpheme The minimal unit of meaning; the word "cats" consists of two morphemes, "cat" and the plural morpheme "s."

morphology The rules that govern use of morphemes in language.

narrative A story, usually given in past tense and usually consisting of a sequence of events, either factual or fictional.

performance The production of speech, which contrasts with competence.

phonology The study of the sound system of a language, especially rules for combining sounds into words.

pragmatics The study of the rules for the social, often conversational, use of language.

rule Knowledge of a linguistic pattern, which may range widely from very implicit knowledge expressed by means of regular patterning of speech sounds to the ability to articulate grammatical laws.

specific language impairment (SLI) A condition in which children struggle with acquisition of many aspects of language even though they are largely of normal nonverbal intelligence.

syntax The rules for ordering words into sentences such as declaratives, interrogatives, and negatives.

aspect of an individual's life. Research has demonstrated that children who excel in language acquisition (1) connect better with parents, peers, and teachers, among others; (2) are substantially less aggressive and more socially competent in a variety of ways; and (3) achieve higher scores on most intelligence tests. Technically, language acquisition is the process by which children develop the ability to produce and understand oral and written language. This process begins before birth with the onset of hearing *in utero* 4 months after conception and, ideally, continues throughout life, although the vast majority of research looks at language acquisition between birth and 12 years of age. Measuring children's language acquisition requires attention to both the comprehension and production of language. Both naturalistic observation and structured elicitation of language production are essential methods for fully understanding this complex process. Language acquisition is a complicated French braid of different strands or levels of language, so researchers must consider a child's progress in mastering phonology, vocabulary, syntax and morphology, discourse, reading, and writing. Parents, clinicians, and educators want to know whether a child's pronunciation, vocabulary, use of plurals and past tense, and narration are normal. Some children acquire more than one language and their progress in all these dimensions must be considered for each language separately, although the acquisition of one language facilitates the acquisition of others. A few children struggle with acquisition of many aspects of language even though they are largely of normal nonverbal intelligence; specific language impairment (SLI) is the technical name for this condition, and early identification of SLI aids in obtaining optimal intervention to minimize the negative consequences of atypical language development. Measuring language acquisition is critical for many reasons.

Language is a cultural, social, emotional, and cognitive phenomenon, and its acquisition reflects and affects every

Introduction

Why Measure Language Acquisition?

The acquisition of language is of considerable importance for many reasons. First of all, language enables children to negotiate social relationships, allowing them, for example, to communicate what is bothering them or what they want and to assert themselves without resorting to physical aggression. Language also becomes increasingly necessary for cognitive development. In fact, most tests of intelligence involve an extensive assessment of verbal ability. In recent years, researchers have become increasingly aware that early language ability predicts subsequent literacy achievement. Many learning disabilities involve language-based reading disabilities that could potentially have been mitigated or even prevented by the diagnosis of language delay in the preschool years. Some children suffer from specific language impairment (SLI), and early identification of SLI allows for more effective intervention. Thus, measuring language acquisition is essential to ensure children's optimal social, cognitive, linguistic, and literate functioning.

When researchers began to assess language acquisition, they were primarily interested in the phenomenon in and of itself, as well as what the close observation of that phenomenon implied about how language is acquired. Those early endeavors have now permitted us to assess individual children, predicting cases in which delay is noticeable in the preschool years. Language is a very complex process, and the disruption of one of its components can compromise others. The measurement of this complex process requires numerous measures, both to understand the process in general and to chart the progress of any child in particular.

Measures of Language Acquisition

There are thousands of measures of language acquisition. Some of these attempt to assess children's linguistic competence, namely, their ability to understand the rules of a language. Others try to assess children's simpler competence at understanding language. Still others depict aspects of children's performance, their use of language. All these aspects are important. Children are unlikely to mark distinctions of which they have no comprehension, but they often comprehend language they cannot yet perform. For example, a girl may understand very well that her name is pronounced "Cassy," yet because she has a lisp she may respond "Cathy" when asked to tell someone her name. We cover here measures of both competence and performance.

Assessment of Acquisition of Bilingualism (or Trilingualism)

Many children all over the world acquire more than one language, either at the same time or staggered.

The assessment of language acquisition in such cases is quite complicated and ideally would involve a comparable assessment of all languages the child is acquiring. Children are often more competent and/or productive in one of their languages, usually the first one spoken to them at home by their parents. Knowledge of this dominant language will transfer to the acquisition of other languages. The notion that bilingualism interferes with language acquisition has been countered by numerous studies and is now viewed as the unfortunate remnant of long-outdated and methodologically unsound research (i.e., experimenters tested children in their new language and/or used tests that had not been standardized for their native language).

Article Overview

There are thousands of tests of language acquisition, so we are not able to review them exhaustively here. We first address issues to be faced in assessing language acquisition, focusing on concerns that must be taken into consideration and trade-offs anyone faces in selecting among the many available measures. Rarely is it the case that any researcher or clinician can rely on only one measure to answer their questions. Next, we introduce some representative measures of the various levels of language acquisition. The final section discusses computer-assisted measurement in this area.

Issues in Assessing Language Acquisition

Age Concerns

The first important consideration in measuring language acquisition is the age of the child. Virtually all measures are devised to address the language acquisition of individuals in a specified age range. Related to this concern is the mental age or stage of language acquisition of the child. For example, although the mean length of utterance (MLU) in morphemes is appropriate until that measure reaches 3.5 morphemes, a point usually reached by children when they are 3 years old, the measure may continue to be of use with older, delayed children. That is, MLU is no longer appropriate to use for children who routinely produce longer sentences (e.g., "I jump/ed out of the car" or "He did/n't cry too much today," both consist of seven morphemes).

Control versus Generalizability of Results

Psychologists have long stressed the importance of standardizing the procedure of a study, or arranging for as many circumstances to be the same for all participants as

possible. Through the exercise of such scientific control, experimenters believe that they can attribute outcomes to the independent variable of interest to them rather than some other, extraneous variable. The difficulty is that such control comes at the inevitable expense of generalizability (the extent to which findings can be applied to other situations outside the laboratory). For example, an experimenter might adopt the method Ebbinghaus used in the 1880s to study the acquisition of words. Ebbinghaus used consonant-vowel-consonant trigrams—nonsense syllables—in an effort to avoid contaminating the experimental procedure by the intrusion of meaning on the laboratory experience. He then measured precisely how many repetitions of “JUM” or “PID” were required for subjects to memorize those nonsense syllables. Researchers eventually discovered that such procedures told them very little about how people learn words in the real world; in other words, generalizability had all but completely been sacrificed for the sake of control. Moreover, unbeknownst to researchers, subjects often turned nonsense syllables into meaningful ones (e.g., “JUM” became “JUMP” or “CHUM”) to ease memorization.

On the other hand, simply observing language in the real world, which maximizes generalizability, would not tell us much about which of the many aspects of some particular situation were responsible for triggering the language observed. Once again, multiple methods of assessment are required.

Naturalistic Observation versus Elicitation

Related to the trade-off between experimental control and generalizability is that between naturalistic observation and elicitation. One of the earliest means used to study language acquisition was a diary of a child's progress, kept by parents who were also often linguists. Such an approach can yield ample, rich data that are true of real situations because they were derived from such situations. However, observation of what a child does, even day in and day out, does not necessarily tell us about a child's capability. Elicitation procedures are best suited to informing us of children's capacity, and by far the best-known such procedure is the wug test developed by Berko Gleason in 1958. Berko Gleason showed children a picture of a strange creature and said, “This is a wug.” She then showed children a picture of two of the strange creatures, saying, “Now there is another one. There are two of them. There are two ____.” Using this procedure, Berko Gleason was able to demonstrate that children were capable of producing grammatical morphemes (e.g., saying, “wugs”) in response to nonsense words they had never heard of before. Children had apparently implicitly acquired certain rules (e.g., for forming plurals)

rather than simply mindlessly imitating their parents' productions.

Longitudinal versus Cross-Sectional Assessment

The assessment of language acquisition can be accomplished by testing groups of individuals of different ages at approximately the same time, called the cross-sectional approach. Alternatively, the same individuals can be tested repeatedly over a number of years, called the longitudinal approach. The cross-sectional approach is more economical of a researcher's time, because wide age spans can be assessed in a relatively short period of time. However, that method gives no information about the particular path or paths of development of individual children, nor does it provide any hints about the possible causes of such development. The longitudinal method, in contrast, provides information both about individuals and potential causes, although it is expensive in terms of time and money and liable to problems if participants drop out. Furthermore, the results of longitudinal studies may not be generalizable to other groups or other generations.

Production versus Comprehension

At first glance the distinction between children's production of language and their comprehension of language may seem identical to the distinction between performance and competence already noted. However, whereas production and performance may be used interchangeably, comprehension and competence cannot. Specifically, comprehension refers to children's understanding of language directed to them (e.g., can the child perform a sequence of orders directed to him or her?), whereas their competence refers to their internalized knowledge of linguistic rules, a more esoteric ability often tapped by asking people to judge the grammatical acceptability of a sentence. For most children, the comprehension of language precedes and exceeds production. Some estimate that children comprehend five times as many words as they produce, for example. Thus, the discrepancy between comprehension and production must be kept keenly in mind by those assessing children.

Research versus Clinical Assessment

Any type of language assessment can in theory be used either to address research issues about the language development of children in general or for clinical purposes to assess the relative progress of a particular child in acquiring language relative to his or her peers. In fact, research on children in general is essential for the clinical assessment of specific children. Whereas some measures

are used interchangeably, many tend to be used primarily in one setting or another.

Levels of Language Acquisition to be Assessed

Thousands of measures of language acquisition differ along all the aforementioned dimensions. Such measures also differ in the aspects or levels of language they assess. A comprehensive survey is thus impossible here. Table I lists examples of measures that assess the comprehension and/or production of language at various levels; such measures differ as to the ages for which they are appropriate, the amount of control versus generalizability they display, whether they are primarily observation or elicitation, and whether they are used most often for research or for clinical assessment. Despite such variety and ingenuity of methodology, the most important method of assessing language acquisition has been and remains the audio tape recorder, along with typed transcriptions of language recorded.

Phonology

At birth, a child’s cries consist of speech sounds that can be audio-tape-recorded and measured by researchers listening carefully or by spectrographic analysis, which gives a visual display of audio signals. These methods of assessing production are useful for individuals of any age. Infants’ perceptions of speech sounds have been assessed by means of what is called high-amplitude sucking, in which an infant sucks a pacifier connected to a sound-generating

system. Infants quickly learn that sucking causes a sound to be produced, and at first they suck frequently in order to hear that sound. After a while, however, infants lose interest, or habituate to the sound, and slow down or stop sucking altogether. At this point, experimenters introduce another sound. If infants begin to suck again eagerly, we can infer that they perceive the new sound to be different from the old one. Using such a method, experimenters have discovered that young infants perceive the difference between speech sounds even of languages they have never heard. By the end of the first year, infants have lost the ability to perceive speech sounds not meaningfully distinguished in the languages to which they have been exposed.

Vocabulary

A child’s earliest words emerge toward the end of the first year of life in the context of interaction usually with parents and are the result of parents imitating children’s babbling and connecting those sounds to objects of interest to the child (e.g., “dada” with the child’s father). Thus, parents are in a good position to report the words their children produce, especially when systematically prompted to do so, which is the approach taken by the MacArthur Communicative Development Inventories. That instrument also asks mothers to report which words their children comprehend. However, a more objective means of assessing a child’s receptive vocabulary is the Peabody Picture Vocabulary Test (3rd edition), which can be used beginning when the child is two and one-half years old and has been normed for individuals throughout the life span.

Morphology and Syntax

When infants are only 12 months old, their comprehension of syntax and morphology can be assessed using the preferential looking paradigm. Infants are seated on their mothers’ laps equidistant from two video monitors, each of which presents a different image. A message that matches one image is presented from a central location. A hidden experimenter measures how long a child watches each of the two videos. Even children who at 17 months can still produce only single words have been discovered to prefer looking at the video congruent with the message. For example, when “Cookie Monster is tickling Big Bird” is presented, children reveal their understanding of word order by looking at the image of Cookie Monster tickling Big Bird rather than of Big Bird tickling Cookie Monster. Older children’s understanding of syntax and morphology is often studied by asking them to repeat complex sentences because they can repeat grammatical structures only slightly beyond their productive grasp. Alternatively, children’s

Table I Examples of Measures of Comprehension versus Production of Language Acquisition by Level

	<i>Comprehension</i>	<i>Production</i>
Phonology	Habituation in high-amplitude sucking	Tape-recording child’s productions
Vocabulary	Peabody Picture Vocabulary Test-III	MacArthur Communicative Development Inventories
Syntax/ morphology	Preferential looking paradigm	Wug test
Discourse/ narrative	Story retelling	Personal narratives Wordless picture book story
Literacy	Reading comprehension section of California Achievement Tests	TROLL (preschool)

understanding can be assessed by asking them to act out what the sentence says.

Children's own production of morphology in spontaneous speech was one of the first aspects of language development studied using the tape recorder. However, Berko Gleason developed the wug test, already described, to reveal children's competence in this area by eliciting responses to novel nouns and verbs. Children performed as if they had acquired a rule for the grammatical procedure, albeit implicitly.

Pragmatics and Narrative/Discourse

Language is a social phenomenon, and a key aspect of its acquisition is its use in various social settings, settings in which speakers often string sentences together into some type of discourse. One frequently studied type of discourse is narrative. When children are approximately 27 months old, they begin to talk about past events. As always, production can be studied by audio-recording children's productions and subsequently transcribing and analyzing them using one of a number of available analyses. Personal narratives have been recorded in many different natural settings, particularly meal times.

A procedure has been developed to elicit personal narratives in a structured but naturalistic conversation by having researchers tell personal stories of their own to prompt children. For example, after making sure a child is comfortable and talks readily with an adult, the adult might say, "See this bandage? Yesterday I was peeling a potato, and I cut my finger. Has anything like that ever happened to you?" This procedure has worked well with children from many different cultural backgrounds.

Fictional narratives are also frequently elicited by using pictures or story prompts (e.g., "Once there was a rabbit who was very, very hungry. . .") and having children make up the rest of the story. One method that has been widely used in different languages consists of having individuals of many ages peruse a wordless picture book and then retell the story told in the pictures.

The comprehension of stories has been more difficult to study, and most often this is assessed by asking individuals questions about (usually fictional) stories they have heard or read or by requesting that the individuals retell the stories. The assessment of story comprehension by retelling is complicated when the individuals being assessed are from a culture other than the one that gave rise to the story in question because individuals of all ages tend to recall stories from cultures not their own in ways that distort those stories to conform to their own expectations of what makes a good story.

Literacy

The last strand or level of language to begin to be acquired is literacy, the ability to read and write. There are numerous measures of individuals' literacy skills, including some that are appropriate when the child is as young as three years (e.g., the TROLL test). Numerous school assignments and many standardized tests such as the Reading Comprehension Section of the California Achievement Tests (CTB) are geared to assessing the literacy skills of school-age children.

Computer-Assisted Assessment of Developing Language

The transcription of tape-recorded language is the most often used means of assessing oral language acquisition at any level. Such transcription is time-consuming and yields data that can take many years and numerous researchers to be adequately analyzed. In order to facilitate this process, MacWhinney and Snow and their colleagues developed in 1990 the Child Language Data Exchange System (CHILDES; this is available to scholars at the Web site). It includes a consistent and fully documented system for transcribing tape-recorded data, automatic processes for data analysis (e.g., calculation of MLU), and a database of transcripts available to researchers. This program facilitates the use of multiple methods of assessment of children's language, which researchers and clinicians alike agree is essential for the measurement of language acquisition.

Glossary

Bayesian probability A measure of the confidence that should be conferred on a statement in view of the available evidence. Degrees of belief should, in any case, be comparable (greater or smaller), but they need not be absolutely quantifiable. Also called subjective probability.

determinism The view that nothing happens without a cause; everything depends on fixed causal laws that with perfect certainty determine what happens. The appearance of chance is due only to the fact that in many cases the causal situation is too complex for us to comprehend.

frequentist probability The relevant frequency of the occurrence of an event in a class of equally possible events. When events occur in large numbers, their probability is often considered (for instance, by Laplace) to converge on a limit in proportion to the number of events. Also called object probability.

naturalism The position that philosophical statements should not be defended by appeals to anything that transcends nature or goes beyond the empirical. Many enlightenment intellectuals held that just moral and legal principles should be founded on empirical knowledge of man and nature (e.g., natural laws and natural rights).

probabilism The view that there is an essential uncertainty at the quantum level of phenomena, for instance, the Copenhagen interpretation of quantum mechanics.

Although living at a time and place of great scientific and political upheaval, Laplace was not a revolutionary, either in his political or in his scientific outlook. In his physics and astronomy, he was a vindicator of the Newtonian science of the epoch rather than an innovator. Apart from his technical contributions to mathematics and science, Laplace was important for the philosophical views that he developed in the presentation of his work and

for the development of quantitative methods in areas in which mathematical treatment had previously been unknown.

Introduction

From the outset, Laplace's research centered on the analytical approach to astronomy and the theory of probability, which in his work were intimately connected. He remained faithful to this pattern throughout his life. The final results were incorporated in his two major treatises: *Traité de mécanique céleste* (1799–1825) and *Théorie analytique des probabilités* (1812). Both were accompanied by verbal paraphrases addressed to an informed but nonmathematical public. The *Essai philosophique sur les probabilités*, first printed in 1814, had a longer life and probably a wider audience than any of his other writings, including its counterpart in celestial mechanics, the *Exposition du système du monde* (published in 1796). The reason for its continuing impact has been, of course, the importance that probability, statistics, and stochastic analysis have increasingly assumed in the natural and social sciences and in the philosophy of science.

Laplace broadened the subject from the mathematics of games of chance into a basis for statistical inference, philosophy of causality, theory of errors, and measurement of the credibility of evidence. He built from old and often hackneyed problems into areas to which quantification and mathematical treatment had never before been applied. As, in his own words, just “good sense reduced to calculation,” he applied his probability calculus to various political and social sciences and practices such as demography, the procedures of judicial panels and electoral bodies, the credibility of testimony, and the determination of insurance risk and annuities.

Laplace was a firm believer in the determinism of nature. The concept of chance in his view does not pertain to reality: it merely expresses our ignorance of the ways in which various aspects of phenomena are interconnected. Imperceptibly small variations in the initial conditions of a mechanism may entail enormous differences in the outcomes after a sufficiently long time, but that mechanism itself must behave in a perfectly determined fashion. The central tenet of Laplace's work was to show how in the final analysis there is a regularity underlying the very things that seem to us to pertain entirely to chance and to unveil the hidden but constant causes on which that regularity depends.

Life and Times

Laplace was born on March 23, 1749, in Beaumont-en-Auge (Normandy). His father was probably in the cider business and certainly well off. There is no record of particular intellectual distinction in the family. Originally destined to enter the Church, the young Laplace enrolled as a theology student at the University of Caen. After 2 years—at the age of 19—he discovered his mathematical inclinations and talents, aborted his studies, and went to Paris (1768). He gained the patronage of d'Alembert, who found him a teaching position at the Ecole Militaire. He held this post till 1776. At that time, it was almost impossible to earn a living in mathematics outside the sphere of the military.

Once settled in Paris, Laplace began reading papers at the Académie des Sciences, but it was only after 3 years and 13 remarkable papers that he finally was elected an adjoint to this venerable institution (1773). In the 1780s, Laplace achieved the depth of results that placed him on a par with Lagrange as an uncontested leader of mathematical analysis. He acquired a senior position in the Académie in 1785 and came to participate in various of its influential committees, among them the committee of weights and measures. The establishment of a metric system was the sole revolutionary endeavor that consistently engaged his warm interest.

His post as examiner at the Corps Royal d'Artillerie (which began in 1784) brought him into contact with ministers and others in positions of power and introduced him to the practice of recruiting an elite by competitive examination. This practice was later greatly expanded in scale and intensified in mathematical content in the procedures for selecting students to enter the Ecole Polytechnique (founded, together with the Ecole Normale, in 1794). Although he never actually taught at the Ecole Polytechnique, Laplace was closely involved in the organization of its educational program and later, especially under Bonaparte, came to dominate it completely. Having kept himself at a safe distance from Paris during the Reign

of Terror (which suppressed the Académie and other learned societies of the Ancien Régime), he was recalled to the capital after its fall (in July 1794) to participate in the reorganization of science at the two newly founded Ecoles. He became a professor at the Ecole Normale.

It was part of this school's mission to carry through a thorough rectification of the language of mathematics, in order to make it more accessible to ordinary people as an essential tool for their various practices rather than remaining the prerogative of leisured gentleman-scholars. At that time, language was taken as constitutive of thought, and the *langue des calculs* as its highest manifestation. By implication, all thought processes were conceived to be in the last analysis forms of calculation. This view had been developed especially by the philosopher Condillac. It represented the received view of the time, as is underlined by the fact that the Ecole Normale in 1794 purchased hundreds of copies of Condillac's *Logique*. Laplace certainly shared the view that calculation was the basis of all human intelligent action.

The revolutionaries had not thought highly of Laplace, but the Emperor Napoleon showed himself sensitive to his great prestige among distinguished mathematicians in France and abroad. He was given a leading role in the militarization of the Ecole Polytechnique, whose enduring egalitarian and republican spirit had to be curbed. The educational program came to turn on mathematical analysis, whereas previously descriptive geometry (a creation of the revolutionary Monge) had played the role of the universal mathematical basis for all the arts of engineering. Later, Laplace was also commissioned by the restored Bourbon monarchy to oversee a further reorganization (1816).

Around 1805, Laplace, with the chemist Berthollet, began to organize scientific meetings at their neighboring homes in Arcueil (just outside Paris), out of which grew the informal Société d'Arcueil, headed by Laplace. Its members, among them the mathematicians Biot and Poisson, strongly advocated a mathematical approach to natural and social sciences and practices. The group had a strong influence on the Institut (successor of the suppressed Académie) and on the program of courses of the Ecole Polytechnique.

During the Arcueil period, Laplace worked mainly on a physical program of research, which for a time was highly influential. The Laplacian School of Physics, as it has come to be called, was founded on the belief that phenomena such as refraction, capillary action, cohesion, crystallization, and even chemical reactions were the result of an attractive molecular force, which was identified with gravity. Laplace hoped in this way to raise the physics of terrestrial bodies to the state of perfection to which celestial physics had been brought by the discovery of universal gravitation. By 1812, however, members of the Société began to favor theories that were in contradiction

with Laplace's views. They, for instance, criticized Newton's corpuscular theory of light and Lavoisier's caloric theory of heat, which had been further elaborated by Laplace and to which he would stick tenaciously for the rest of his days.

Napoleon made him chancellor of the Senate and, subsequently, count of the Empire (1806). In 1814, Laplace sided with the monarchists and voted against Napoleon in the Senate. In 1817, the king honored him for his services with the title of marquis. Laplace died on March 5, 1827 in Paris.

Determinism of Nature

The idea of changing the cherished Newtonian system of the world seems never to have entered Laplace's mind. Rather, he sought to perfect it by the means proper to his generation and milieu, that is, by mathematical analysis. The overwhelming success of Newtonian mechanics induced the belief in the universal validity of mechanistic philosophy, whose core is the explanation of phenomena in terms of a mechanism in which the whole succession of motions is determined by the state of the moving system at any particular time. In contrast to religious belief, the belief in a fully determined universe was a faith that supported naturalism. Well known is Laplace's remark to Napoleon that there is no need for the hypothesis of God's intervention in the system of the world. On the other hand, because natural phenomena can be described by differential equations, the determinism of nature was supposed to guarantee under specified initial conditions the existence of unique solutions to differential equations—unless they are altogether “unnatural.”

Laplace shared the optimistic enlightenment views of the universal applicability of analytical procedures: “What one observes in Analysis happens similarly in Nature, whose phenomena are indeed just the mathematical consequences of a small number of invariant laws.” He defined his program as “reducing the whole of mechanics to pure analysis,” followed by its application to celestial mechanics, the paradigm case of purely analytical calculation of “the changes that the course of time has effected, and still effects, in this system.” Commenting on Clairaut's corrected prediction of Halley's comet, Laplace concluded, “the regularity which astronomy shows us in the movements of the comets doubtless exists also in all (other) phenomena. The curve described by a simple molecule of air or vapor is regulated in a manner just as certain as the planetary orbits.” Consistent with this view, in his Arcueil period he set out to solve the problems of capillary action, the speed of sound, and the refraction of light and to develop a general theory of heat and gases through the analysis of a microastronomical model of central forces of

attraction acting on point masses. Using the same deterministic model, he also tackled psychology, which he conceived as a continuation of empirical physiology. Roughly speaking, he modeled the seat of our thoughts after a system of resonators coupled to the environment, whose vibrations are subjected to the laws of dynamics.

Laplace saw himself as a strict follower of Newton, who was believed to have been a pure inductivist abhorring hypothetical reasoning. He went so far as to claim that Newton's successes derived from the circumstance that in his time just enough empirical knowledge of mechanical phenomena had been assembled for him to infer the general principles and laws of mechanics from these facts. Newton's works, Laplace asserted in 1796, have supplied

the best models ... for gathering data and subjecting them to the calculus.. One must select or produce the phenomena that are best suited to this purpose, multiply them under varying circumstances, and find out what they have in common. In this way one ascends successively to more and more extensive relationships, to reach finally the general laws, which then have to be verified ... This analytical relation of particular facts with a general fact is what constitutes a theory.

Although Newton himself had had serious qualms about the possibility of action at a distance, Laplace used it as a necessary basis of all mathematical physics, claiming that natural phenomena are in the last analysis reducible to intermolecular attraction on the model of Newton's theory of gravitation. As we have already seen, he also stubbornly stuck to the corpuscular theory of light, even after the experiments of Fresnel had tipped the balance so much in favor of the wave theory.

He set himself the task of proving that Newton's theory of gravitation suffices to solve all problems in its domain and therefore constituted “the true System of the World.” The best statement of Laplacian determinism undoubtedly is that given by Laplace, himself:

We ought then to regard the present state of the universe as the effect of its anterior state and as the cause of the one that is to follow. Given for one instant an intelligence which could comprehend all the forces by which nature is animated and the respective situations of the bodies of which it is composed—an intelligence sufficiently vast to submit these data to analysis—it would embrace in the same formula the movements of the biggest bodies of the universe as well as those of the lightest atom; for this intelligence nothing would be uncertain and the future as well as the past would be present to its eyes. The human mind offers, in the perfection which it has been able to give to astronomy, a feeble idea of this intelligence. Its discoveries in mechanics and mathematics, added to that of universal gravity, have enabled it to comprehend in the same analytical expressions the past and future states of the system of the world. Applying the same method to some other objects of knowledge, it has succeeded in

referring observed phenomena to general laws, and in foreseeing phenomena which given circumstances ought to produce.

Probability and Human Affairs

It is only because of our lack of knowledge and our limited mental capacity that we have to appeal to the theory of probability, which is, as it were, an instrument for repairing defects in our knowledge. Chance has no reality in itself; it is nothing but a term for expressing our ignorance of the way in which the various aspects of a phenomenon are interconnected. Because nature knows nothing of chance, the notion of a statistical law (of nature) was a contradiction in terms for Laplace. The object of probability theory is precisely to show that the very things that seem to pertain entirely to chance in the final analysis exhibit a certain regularity and to unveil the hidden but constant causes on which that regularity depends. Thus, he, for instance, established that the planets' seeming aberrations from Newtonian law were periodic and hence part of the determined order of Nature—they were due to the gravitational influence of the other planets and of comets.

It was from mathematics, especially his investigations of difference equations, that Laplace came to the theory of probability. In articles written around 1773, he applied the analytical methods that he had developed to the theory of chance, and they at the same time complemented his new departure into the determination of cause. These were the writings in which, according to Gillispie, Laplace "began broadening probability from the mathematics of actual games and hypothetical urns into the basis for statistical inference, philosophic causality, estimation of scientific error, and estimation of the credibility of evidence, to use terms not then coined."

The theory of probability owes more to Laplace than to any other individual. He considered the theory from all aspects and at all levels, and his *Théorie analytique des probabilités* is replete with new analytical methods still in use today. We find there for instance the theory of generating functions, which Laplace had already developed in the 1770s as a means of estimating the ratio of the number of favorable cases to the total number of all possible cases. The book contains also the method of least squares for the combination of numerous observations. This method had been suggested by Legendre on practical grounds, without any principled basis in probability theory, but Gauss and then Laplace gave it a variety of formal proofs, on which the entire theory of errors has since been based. It is with reference to least squares that Laplace conceived the ideas that now serve as the

foundations of statistical theory: the idea that every statistical procedure is a game of chance played with nature, the idea of a loss function and of risk, and the idea that risk may be used for defining the optimality of the statistical method concerned. Further important new mathematical tools were the method of recurrent sequences and of characteristic functions, also called Laplace transforms, which are widely used today for tackling differential equations.

The second edition (1814) contained, apart from several new supplements, an introduction that subsequently was published separately as *Essai philosophique sur les probabilités*. Laplace introduced it as an extended version of lessons that he gave at the Ecole Normale in 1795: "I present here without the aid of analysis the principles and general results of this theory, applying them to the most important questions of life, which are indeed for the most part only problems of probability." This explains the avoidance of formulas and technical mathematics; actually large tracts of the *Essai* are transpositions into common language of what in the *Théorie analytique* had been developed mathematically.

"Strictly speaking," Laplace went on, "it may even be said that nearly all our knowledge is problematical; and in the small number of things which we are able to know with certainty, even in the mathematical sciences themselves, the principal means for ascertaining truth—induction and analogy—are based on probabilities; so that the entire system of human knowledge is connected with the theory set forth in this essay."

The leading idea of the book is that each particular phenomenon in reality, including social and political phenomena, is governed by causes of two distinct kinds, the permanent and the accidental causes. In each particular phenomenon, the effect of accidental causes may appear stronger than that of the permanent causes, with the result that such phenomena become the subject for probabilistic investigations. On the other hand, in a long series of similar occurrences, the accidental causes average out and the permanent causes prevail. This is called the weak version of the theorem of large numbers formulated by Bernoulli, who is given due credit by Laplace. Considerations such as these are, of course, quite usual with reference to lotteries, games of chance, insurance risk, and so on, but Laplace built them into areas in which quantification and calculation had previously been nonexistent, especially various political and social sciences and practices (e.g., demography, procedures of judicial panels and electoral bodies, and credibility of testimony).

It follows again from this theorem that in a series of events indefinitely prolonged the action of regular and constant causes ought to prevail in the long run over that of irregular causes. It is this which renders the gains of lotteries just as certain as the products of agriculture; the chances

which they reserve assure them a benefit in the totality of a great number of throws. Thus favorable and numerous chances being constantly attached to the observation of the eternal principles of reason, of justice, and of humanity which establish and maintain societies, there is a great advantage in conforming to these principles and of grave inconvenience in departing from them. If one consults histories and his own experience, one will see all the facts come to the aid of this result of calculus. Consider the happy effects of institutions founded upon reason and the natural rights of man among the peoples who have known how to establish and to preserve them.

Laplace defined the probability of an event as the ratio of the number of cases favorable to that event to the number of all the possible cases. This suggests a frequentist interpretation of probability, which is often contrasted with the subjective notion (attributed to Bayes, who is mentioned once in the *Théorie analytique*) of “degree of belief.” At that time, however, this distinction was not made. The *Essai philosophique* became the fountainhead of the frequentist interpretation, because the decisive role is given to frequencies, but in many places Laplace also handles probability as a (Bayesian) measure of confidence or diffidence, independent of any frequency connotations.

Laplace arrived at results very similar to those of Bayes, tacitly relying on the assumption that possible causes are equally likely if there is no reason to believe that one of them is more probable than any other. As the inverse square law was the final touchstone of mathematical astronomy, so the principle of equal prior probabilities was the touchstone of his mathematical theory of probability.

The intensity of rational expectations appears here as the decisive moment in assigning probabilities. On the other hand, a considerable part of the *Essai* is devoted to illusions that give rise to mistakes in assigning probabilities to events, and here probability appears as something independent of the subjective state of mind of individuals.

So it seems that Laplace used an objective notion of probability in the cases for which we have sufficient information and a subjective notion in the cases for which insufficient information is available. On the one hand, his calculations depend on the consideration that the probability of events that occur in large numbers converges on a limit in proportion to the number of events; on the other hand, he held that probability is relative to our state of knowledge or ignorance and not to nature. The more frequently a certain correlation between events is observed, the greater is its probability and the stronger our belief; hence, the objective probabilities of experience and the subjective probabilities of belief were, in his mind, mirror images of one another.

The mathematical theory of probability was, in Laplace’s words, just “good sense reduced to a calculus.”

The apparent mishmash of applications to gambling, insurance, astronomy, medicine, reliability of testimony, accuracy of tribunal judgments, economic theory of value, and reasoning from known effects to unknown causes had as a common background that all were posed in terms of reasonable belief and action based on that belief. The calculus of probabilities shared with the social sciences and practices of the Enlightenment a common ground in that they all had as their object of study the psychology of the rational individual. But when Laplace discussed the relationship between psychology and probability, this was primarily to expose the psychological roots of probabilistic illusions, which included beliefs in astrology and divination. The “good sense” that in Laplace’s theory was reduced to a calculus was the good sense of the *homme de lumières*, combating ignorance, error, prejudice, and superstition.

Law

Eric A. Posner

University of Chicago, Chicago, Illinois, USA

Glossary

civil law A system of law in France, Germany, and many other countries that is based mainly on statute (the civil code), rather than on judge-made law.

Coase theorem If transaction costs are zero, then the allocation of legal entitlements does not determine their use; instead, the entitlements will be traded to their most efficient use.

common law A system of law originating in England, and characteristic of the United States and other countries, that is based on judge-made law.

exemption law A law that protects the assets of defaulting debtors against seizure and liquidation by creditors.

expectation damages The standard remedy for breach of contract; the victim of the breach is entitled to the amount of money that would put him in the financial position that he would have been in if the contract had been performed.

formalism A characteristic of legal systems, or areas of law within them, formalistic laws are those that are clear rules rather than vague standards.

liability rule A type of legal remedy that grants a person who has been wronged the right to monetary damages.

property rule A type of legal remedy that permits the person who has been wronged to obtain an injunction against the wrongful act.

specific performance A remedy for breach of contract that gives the victim of breach the right to have the contract performed.

transaction cost The cost of negotiating, writing, monitoring performance with, and enforcing a contract.

Examples of social science methods used in law come mainly from efforts to apply economics, psychology, and sociology to legal questions. The methods from these disciplines permit one to evaluate the influence of laws or legal institutions (such as courts) on social

behavior such as crime, to explain how legal institutions function, and to explain why existing laws and legal institutions came into existence.

Introduction
