Traditional legal scholarship, sometimes called doctrinal scholarship, is an interpretive enterprise. Using legal materials such as statutes and judicial opinions, scholars attempt to identify what the law is, that is, whether some particular act *X* is permitted or regulated by the law, and in the latter case, what the sanction will be if the law is violated. Although doctrinal scholarship continues to be conducted, it was attacked in the early 20th century for its preoccupation with the “law on the books” to the exclusion of “law in action.” A statute might prohibit *X*, but have no influence on social behavior because the statute is ignored by prosecutors, judges, juries, potential litigants, and others, or because the people to whom the law is directed can accomplish their original goals without violating the statute. The critique of doctrinal scholarship provoked a turn toward social science; legal scholars hoped that social science methods would enable them to understand how the law works, how it influences behavior in society, and how people and governments achieve their goals through law rather than through other means.

The earliest social science work in legal scholarship occurred during the 1920s and 1930s under the influence of a movement known as legal realism. It is generally regarded as a failure: it counted things rather than proposing and testing theories. Many decades passed before social scientific methods in legal scholarship became influential. In the 1960s, a movement known as “law and society” applied empirical sociological techniques to legal problems. Law and society scholars used surveys and other data sources to investigate how people thought

about law, whether they understood or paid attention to it, and how the law affected behavior.

Beginning in the late 1960s and early 1970s, a movement known as “law and economics” applied rational choice theory to legal problems. Law and economics, which has become the dominant social science methodology in legal scholarship, typically asks, What effect will some law Y, as opposed to some other possible law Z, have on people’s behavior, assuming that people are rational in the sense defined by economics? There is also a growing empirical literature that uses statistical and qualitative methods to evaluate the theoretical predictions.

A third important methodology is psychology. The law and psychology literature typically looks at how psychological theories predict behavior in legal settings and tests these predictions usually under experimental conditions. A large literature of jury studies investigates how jurors make decisions. Additional work applies insights from cognitive psychology to a wide range of laws and legal institutions.

This article discusses a few examples of social science-inspired theory and testing in legal scholarship. Comprehensiveness is impossible; the examples will illustrate the main trends.

Law and Economics

Criminal Law

The application of economics to criminal law has its roots in Beccaria and Bentham, but the first modern piece of scholarship is an influential 1968 article by Gary Becker. Becker’s methodological innovation was to treat the criminal sanction as the “price” of engaging in socially disapproved behavior, such as murder and robbery. Individuals rationally choose to engage in crime when the benefits, which include monetary returns as well as intrinsic pleasure, exceed the expected cost, which is the criminal sanction discounted by the probability of arrest and conviction. An increase in a criminal sanction should have the same effect as the increase in the price of ordinary goods: individuals will engage in less of the sanctioned behavior. (Many criminologists reject Becker’s views.)

Lawyers and policy analysts typically want to know more than this. If the sanction for robbery is increased, will potential robbers switch to a lawful occupation or to burglary instead? If the punishment for robbery is too severe, and thus too close to the punishment for murder, will robbers be more likely to murder their victims because the extra sanction is now so low? Should repeat offenders receive higher sentences? These, and similar questions, can be addressed using Becker’s framework.

The focus of the empirical literature has been the relationship between the criminal sanction and the crime rate. Authors test the hypothesis that an increase in punishment reduces crime through the deterrence effect, as opposed to some other process, such as the incapacitation of people who would commit crimes if they were not in prison. It is also possible that criminals are not deterrable: they might discount future payoffs or sanctions too much, miscalculate the probability of being caught or convicted, and so forth.

One representative empirical study attempts to distinguish the effects of deterrence and incapacitation. In a 1999 paper, Kessler and Levitt studied California’s Proposition 8, one of the most famous “three-strikes laws,” which increased the punishment for certain repeat offenders. If imprisonment has a deterrent effect, then a three-strikes law should immediately deter people from committing the crimes to which it applies. If imprisonment has no deterrent effect, but only incapacitates, then the effect of these laws will be felt only after a delay. The reason is that the new incapacitation effect created by the laws will be felt only after criminals serve as much time in prison as they would have if the laws had not been enacted.

Kessler and Levitt tested the deterrence and incapacitation effects of Proposition 8 by comparing two sets of data. They distinguished the crimes eligible for the sentencing enhancement under Proposition 8 (generally, serious felonies) and those that were not. The rates for eligible crimes and ineligible crimes declined immediately after Proposition 8 came into effect, but the rate for eligible crimes declined more rapidly, suggesting that the law, rather than an omitted variable, caused some of the reduction in crime. In addition, they compared the difference between the eligible and ineligible crime rates in California and the difference between two similar sets of crime rates nationwide. The difference in California increased more than the difference nationwide, indicating that the law, rather than an omitted variable, caused the increase in the difference between the eligible and ineligible crime rates. In these ways controlling for trends within California as well as national trends, Kessler and Levitt found an immediate 3.9% drop in the eligible crime rate. After 3 years, the decline was 7.9%. By this time, the incapacitation effect could have kicked in, but the study suggests the initial 3.9% drop was due entirely to the deterrence effect.

Kessler and Levitt relied on a simple comparison of changes in the crime rate, rather than regression analysis, because California was the only state in which three-strikes laws were both created and vigorously enforced. Many other empirical studies of criminal law exploit interstate variation in criminal law and punishment and therefore can rely on cross-sectional and, sometimes, panel data.

Debtor–Creditor Law

Many people have trouble paying their debts and default on their loans. Numerous federal and state laws regulate the means by which creditors may obtain compensation for their losses. Under federal bankruptcy law, debtors may periodically file for bankruptcy, which usually results in the discharge of their debts. But even if debtors do not file for bankruptcy, state garnishment laws prevent creditors from obtaining more than a fraction of future income, and state exemption laws limit the assets that can be seized and liquidated.

State exemption laws hold particular interest for scholars. One reason for this is that the federal bankruptcy system incorporates the state exemption laws and, in addition, creates a generous system of federal exemptions that serve as a floor for the state exemptions unless states take the trouble of opting out of the federal system. The state and federal exemption laws typically allow individuals to protect their principal residence, or some fraction of the equity (in some states, an unlimited amount of equity), and furniture and other goods up to designated values, sometimes tens of thousands of dollars. However, many states are less generous, and the extreme cross-state variation in the generosity of exemption laws makes them an attractive subject for empirical study.

Although the modern system of American bankruptcy law originated in 1899, and many state exemptions are even older, current law was heavily influenced by a reform act passed in 1978. This law greatly expanded bankruptcy protections; one of its provisions was the creation of the parallel federal system of exemptions described above. Supporters of the 1978 reform act argued that these expanded protections were justified by sharp credit practices that took advantage of unsophisticated debtors, who often filed for bankruptcy because of unanticipated events such as divorce or illness. Although opposition to the reform was muted, shortly after the reform became law the bankruptcy filing rate skyrocketed. Creditors complained to Congress, which cut back some of the protections a few years later, but these protections remained more generous than they had been prior to 1978.

Economists and legal scholars have studied the effect of bankruptcy protection on the credit market. Economic models of the credit market posit that individuals borrow money in order to smooth consumption over time. If income increases with age, while the marginal value of a dollar remains constant, the individual would want to move dollars from the future to the present. Creditors will supply these dollars as long as debtors pay back the loans plus interest to compensate for the time value of money, inflation, the risk of default, and similar factors. In a competitive market, the interest rate will be just enough to cover these costs; everyone willing to pay the interest will be given credit.

Debtor protection law, including bankruptcy and exemption law, has two opposing effects on the unregulated equilibrium. On the one hand, debtor protection makes credit more attractive because it limits the adverse consequences of default; this should increase the demand for credit. On the other hand, debtor protection increases the losses of creditors; this should reduce supply. Many economists would assume that debtor protection law in the aggregate restricts credit—reduces the supply, increases the cost, or both—because debtors and creditors could individually negotiate insurance contracts if debtors wanted to be protected from default. They do not, for the most part, suggesting (unless there is a market failure of some sort) that debtors are simply not willing to pay for insurance. But this is only theory; the actual effect of debtor protection laws can be determined only by empirical tests.

Gropp *et al.* conducted one such test in 1997. Because exemption laws vary by state, one can gauge the effect of these laws through cross-sectional comparison. The main independent variable is the effective exemption level (divided into quartiles): in each state, this is the higher of the federal floor and the state exemption (except in the states that have exercised the right to opt out of the federal system, in which case residents must use the state exemption). The hypothesis is that credit will be tighter in states with higher exemptions.

Gropp *et al.* conducted a number of tests. Their first regression shows that individuals in the highest exemption states are significantly more likely to be turned down for credit than individuals in the lowest exemption states. A second regression shows that the amount of debt carried by individuals is higher in low-exemption states than in high-exemption states. A third regression shows that interest rates are higher in states with generous exemptions, although not for debtors with significant assets, who probably pose less of a risk for creditors, who would be able to obtain a greater proportion of the debtor's wealth even in bankruptcy. The three regressions are consistent with the hypothesis that generous debt protection reduces the supply of credit. Because creditors expect that they will not recover the full value of their debt when debtors default, they charge a higher interest rate or refuse to issue loans in the first place.

There are many other studies on the regulation of the credit market. These studies tend to find that the regulations restrict credit without providing any offsetting benefits, though some studies find no effect.

Comparative Law

La Porta and his coauthors have written a series of papers examining cross-country differences in the law; they seek to explain why laws differ across countries,

and what effect these legal differences have on economic performance and institutional structure. Because legal traditions are so different, these studies face significant empirical difficulties.

In 1998, La Porta *et al.* investigated investor protection laws in 49 countries. These laws are designed to prevent managers of corporations from violating the rights of equity-holders and debt-holders. Generally speaking, equity-holders have the right to a share of the corporation's profits and to vote on certain decisions made by the firm, including appointment of directors. Debt-holders have the right to principal and interest and to seize a portion of the corporation's assets if it defaults on the debt. These rights have value only if legal institutions enforce them; if they do not, managers can pocket the money that would otherwise be due to the holders of securities. The law is designed to prevent managers from taking assets that belong to corporations, both directly and through subterfuge, when these assets should be used to generate revenues for distribution to debt-holders and equity-holders. This is true in all countries, though the details differ significantly, as does the quality of legal enforcement.

One of the problems with studies such as La Porta *et al.*'s is that legal rights in different countries vary along many dimensions. Some countries have a one-share—one-vote rule, which prohibits corporations from issuing shares with different voting rights. Other rules, which can be found in some countries but not others, regulate the use of proxies for voting, cumulative voting procedures, and the treatment of minority shareholders by the majority, mandate dividends, and so forth. In order to enable cross-country comparisons, La Porta *et al.* constructed various indices. The main index is a score from 0 to 6, which is derived by giving each country 1 point for each of six major shareholder rights that are protected in its legal system. A simple regression shows that countries with an English common law origin offer significantly greater shareholder protections than countries with French, German, or Scandinavian civil law origins.

Countries also afford a diverse array of legal protections to creditors. Rules govern whether creditors can immediately repossess assets when the debtor enters bankruptcy or must wait, subordinate creditors' claims to those of other interests, give management more or less control in bankruptcy, and so forth. La Porta *et al.* constructed an index of creditor rights and again found a great deal of variation across countries, with common law countries offering the greatest protections.

Thus far, this article has discussed formal investor protection laws, but there is the equally important question of whether these laws are enforced. La Porta *et al.* examined a variety of measurements of law enforcement, including scores for the efficiency of the judicial system, the rule of

law, corruption, risk of expropriation, risk of contract repudiation, and accounting standards. Gross National Product (GNP) per capita is strongly correlated with quality of legal enforcement; when this is controlled for, English common law origin countries score better than French civil law origin countries but worse than German civil law origin countries.

The final question investigated by La Porta *et al.* is whether these differences in investor protection law have any effect on the economy. They focused on ownership concentration: the extent to which ownership of a corporation is concentrated in the hands of a few people rather than dispersed across thousands of shareholders. One hypothesis is that if investor protection laws are weak, then ownership will be concentrated. The reason is that minority shareholders will fear that they will be exploited by majority shareholders and managers unless they have legal protection. A regression with various controls lends support to this hypothesis. French civil law origin countries, for example, have the weakest investor protection laws and the most concentrated ownership. Note that including the legal origin of countries addresses concerns about direction of causality; e.g., governments in countries with highly concentrated ownership are lobbied by businesses to legislate weak protections. The legal origins date back centuries and are likely to be exogenous.

The study reveals a great deal about variation of investor protection laws across countries and the effect of these protections on ownership concentration. Its larger significance is its illustration of the methodological solutions to problems arising from cross-country comparisons of legal systems.

Law and Psychology

Property Rights and the Endowment Effect

One of the most famous ideas in law and economics is that, in the absence of transaction costs, resources will be transferred to their most efficient use. To understand this idea, suppose that two people, A and B, own neighboring parcels of land. A's factory generates noise and pollution, which interferes with B's hotel. Under the law of nuisance, B might have a right to enjoin A from producing noise and pollution; whether B does have such a right depends on numerous legal variables. But Coase argued that it does not matter whether A has the entitlement to make noise and pollution, or B has the entitlement to be free from noise and pollution, because the entitlement will end up in the hands of whoever values it more. If the law grants B the entitlement to be free from noise and pollution, but A's factory makes enough money to fully compensate B for the loss of that entitlement, then B will sell the entitlement

to A. If the law does not grant B that entitlement, then there will be no such transaction. Thus, if A values the entitlement more than B does, A will end up with it, and similar logic applies if B values the entitlement more than A does. The initial allocation of entitlements does not affect the final allocation.

This argument has been extended to the topic of legal remedies. Suppose that B is granted the entitlement; there is a further question of whether B should be protected with an injunction or with damages. In the first case, B can sue to enjoin, that is, prohibit, A from producing noise and pollution. In the second case, B cannot stop A from producing noise and pollution but is entitled to monetary compensation equal to B's loss. The Coase idea has been interpreted to suggest that it does not matter for the allocation of the entitlement whether the law gives B damages, an injunction, or indeed no remedy at all. Regardless of the remedy or lack of remedy, A will stop polluting if and only if B's valuation is higher than A's: the only difference is who pays whom, and how much.

One criticism of the Coase idea is that it assumes that a person's valuation of a piece of property is independent of whether he owns it. The psychology literature suggests that there is an "endowment effect," according to which a person values something more if he owns it than if he does not own it. A well-known experiment found that subjects who were given coffee mugs would sell them only for a higher price than similarly situated subjects would buy them for. This is a puzzle for economics, which assumes that people value goods the same regardless of whether they own them. If the endowment effect is significant enough—and there is some doubt about this—then Coase's idea would be wrong. If B is given the entitlement, then B will value quiet and clean air a lot; if B is not given the entitlement, he will value quiet and clean air a little. Although trades will sometimes still be possible, the initial allocation will partly determine the final allocation.

If this is true, then the conclusion about legal remedies might be wrong as well. But here there is a further question: what ownership characteristics are necessary for the endowment effect to function? Most property rights are protected by a mix of injunctive and damages remedies, but is it possible that people might regard these remedies differently and value property that is protected by stricter remedies more? In 1998, Rachlinski and Jourden tested this hypothesis in an experimental setting, in which students were given a story about a nuisance dispute and asked a series of questions about whether they would trade entitlements. Students were told that they owned a piece of property whose value was reduced by the activities of a neighboring landowner. In one scenario, the students were told that their entitlement was protected by damages; in another scenario, the students were told that their entitlement was protected by injunction. Rachlinski and Jourden found that the students valued

their entitlement more, and were less willing to sell it to the landowner, if it was protected by an injunction rather than damages. This suggests that the endowment effect is stronger when legal remedies are stricter and implies that the allocation of property rights is not independent of the type of legal remedy.

The study is notable because it relies on an experiment rather than on data collected from the field. Experiments have been heavily criticized: typically, they rely on students, who may not be representative, and subjects are often paid nothing or a small amount, so that their motivation is not the same as that of people in the real world. Nonetheless, experiments are useful for isolating certain phenomena that are not easily observed outside the laboratory and they have become increasingly popular in law, as they have in economics.

Juries and the Psychology of Deliberation

Legal scholars have long been interested in understanding how juries deliberate and make decisions. A literature going back several decades has analyzed jury decision-making using either reports of actual jury deliberations or laboratory experiments in which subjects are asked to play the role of juror.

In 1984, Cowan *et al.*, for example, investigated whether jurors who are unwilling to impose the death penalty are less likely to convict defendants than jurors who are willing to impose the death penalty. This question is important because under traditional rules, a person can serve as a juror for a capital murder trial only if he is not philosophically opposed to the death penalty and is willing to impose it under the appropriate legal conditions. Jurors are required to apply the law and the exclusion rules are designed to ensure that they will. The problem is that people willing to impose the death penalty may not be representative of the population. If people willing to impose the death penalty are more likely to convict, then defendants accused of capital murder are likely to receive a jury biased in favor of conviction.

To test their hypothesis that "excludable" jurors are less likely to convict than "death-qualified jurors," Cowan and her coauthors had their subjects watch a reenactment of a capital murder trial and then deliberate in mock juries. Consistent with the hypothesis, the excludable jurors were significantly less likely to vote for conviction than the death-qualified jurors were, and this was true both prior to deliberations and after the deliberations. Some evidence also suggested that juries with a mixture of excludable and death-qualified jurors performed better than juries composed entirely of death-qualified jurors. These results were consistent with the findings of other studies and have had influence on the development of death penalty doctrine in the courts.

Research on jury decision-making has been influenced by the cognitive psychology literature. A 1998 article by Sunstein *et al.* and a 2000 article by Schkade *et al.* exemplify this research. Both studies were based on large-scale controlled experiments, in which several hundred individuals were given a fictional legal dispute and asked to resolve it as a mock juror. The first study investigated whether the judgments of individual jurors were predictable, in the sense that the judgment of one juror was a good prediction of the judgment of another juror. They found that jurors ranked cases by the severity of the legal wrongdoing in a consistent fashion, but that jurors' judgments about appropriate money damages varied wildly. This result was consistent with psychological studies that indicated that individuals evaluated outcomes more consistently when given a closed scale than when given an open scale. In the study, jurors were asked to rank their outrage and their intent to punish on a scale from 0 to 6 and then to award damages on an unbounded scale (as is usually the case in legal proceedings when damages are intended to punish rather than to compensate). The rankings were consistent because the scale was closed; the damages were inconsistent because the scale was open.

Critics of the first study pointed out that real jurors deliberate in groups before deciding on a monetary award; it is possible that deliberation eliminates extreme outcomes and results in more consistent awards. By contrast, in Sunstein *et al.* the monetary awards were statistically created from randomly matched aggregates. Schkade *et al.* therefore instructed the experimental subjects to deliberate in groups of six. Surprisingly, although the postdeliberation rankings of outrage and intent to punish were similar to the statistical rankings in the prior study, the postdeliberation awards exhibited even greater variance than the statistical awards (they were also more severe). The authors discuss a number of possible explanations for these results; one of the most interesting is group polarization—a phenomenon whereby, in a group, people tend to herd toward one extreme or the other, rather than the median of their original positions.

Law and Society

The “law and society” movement is older than the literatures on law and psychology, and law and economics, but has had less influence in the mainstream legal journals. The reason for this may be that law and society scholarship draws on many different academic traditions and thus lacks a unified theoretical core.

Contractual Relationships

Macaulay's 1963 study of business relations among firms that do business in Wisconsin is a landmark in law and

society scholarship. Macaulay interviewed 68 businessmen and lawyers and asked them to describe how they use contracts to structure their business relations. He found that businessmen, to a surprising extent, avoided using detailed contracts and refrained from litigation if a dispute arose. Businessmen believed that too much emphasis on legal rights and lawyers, and too much planning in advance of possible disputes, can undermine the establishment of trust.

The main significance of Macaulay's study was its demonstration that the law on the books and the law in action can be very different. Although legal scholars had suspected as much, there had been no persuasive empirical support for this view and Macaulay's study showed that even sophisticated people who had access to legal advice frequently did not pay attention to their legal rights. Macaulay's work stimulated empirical scholarship of the legal system and especially the use of the survey to measure the law's effect on behavior. His influence has also been felt in law and economics, including the work of Ellickson (1991) and Bernstein (1992), who have followed Macaulay's lead in arguing that people frequently ignore, or are ignorant of, their legal rights and rely on social norms and informal groups to regulate their behavior.

The Distributive Impact of Litigation

In 1974, Galanter launched a long line of studies by arguing that wealthier individuals and business are more likely to win lawsuits than poorer individuals are. Studies of trial and appellate litigation, in the United States and other countries, have confirmed that the win rate is positively correlated with wealth and that businesses and governments win more frequently than individuals do. These studies have relied mainly on records of judicial decisions, which are widely available.

Many explanations have been proposed for this pattern. One theory is that the law is biased in favor of the wealthy. But there is no baseline for determining whether the law is biased or unbiased, and in any event when the law is changed in favor of the poor, the win rates do not change. Another theory is that wealthier people hire better lawyers. But better lawyers settle (or should settle) in order to save their clients unnecessary litigation expenses and they should take on harder cases. Thus, it is not clear whether wealthier people should win more often or instead should settle more often and litigate more difficult cases. A third theory is that wealthier individuals, and especially businesses and the government, are repeat players and are willing to fight harder in order to discourage others from bringing new suits against them and to establish favorable precedents.

Citation Studies

Legal materials have been available on computer databases for many years. Judicial opinions, statutes, scholarly articles, and similar sources can therefore be easily collected, converted into data, and analyzed with statistical methods. A new focus has been the use of citations to measure, and to determine the causes of, the influence of judges and scholars.

Judges play an important but poorly understood role in the legal system. The legal system is divided into federal and state law; the federal government and the state governments all have their own judiciaries. The federal system is divided into trial (district) courts, appellate (circuit) courts, and a court of last resort (the Supreme Court). There are hundreds of federal judges and thousands of state judges.

In 1998, Landes *et al.* focused on the federal circuit judges. Judges hear cases in panels of three (usually), and the senior judge on the panel chooses one of the judges to write an opinion for each case that they hear. The opinion is usually signed by the judge who writes it and is published. The opinion is binding precedent in the circuit and can be a nonbinding but persuasive authority for judges outside the circuit. If well-reasoned opinions are influential, then one would expect this influence to show up particularly in citations to the opinions by judges outside the circuit in which the opinions were issued. These judges do not have to cite a relevant extracircuit opinion because it is not binding; if they do so, the reason is likely to be that the opinion is persuasive.

Landes *et al.*'s database consisted of opinions written by most of the judges sitting on the courts of appeal in 1992. The question that interested Landes and his co-authors is what determines the level of "influence" of a judge, where influence is assumed here to be the frequency of citation. Citations, they argue, are a function of the judge's "capital"—his stock of opinions—and other judges' demand for that capital. Capital is a function of the judge's years of experience, whether he has retired, and so forth. Demand is a function of the judicial workload at any given time, the size of the circuit in which the judge operates (because each circuit has its own interpretations of the law, within-circuit citations are higher than inter-circuit citations), whether the judge has the power to assign opinions to himself (the chief judge of the circuit), and similar variables. The capital variable in the equation reflects the assumption that judges who work for a long time build up a reputation for writing good or bad opinions, and demand reflects the assumption that some opinions are more useful than others. The two variables are multiplied together in the regression equation.

Regressions confirm that citations increase with tenure but at a decreasing rate. Each new opinion builds up the capital stock but the earlier opinions depreciate at a rate

faster than replacement. Retired judges and judges on senior status (a twilight before retirement) are cited less often than other judges. Chief justices do not increase citations. The regressions enable the authors to rank judges by comparing their residuals, that is, the fraction of citations that cannot be attributed to years of experience and the other independent variables. Circuits are also ranked for influence.

Next, the authors tried to determine the factors that explain influence, that is, the citation ranking. They collected demographic and other variables that might be relevant. Their findings are as follows: (1) Judges who cite their own opinions a lot are also frequently cited by other judges; perhaps this is because self-citers take more of an interest in writing opinions (many judges do not write their opinions but delegate to law clerks). (2) Judges in specialized circuits (for example, the Federal Circuit, which specializes in patent disputes) have less influence on judges outside their circuits, no doubt because their opinions have less relevance to the average case. (3) Judges with law degrees from Harvard University and Yale University have more influence than other judges; this may be because they are more intelligent, received better training when in law school, or benefit from networks. (4) The race and sex of a judge do not have an impact on his or her influence. (5) Academic achievement (honors) has little or no impact. (6) Prior judicial experience has little or no impact. (7) Conservative judges are no more influential outside their circuit than liberal judges, but are more influential within circuits. (8) American Bar Association ratings of judicial nominees were not predictive of influence, except that those judges who received the lowest rating were less influential.

Citation analysis has been heavily criticized. Citations are a crude proxy for influence and other variables that one might care about, and citation studies often seem to be driven by data rather than theory. Nonetheless, law enforcement depends to a great extent on judges, prosecutors, and other legal actors caring about their reputations, and the citation is, thus far, the most objective measure of this important variable.

Lazarsfeld, Paul

Terry Nichols Clark

University of Chicago, Chicago, Illinois, USA

Glossary

contextual analysis Comparing patterns of individuals across different contexts (such as big and small cities) to measure distinct individual and contextual effects.

fourfold table/cross-tabulation Simple tabular presentations to quantify processes that have otherwise been handled casually.

panel study Repeated surveys of the same persons over time, to help specify causal paths.

postindustrial society A label signifying the paradigmatic revolution that Lazarsfeld and associates helped generate.

Paul Lazarsfeld and his many associates made multiple specific contributions to social science by cumulatively encouraging two paradigmatic transformations: the first was the joining of European theory with systematic empirical research, and the second was the shifting of focus from production and work to consumption and leisure, to understand postindustrial society. Lazarsfeld changed the social sciences. He might have worked on mathematically sophisticated issues with a coterie of like-minded associates, but instead collaborated with dozens of talented persons, some strongly nonquantitative. This makes his unique contribution harder to specify. Born in Vienna in 1901, he studied mathematics and social science at the University of Vienna. In America after 1933, he worked on survey research in New York and was professor of sociology at Columbia University until his death in 1976.

Research Overview

Major Contributions

Paul Lazarsfeld helped launch several new fields of social measurement and approaches to study them. Before

Lazarsfeld, market research was anecdotal and casual. His techniques for large empirical surveys of consumers today define market research. He developed surveys to measure the policy views of individual voters, to assess personal friendships, and to chart other processes previously handled more intuitively. His books *The People's Choice* (1944) and *Voting* (1954) are the foundations of contemporary political behavior studies. Lazarsfeld refined survey methods for mass communications. Before him, many believed that radio and newspapers manipulated individuals and had huge impacts. These “mass society” arguments held sway with most intellectuals and commercial firms. He showed instead how media effects were generally more limited and operated differently.

In politics, product marketing, and mass communication, Lazarsfeld showed that direct messages from elites were seldom accepted by individual citizens, as many had suggested; rather, key impacts were indirect, often via “opinion leaders” who would talk with their friends, thus selectively accepting, rejecting, or adapting news, advertisements, and political messages. Such processes constituted a “two-step flow of communication”—first through the media, second through the personal contact—which Lazarsfeld documented with detailed analyses of neighbors discussing politics and women choosing groceries and clothes. He considerably strengthened social science methodology, by developing new techniques and writing about how to refine or transform older methods by more self-conscious analysis.

Although his Ph.D. was in mathematics, most of his methodological work was written in very clear, simple language, and aimed to change how social scientists and policymakers thought and worked. His success was impressive. His impact came often from finding a new, creative solution to a “hot” problem that others had addressed more casually. Many of his solutions were so

elegantly clear that others could and did immediately adopt them, and extend them further. The mathematics and statistics used were the simplest possible for the task. For instance, to sort out distinct effects of media content, personal discussions, and other factors, Lazarsfeld developed the “panel study,” reinterviewing the same persons over time to monitor change, such as during a political or advertising campaign. He reported differences in cross-tabulations, and analyzed turnover across cells.

In a paper on “The Art of Asking Why?,” Lazarsfeld showed that simply asking “why” often gets a simplified response, but that a richer picture of processes often emerges if the process is studied and an accounting scheme of likely answers is developed and is used to structure probes. To analyze effects of several variables, Lazarsfeld showed how multicausal analysis was necessary. But he continually sought to transcend the simple, linear models (as in ordinary least-squares regression) by showing how to measure interaction effects (such as a third variable *Z* shifting the effect of *X* on *Y*) or contextual effects (such as Marx’s suggestion that low salaries generate more worker discontent in large, as compared to small, factories). The methodological treatise by Lazarsfeld, *The Language of Social Research*, became popular in America as a guide for practitioners and students. With a former student, Raymond Boudon, the treatise was transformed into a theoretical–philosophical work in the French adaptation, *Le Vocabulaire des Sciences Sociales*. Lazarsfeld encouraged mathematical work in social science and developed “latent structure analysis,” but such approaches went beyond most of his collaborators. His creative thrust was to claim large, new terrains and analyze them in a more self-conscious and methodologically explicit manner than did his predecessors. He showed how past simplifications brought misleading results. Unhappy that most history of social science considered only theories, he helped develop the history of empirical social research as a subfield. Most contributions by Paul F. Lazarsfeld were by-products of collaborative work with Robert K. Merton and many talented students and colleagues, first in Vienna, then at Columbia University.

Father of Postindustrial Society?

“In Russia the Revolution succeeded, so they need engineers; in America, the revolution failed, so we need Sociology.” Here is classic Lazarsfeld: self-deprecating humor, the whiff of a secret agenda, an ideological program, and an immigrant’s revolutionary commitment to build a new society. Consider one specific reading of Lazarsfeld’s slogan: that sociologists, especially at Columbia, helped chart and explain the workings of postindustrial society—even if “postindustrial society” was not conceptualized until years after their major contributions.

This is a broader formulation than Lazarsfeld proposed, but it clarifies his impact. The major counterinterpretation is that Columbia sociology was a handmaiden to capitalism. Lazarsfeld’s neosocialist slogan directly contradicts the simple view that Lazarsfeld and Columbia “sold out” to American capitalism—as argued in various ways by critics, from C. Wright Mills to Alvin Gouldner to the Frankfurt sociologists.

In contrast to some critics, it can be posited that Marxism was incorporated into the Columbia amalgam of sociology from its very origins in the 1930s, and continued in ways often overlooked. For instance, *Marienthal* was Lazarsfeld’s 1932 study of the unemployed in a depression-devastated community, detailing how persons out of work suffered psychological damage. Merton’s 1937 *Science, Technology and Society* showed how modern science was driven ahead by the twin forces of technology (in a broadly Marxist manner) and the Protestant religion (broadly Weberian). Merton and Lazarsfeld’s personal involvements with left political movements in their formative years were deep and intense, as others have detailed. Columbia sociologists, led by Lazarsfeld and Merton, helped create modern sociology through a continuous dialogue, albeit often latent, with Marxist themes and concepts. This holds in many areas, on examination of their shifts from past topics chosen for study (dress shoppers in Decatur, Illinois, rather than unemployed workers), or of their shift from a top-down focus in organizations to bottom-up cooptation. Core concepts were invented or redefined (e.g., from the proletariat to student activist, from politics as part of production to part of consumption).

Lazarsfeld’s contribution may be framed with the concept of postindustrial society, first by identifying sources for the concept in subfields of Columbia sociologists after the 1930s. The gradually resulting framework generated a paradigm shift away from Marxist-inspired thinking, but this shift was largely “unannounced,” in that elements of Marx continued in many Columbia studies. The big bang built on smaller “revolutions” in subparadigms, such as organization theory and mass media; together, they generated a deeper overall change. This is all the more intriguing because the label and conceptualization of “postindustrial” from Bell only came later, following much of the innovative Columbia work. Alternatives are charted in Table I, showing the specific concepts and their main competitors, Marxism and Individualism.

More generally, Lazarsfeld and the Columbia armory of ideas have an elective affinity with postindustrial society in ways that were not recognized or scarcely mentioned in earlier years. This is in good part because the concept of the postindustrial society crystallized only after the most vibrant years of Lazarsfeld and Merton. Similarly, Hegel’s owl of Minerva took flight only as dawn neared. The label “postindustrial society” came

Table I A Core List of Elements Contrasting Columbia Sociology with Neo-Marxist and Individualistic Concepts^a

<i>Columbia/postindustrial society concept</i>	<i>Neo-Marxist concept</i>	<i>Individualistic concept^b</i>
Consumption	Production	Utility, preferences (more abstract)
Leisure	Jobs	Work and amenities
Consumers	Workers	Subsets of utilities, clusters of attitudes
Home	Workplace	Individual
Women and their families	Men and their work	Less attention to context
Personal influence, social interaction	Social structural characteristics (class, etc.)	Interaction
Citizen focused	System focused, e.g., capitalism, aristocracy	Individual/preferences/personality focused
Buying consumer products	Investing capital	Maximizing utility
Talking with friends to form opinions	Organizing class consciousness	—
Informal organization; unanticipated consequences	Class conflict	—
Organizational/management structure	Ownership of the means of production	—
Goal displacement; cooptation; subcultures	<i>Classe an sich</i> to <i>classe fuer sich</i>	—
Issue politics, issue specificity	Coherent party program	Cognitive consistency
More social liberalism, e.g., new women's roles	Fiscal/economic policy positions	Attitude structure
Voluntary associations	Vanguard party focus	—
Cross-pressures, role conflict	False consciousness	Cognitive dissonance
Pluralism	Power elites	—
Autonomous mass media	Class-controlled propaganda	—
Autonomous scientific community	Science subordinated to hierarchy	—
Students as political vanguard	Proletariat moving toward revolution	—
New class	Fordism/regulation theory	—
Knowledge research and development/high technology	Manufacturing products	—
Rising professional autonomy of workers	Rising global monopolies, regulated by states	—
Weak unions and parties, strong individualism	Strong unions and class-based parties	—
Consumer-based individual aesthetics	Historical materialism	—
Democratic processes	Class responsiveness	—
Intellectuals/cultural creation	Class domination, surplus value	—

^a Source: A decidedly flawed memory of a former Columbia student (T. N. Clark).

^b Individualistic theories tend not to address some more social structural items, hence the column is sometimes left blank.

from two books by Daniel Bell, published in 1973 and 1978. Overlapping ideas were elaborated by Seymour Martin Lipset, Ronald Inglehart, and the present author's writings in *The New Political Culture* (Table II charts the main themes). Deeper than labels and specific studies are the prototheory, implicit hunches, and a prescient sensitivity as to how society worked—or what Weber called choosing the research topic. Lazarsfeld often operated with brilliant intuition. Later, Merton clarified the operation of identifying “strategic research sites.” Choosing the precise topic and angle is often the single most critical aspect of a brilliant study, as the following examples suggest.

The Columbia synthesis built on elements of American society that distinctly differed from European society,

with its peasantry, class, work, and party-defined patriarchal, authoritarian social structure. Instead, the new structure was driven by consumption, not production; by the household, not the job; by leisure, not work. Thus voting was not seen as “explained” exclusively by men and fathers working on an assembly line, but also by women and mothers, chatting with their neighbors about whom to vote for while listening to soap operas. These new participants in the system made decisions for political candidates following rules like those for buying Campbell's soup and, later, Mary Kay cosmetics. The core elements charted in Table I were refined in works such as those cited in Table II. These works comprise an exploration of only a few of the themes that illustrate the transformations wrought by Lazarsfeld and his collaborators.

^a The point of this table is merely to highlight, quite roughly, major differences in emphasis among alternative formulations of postindustrial society. The main references are Bell's *The Coming of Post-Industrial Society* (TCPIS) and *The Cultural Contradictions of Capitalism* (CCC), various works by Lipset, especially *Political Man* and *American Exceptionalism*, and by Inglehart (*Modernism and Post-Modernism*), and *The New Political Culture* (NPC) by Clark *et al.*

Discussion of Selected Core Concepts

Consumption vs. Production, Leisure vs. Jobs, Consumers vs. Workers, Home vs. Workplace, Autonomous Mass Media vs. Class-Controlled Propaganda

With support and encouragement from Frank Stanton, chief researcher and then president of the new Columbia Broadcasting Company, Lazarsfeld charted the rise of the media and how it related to average citizens. Many studies were published in *Radio Research*, which Lazarsfeld and Stanton edited. What they found in these first-ever serious media studies did not support the Adorno/Horkheimer/Marcuse Frankfurt Marxist view that the media organizations were capitalist tools to dominate and manipulate citizens. Lazarsfeld and Stanton instead suggested a limited, information-purveying role; citizen-shoppers used the media, but core views were seldom transformed by the media.

This “limited effects” interpretation of the media is considered a main finding of Lazarsfeld-inspired research. Yet it is often overdrawn. The media could have impact, in some situations. Indeed, in 1948, prefiguring a much-repeated theme, Lazarsfeld and Merton elaborated contextual characteristics that should enhance or suppress media impacts (monopoly of information, consistency with values, and personal contacts).

Columbia sociology and preeminently Lazarsfeld have been criticized for being opportunistic, responding to market demands, following the money, and consequently defending capitalism. This is too simple and deterministic. It ignores the fact that much if not most money for social science in the depths of the depression came not from corporate sources, but from the federal government—as judged by prefaces of major books by W. Lloyd Warner, Stuart Chapin, and others. Lazarsfeld did work on government propaganda studies during World War II.

The New York foundations had a long and strong tradition of supporting work on poverty, such as Lazarsfeld's *Marienthal*. The media supported polls, and *Life* magazine even underwrote *The People's Choice*. Why did Lazarsfeld not pursue such more established funding sources and research questions? The view that he "simply" followed the money illustrates precisely the sort of one-factor thinking that Lazarsfeld critiqued in his famous "The Art of Asking Why?," the main point of which is analogous to Marx's criticism of simple self-interest, income-maximizing interpretations, which he dismissed by labeling them *Benthamismus*.

Clearly, Lazarsfeld's fund-raising had a colorful and opportunistic flair—which he loved to flaunt in the right company. The simple critics were taken in by (or interpreted too literally) his *double entendres* and teasingly exaggerated bravado. Yet other smart persons at the time made other choices, perhaps equally opportunistic or rewarding—as the contrasts in Table I indicate. Lazarsfeld's uncanny instinct for capturing what was new and distinctive about American society, and its driving changes (radio, advertising, marketing research, citizen-oriented voting studies, etc.), led him both to propose new and innovative research on these topics and to work with foundation and corporate officials attracted by the cutting-edge quality of these concerns (including Frank Stanton at CBS, Bernard Berelson at the Ford Foundation, and Jeremiah Kaplan at the Free Press.)

Merton and Lazarsfeld did not analyze Hitler's or Roosevelt's speeches, but did examine Kate Smith's talk shows, her war bond sales appeals to average folks, and similar messages. This resulted in elevating Smith, a 1940s Oprah Winfrey, in a way elitist Europeans found repulsive. The media do not plead, they command, was the Frankfurt counterinterpretation. As a methodological by-product, the F(ascism) scale was generated, to capture the deep structure of authoritarianism that lay behind fascist dominance, yet that remains hidden perhaps in all of us. By contrast, Merton and Lazarsfeld developed and refined methods for recording emotion as people watched a documentary or short film, urging them, for instance, to use less meat in their cooking; a follow-up focus interview probed as to how and why people made their actual choices. Merton and Lazarsfeld sought to build a disciplined way of making researchers listen to and converse with their "subjects," and genuinely learn from them, not to use them simply to test or to illustrate theories.

A persistent subtheme of Lazarsfeld's media work was a critique of simple individualism, as a simplifying aspect of American ideology and misleading "explanation." For instance, Lazarsfeld wrote that "radio has so far been a conservative force in American life.... [In many radio stories or soap operas] all problems are of an individualistic nature. It is not social forces but the virtue and

vices of the central characters that move the events along. People lose their jobs not for economic reasons but because their fellow men lie or are envious." This general skepticism about individual explanations persists in most Columbia sociology. Lazarsfeld was criticized by some as promoting atomistic views of society by using surveys of individuals. But he and others consistently distinguished their interpretations from the more classically individualistic perspective common among many psychologists, economists, and some political scientists then and later.

Organizational/Management Structure vs. Ownership of the Means of Production; Goal Displacement; Cooptation; Subcultures vs. Classe An Sich to Classe Fuer Sich

Weber studied the Prussian bureaucracy, elevating it as the ideal type of modern society. The specter that it would dominate led him to the "iron cage" metaphor. When he wrote *Politics as a Vocation*, he spoke of parties and their leaders—minimally of citizens or civic groups. Similarly, his student Robert Michels formulated the "iron law of oligarchy" in studying the leadership of the German Social Democratic Party. Lazarsfeld grew up in the heady air of Socialist Party political leadership and elite personal intrigue in Vienna. He not only knew the issues intimately; they drove much of his professional agenda in his early adult years. He did surveys of socialist youth groups, and sought to codify how to attract recruits and mobilize them effectively.

In America, Lazarsfeld turned to the extreme non-elite—in Elmira, New York or Decatur, Illinois—to study how housewives chose to buy red shoes and vote for Franklin Delano Roosevelt. Charting the cognitive maps and social contexts of average Americans to understand their decisions led to some revolutionary findings, contrasting with those of his Columbia colleague Robert Lynd (known for his best-sellers *Middletown* and *Middletown in Transition*). Lynd's second book relied heavily on neo-Marxist concepts and had much in common with Lazarsfeld's *Marienthal*. But in the first large-scale survey studies of voting and political behavior ever conducted, *The People's Choice* and *Voting*, Lazarsfeld and his associates contradicted the Lynds, the Marxist organizers, and the League of Women Voters in suggesting that citizen "apathy" (nonvoting and low participation in civic groups and parties) could make democracies more flexible. Unlike Weber's focus on Prussian bureaucrats and party leaders, Columbia researchers studied organizations less from the top than from the middle (where bureaucrats redefined goals and rationality) and the outside (in how organizations interfaced with their environments), leading to concepts such as Selznick's cooptation.

Organizational Subcultures and Their Autonomy vs. Ownership of the Means of Production

The work of Lazarsfeld and colleagues led to a new paradigm for organizational theorizing. By including corporations, governments, and universities, and looking for common themes, they transcended the “capitalist–worker” or “public–private” divides. Rather, they reported multiple sources of change and conflicts. The Columbia synthesis moved the social psychological theorizing about organizations from Harvard and Michigan into more structural coherence, by blending it with the European institutional traditions, and added a new subtlety and complexity. Merton stressed organizational subcultures and contextual variability, whereby the subcultures and tensions inside organizations led to and explained slacking soldiers or alienated government staff, such as postal workers.

The most dramatic American manifestation of the authoritarian leader in the 1950s was Senator Joseph McCarthy, whose House Un-American Activities Committee pursued labor union leaders, academics, and others suspected of “anti-Americanism.” Many lost their jobs, especially in Hollywood. This Cold War virulent anti-Communism was seen as a clear product of capitalism by observers such as the Frankfurt sociologists. But Lazarsfeld, always the skeptic, proposed a major national study to assess the impacts of McCarthy and other political constraints on academic freedom in universities and colleges. Did McCarthy really lead people to be more cautious in what they said and wrote and taught? He showed that universities resembled other organizations studied by Columbia researchers. The American academic community was not a simple top-down structure, not a factory-like hierarchy in which a board of trustees or even Senator McCarthy could cajole students to embrace capitalist theories and consume capitalist products. Rather, in *The Academic Mind*, Lazarsfeld, Felix, and Thielens sought to probe empirically what Parsons and later Habermas did theoretically: contrast the authoritarian, controlling specter of a McCarthy (or Hitler) with the egalitarian/collegial/decentralized ethos of the professional. This was a model for a new sort of workplace, one that deeply conflicts again with the Prussian/Weberian imagery. Lazarsfeld engaged David Riesman, a nationally renowned academic, skilled ethnographic observer, and openly leftist and anti-McCarthy figure, to review *The Academic Mind* and to reinterview some of the same academics across the country. Riesman did, and endorsed the main findings of the book: most academics were not scared of McCarthy and carried on their activities without fear. This added another piece to the picture of a paradigm change.

Contextual Analysis

The opposite extreme from the Prussian bureaucracy was the atomized individual of Michigan voting studies or

neo-classical economist consumers. These theories have an elective affinity with the ideological individualism of the broad Protestant majority in political science and American politics. But Lazarsfeld and the Columbia group differed in locating the individual in a strong social context. They strategically chose research sites and methodology to highlight such contextual effects. They did not use national surveys of individuals like Campbell and Converse did at Michigan, or an ecological neighborhood voting method like Gosnell did in the Chicago tradition, which submerged the individual voter into the neighborhood mass. Rather, the genius of *Voting* and *Personal Influence* was showing how networks of friendship would bring filiation and encouragement toward voting for FDR or buying dresses. These constraints and subtle influences may have had more visibility to an immigrant Jewish observer who was self-consciously marginal.

Transforming Social Science

Lazarsfeld’s largest contribution is the hardest to specify: he transformed social science. Sociology, economics, and political science in the 1930s had theoretical traditions and empirical traditions, but they seldom joined. The grand theories of social science were European. Public opinion, basic values, political support, confidence in government, and even the Gross National Product were unmeasured concepts in 1930. In America, Pitirim Sorokin and Talcott Parsons continued this European tradition at Harvard. Distinctly American work was problem-oriented and empirical. The center of social science was The University of Chicago in the 1920s and 30s. Its leaders in sociology, Robert Park and Ernest Burgess, did not seriously join their empirical work with European theories. Sociology changed at Columbia in the 1940s and 1950s, when Lazarsfeld, Merton, and talented students set a new tone in their many publications. They seriously joined the European theories with empirical work to create a new amalgam: “middle-range theories” were codified and tested using fourfold contingency tables. Previously disparate activities were merged, generating far more powerful results. Students from Columbia became professors at other leading universities, and in the 1960s the social sciences changed irrevocably. The persons and organizations mentioned here all helped. Although these are large claims, they are supported by at least one slim bit of evidence. The following excerpt is from a major theoretical work of two non-Columbia centers, Harvard and Chicago (*Theories of Society*, 1961, by Edward Shils, edited by Talcott Parsons, Edward Shils, and two Parsons students, pp. 1407–1408):

In the 1930s, American sociology underwent a marked expansion . . . It was helped by the Great Depression, by

the influx of German and Austrian refugees . . . Research became more sophisticated through the development of a new statistical discipline, and through the improvement in interviewing techniques under the influence of psychoanalysis and the public opinion polling industry . . . Sociology—which was once an earnest, uncouth subject, a subject of the American Middle West, a dreary scholastic classificatory scheme of the German universities—has invaded the parlors of the most refined intellectuals of the United States and Europe.

Admiring the Columbia team, Parsons sought to recruit a “Lazarsfeld” (Sam Stouffer) and join his theory to empirical work. Chicago hired a series of Columbia graduates. In economics, econometric work increasingly joined abstract theory, encouraged by the National Bureau of Economic Research, which brought many academics to its New York headquarters. Political science was analogously revolutionized, by Robert Dahl and Gabriel Almond at Yale, V. O. Key at Harvard, Philip Converse at Michigan, and others. Lazarsfeld was a leading consultant to the Ford Foundation, which substantially funded such developments in the 1950s and 1960s in the United States and internationally. Lazarsfeld and Merton proposed to Ford a new center, which became the Center for the Advanced Study of the Behavioral Sciences in Palo Alto, California, fostering these approaches. In Europe, the European Consortium for Political Research (ECPR) was launched by Stein Rokkan, who collaborated with Columbia-trained Seymour Martin Lipset. The ECPR included just a few young turks in the 1960s; by the 1980s, it was the European establishment. International professional groups such as the International Sociological Association and its research committees, the International Political Science Association, and others brought social scientists the world over into contact with analogous developments. The tone and focus of the social sciences obviously shifted. Did Lazarsfeld and Columbia play a role in this? Why and how? Paul Lazarsfeld was charming and engaging when captivated by a new idea, as well as dynamic, manipulative, original, and stimulating. He sought to have global impact, and engaged many to join the effort.

The Intellectual Machine: Research Institutes and More

Columbia sociology sometimes looked more like the French model of the national clientelist university than the normal American model of departmental domination. How did Clark and Merton build such a vast intellectual empire, converting Columbia sociology into a global standard? Lazarsfeld said many times that to advance an intellectual agenda required a machine. His major

examples were the research institutes that joined the methods of survey research, the money of government and commerce, and the intellectual ferment of the university. He delighted in recounting incidents illustrating his manipulative prowess; he would grin and laugh and tease as he cajoled others to join in. He evoked images of a political candidate, a mafia boss, a Wall Street banker, and Don Juan. He fascinated and entertained while deliberately shocking. He was a European prince who created his own court and intrigues.

What precisely did he mean by a machine? And how did it influence so powerfully? Though he often discussed research institutes as examples, he surely did not intend the impersonal, bureaucratic, efficient sort of organization that thrives on many American state university campuses. His archetype was rather the Bureau of Applied Social Research (BASR), and later Chicago’s National Opinion Research Center (NORC) of the Pete Rossi era (1960s). How were they distinct? The term “machine” suggests an informal organization that permits exchange of resources in ways sometimes interstitial, if not illegitimate, for official organizations, such as governments or universities. Merton’s famous essay on manifest and latent functions stressed the opportunity structure that political machines provide to ambitious persons who might not succeed by following normal rules.

Clientelism is a more general concept than machine, but overlaps in meaning. Clientelism refers to allocation of private goods, such as jobs or grants, by a patron to his clients, with an expected return of favors that reinforces patron leadership. In an officially universalistic context, the clientelist resource exchanges are thus quasilegitimate or illegitimate insofar as they shift decisions and reward patterns. The BASR’s clientelism was clear. Like the Sorbonne patron, Lazarsfeld would allocate jobs, grants, and favors to his subordinates in princely manner, expecting total loyalty. His classic strategy was to win large grants from corporations or foundations, then siphon off funds to aid poorer projects, illustrating what his students labeled “Robin Hooding” (they would be paid to work on one project, but advance a second or third or fourth as well). At the Paris conference, others noted similar patterns. Merton termed the BASR a “commune, a family, a *Gemeinschaft*, a youth group.” According to David Sills, Lazarsfeld said that “nepotism is my key to administration. Who can you trust more than your family to carry things out?” This dramatically self-deprecating language was more than chance. Merton noted that Lazarsfeld would say that he “overcharged clients,” regularly “used nepotism,” and “schemed and plotted” about future plans.

But a clientelist model is too simple to explain Lazarsfeld and the BASR. It was interpenetrated by the more universalistic norms of science, stressing new ideas, creativity, original publication, and corresponding international, market-driven rewards. Lazarsfeld sometimes

leaned over to build in checks against personal bias, to counter the particularistic tendencies. He engaged students to help refocus and rewrite even work by stars such as Nicholas Rachevsky, if it could be improved. Lazarsfeld applied the same stringent criticism to himself, even if it meant that he missed the deadlines of foundations and book publishers. More than once he said that “when the book is published, will they ask did it meet the deadline? No! People will ask, is it a good book?” He distrusted mere reputation; he sought independent readings, again and again, by the young, by outsiders, to cross-validate and stimulate repeatedly. These various examples illustrate his powerful commitment to scientific universalism, the Mertonian norms. Even so, they do not suffice to explain his machine.

The early to mid-1960s were years of great affluence for social science research; it was much less necessary to engage in Robin Hooding. However, this also meant a shift toward more universalistic criteria for awarding grants, and put the BASR in more open, direct competition with institutes at other universities. Perhaps Lazarsfeld's shift of interest toward Paris and Europe in the 1960s was related to this shift in the U.S. rules of the game toward universalism. In his last years, he wrote about adding his own tradition to the history of social science. His place is now secure.

Glossary

conceptual tests Measures of priming using retrieval cues that are conceptually related to studied items; these tests are considered to be conceptually driven because performance on them is affected by manipulating conceptual (meaning-based) processing.

cued recall A technique in which participants are provided with retrieval cues and are asked to recall studied items related to the cues.

explicit memory tests Measures of conscious, intentional recollection of specific learning events.

free recall A test in which participants recall as many studied items as they can, in any order they choose.

implicit memory tests Indirect measures of retention.

perceptual tests Measures in which participants are asked to identify or complete degraded stimuli; these tests are considered to be perceptually driven because performance on them is affected by manipulating perceptual processing.

priming Improvement in performance on a test that assesses retention indirectly; the measure of primary interest in implicit memory tests.

recognition tests Measures in which test participants are asked to decide whether they recognize test items from the study list, amid distracters or lures (a yes/no recognition test), or are asked to pick out the correct test item from a set containing distracter items (a forced-choice recognition test).

word fragment completion Test in which participants are presented with word fragments and are asked to complete them; priming is measured as the improved ability to complete fragments with words that had been previously presented.

Learning and memory can be measured in a variety of ways. Some of the prominent methods of measuring

retention are based on several popular paradigms used in cognitive psychology. These are surveyed in this article; coverage is selective and other techniques exist for more specialized purposes. Different measures of memory, even for the same experiences, may not always agree in their assessment, and such dissociations among memory tests provide important insights into the proper understanding of human memory.

Origins of Memory Measurement

Achievements of Hermann Ebbinghaus

The measurement of learning and memory dates back to the seminal work of Hermann Ebbinghaus, who developed the first reliable measures of memory and published his original results in 1885 in his great monograph, *Memory: A Contribution to Experimental Psychology*. Ebbinghaus created lists of nonsense syllables (e.g., JUK-WAF-KOB, etc.) that varied in terms of their length. He measured the number of trials (or the amount of time) it took to learn each series of syllables, to accomplish one perfect recitation of the entire list, a measure he called original learning. After a retention interval that could last several minutes, hours, days, or even weeks, Ebbinghaus measured the number of trials (or the time) it took to relearn the list of syllables. The difference between measures of original learning (OL) and later relearning (RL) is known as the savings in relearning. For example, if it took 20 trials to learn a series of syllables perfectly during original learning and, later, it took 10 trials to relearn the series, the savings in relearning would be 10 trials. Ebbinghaus expressed

retention performance as a savings score, defined as $[(OL - RL) \div OL] \times 100$ (or 50% savings, in this example).

One beauty of the savings method, and one reason Ebbinghaus preferred it, was that retention could be measured independently from whether the person being tested could consciously recall anything from the original learning experience. Even if a person does not have any recollection of the original list, retention of the experience can be detected by the method of calculating savings in relearning. Thus, a decade before Freud proposed his ideas about unconscious memories, which led several generations of psychologists to wonder how unconscious memories could be studied empirically, Ebbinghaus had already supplied one promising solution to the problem: the method of savings in relearning.

Strength Theory and Measurement

One beguiling idea about human memory is that memories vary in terms of a unidimensional quantity, often referred to as “memory strength.” Memories that can be easily recalled are thought to have greater strength, whereas those that can be recalled only with difficulty are thought to be weaker. Although (without further elaboration) strength theory simply redescribes the phenomenon to be explained, nonetheless, the notion of memory strength has been reified in several conceptions of memory and still holds currency in various forms even today. Strength theory also makes a strong prediction regarding the measurement of memory: if memory strength is the critical quality determining performance on any memory test, then different measures of memory should be correlated (even though they may vary in their ability to detect memories of different strengths). That is, although some measures may be more sensitive than others, all memory tests ultimately assess the same underlying quality of memory strength.

Consider the following simple example. A typical laboratory method of assessing retention involves the initial presentation of a list of words and the measurement of performance on one or more memory tests given at a later time. Consider five words (items A, B, C, D, and E) presented within a longer list of words. After studying the list, one group of individuals is given a sheet of paper and simply asked to recall as many of the words as they can remember, in any order they choose. Assume that B and D are recalled on this free recall test. A second group of individuals is given a memory test in which words that are associated with the studied words are presented as cues. For example, if “chair” had been a word presented on the study list, “table” might be given as a cue. The study participants might now recall more items on this cued recall test than they could on the free recall test. Finally, a third group of individuals is given a memory test in which

items that had actually been presented on the study list (such as chair) are mixed in with other plausible candidate items that had not been presented (such as stool). In this recognition memory test, study participants are asked to identify the items that had been presented on the original study list.

The ideas behind strength theory are illustrated in Fig. 1. The different items presented on the study list (A through E) vary in terms of their strength, with items B and D being the strongest. According to strength theory, free recall is an insensitive measure of memory, because only memories with the greatest level of strength are recalled. Free recall tests require a great amount of strength to cross the conversion threshold for recall, indicated by the top dashed line in Fig. 1. Cued recall tests are more sensitive measures and are able to detect weaker memories, such as item C in Fig. 1. Finally, recognition memory tests are the most sensitive measures of memory strength; they are able to detect all items recalled in free and cued recall tests and one additional item (E) that was too weak to be detected by the other methods. In short, the principal assumptions of strength theory are that particular memories vary in terms of their strength and that methods of assessing retention differ only in terms of their sensitivity to memory strength.

This story is tidy but wrong. In fact, different measures of memory assessed across items, people, or other independent variables are not always positively correlated, as predicted by strength theory. In fact, measures of memory may be completely uncorrelated or even negatively correlated with each other. For example, consider the effects of word frequency (i.e., the frequency with which a word occurs in a language) on memory performance measured on two different memory tests. In free recall tests, high-frequency words tend to be better recalled

Figure 1 Strength theory. Different memory traces (A through E) vary in terms of their strength, and different measures of memory differ in their sensitivity to memory strength.

than low-frequency words are. Thus, it is reasonable to conclude that high-frequency words are stronger compared to low-frequency words. However, in recognition memory tests, low-frequency words better recognized than high-frequency words, leading to the odd conclusion that low-frequency words must have greater memory strength than high frequency words. Neither conclusion is correct. Instead, interactions between independent variables and performance on different memory tests indicate that strength theory is simply the wrong way to conceptualize human memory. Different measures of memory do not assess a single quality that varies along a single dimension.

Encoding/Retrieval Interactions and Their Implications

Processes of learning and memory are typically conceptualized as involving three stages: encoding, storage, and retrieval. Encoding is the initial registration and acquisition of information, storage is the maintenance of information over time in the nervous system (represented as a memory trace), and retrieval is the process whereby stored information is brought back into conscious awareness or otherwise affects ongoing behavior. Strength theory essentially proposes that encoding conditions will produce main effects on performance measured on different memory tests and will never interact with retrieval conditions, because different memory tests simply vary in terms of their sensitivity to memory strength. However, the literature on human memory is replete with examples in which encoding and retrieval conditions interact. The example mentioned previously, that high-frequency words are better recalled than low-frequency words are, whereas low-frequency words are better recognized than high-frequency words are, is one example of an encoding/retrieval interaction.

Larry Jacoby has designed compelling experiments demonstrating that two different measures of memory with great surface similarity can be uncorrelated or even negatively correlated. Participants in Jacoby's experiments were presented with lists of words under various study conditions and were given one of two different memory tests. One group of individuals was given a standard yes/no recognition memory test, in which they were presented with a long list of test words and were asked to determine which words had been previously studied. The other group of individuals was given a test that involved identifying words presented at very fast rates (around 30 msec per word). The proportion of words correctly identified was the dependent measure. Some of the words flashed during the test had been presented on the study list but other test words had not been previously studied. In this speeded word identification test,

the improved ability to name the briefly flashed words that had been presented during the study phase is known as priming.

In one of Jacoby's experiments, the independent variable was the level of processing of words during the study phase. Students were presented with one of three questions that oriented them toward either the surface features of the target word (e.g., "Is the word in all capitals?"), the sound of the word (e.g., "Does the word rhyme with chair?"), or the meaning of the word (e.g., "Is the word a type of animal?") before the presentation of each target word (e.g., BEAR). These three different orienting questions manipulated the level of processing that individuals performed on each word. The effects of levels of processing on performance in the two different memory tests are depicted in Fig. 2. In the recognition memory test, the typical levels of processing effect was observed: individuals were best at recognizing words they had processed at a meaningful level and worst at recognizing words they had processed at only a surface level, whereas processing the sounds of the words produced intermediate recognition performance. In contrast, consider performance on the speeded word identification test, shown in the right panel of Fig. 2. In this test, priming was measured as the difference in performance between naming studied and nonstudied words. Although all of the priming scores were positive, indicating retention of the studied words, all three encoding conditions produced equivalent levels of priming! Levels of processing, which had such a profound effect on recognition memory, had no effect on priming. Although both tests were measuring retention of the same list of items, the two measures were completely uncorrelated in this experiment.

In another experiment, Jacoby demonstrated that measures of recognition memory and speeded word identification could even be negatively correlated. In this experiment, individuals studied a list of words under one of three different encoding conditions: they were either asked to read the target words in a neutral context (XXXX-cold), to read each word paired with its opposite (hot-cold), or to generate each target word given its opposite (hot-????). Thus, in all three conditions, participants said out loud the same list of target words, but the means of having participants produce the words differed dramatically. The effects of these encoding manipulations on performance in the two different memory tests are shown in Fig. 3. Although generating the target words produced the best performance on the recognition test and reading the words in a neutral context produced the worst performance (a finding known as the "generation effect"), the opposite pattern of results was observed in the speeded word identification test: reading the words produced better identification performance than did generating the words! The results of Jacoby's experiment demonstrate that two

Figure 2 Levels of processing during encoding have a profound effect on recognition memory performance, but no effect on speeded word identification. The two memory tests are not correlated. Based on data from Jacoby and Dallas (1981).

Figure 3 Generating words during encoding produced better recognition, compared to simply reading words (the generation effect). In contrast, reading words produced better performance on the word identification test, compared to generating words. The two memory tests are negatively correlated. Based on data from Jacoby (1983).

measures of memory that appear to be very similar on the surface may be negatively correlated with each other under some circumstances.

Interactions between encoding and retrieval conditions demonstrate that measures of retention can reveal positive, zero, or negative correlations with one another. These encoding/retrieval interactions have an important

implication for understanding human memory: although the concept of memory is labeled with a single word, it is hardly a single entity. Many different types of memory exist, and there are several different valid measures of memory. Some of the most prominent ways to measure memory are considered in the following discussions.

Explicit Measures of Retention

One important distinction in the field of human memory is that between explicit and implicit measures of memory. Briefly, explicit memory tests involve conscious, intentional recollection. If you are asked to describe what you had for dinner two nights ago, you must mentally travel back in time and retrieve information about that specific event. Explicit retrieval involves conscious awareness of this mental time travel. Endel Tulving has referred to explicit retrieval as involving the use of episodic memory, a memory system that enables people to remember their personally experienced past. There are several differences between explicit and implicit measures of retention; in the next section, several different explicit tests commonly used in research on human memory are described.

Free Recall

In most explicit tests of memory, participants are exposed to a set of material on which they will be tested at a later point in time. The material can consist of words, pictures, sentences, stories, videotapes, and other types of data. In a free recall test, participants are asked to recall as many of the studied items as they can, in any order they choose. Because no overt retrieval cues are provided, they must rely on their own strategies in order to retrieve the items. Free recall is perhaps the most effortful explicit memory test.

Cued Recall

In a cued recall test, participants are provided with retrieval cues and are asked to recall the studied items related to the cues. Retrieval cues can have a high or low associative strength (a measure of their degree of association with the target words). For example, “table” might be a strong cue to retrieve the word “chair,” whereas “glue” would be a weak cue in this case. A retrieval cue can also be a graphemic cue, in which a portion of the word is provided at test (e.g., “ta__ or __le” or “t_b__”). Yet another type of retrieval cue is a phonemic or rhyming cue: participants may be told to recall studied words that rhyme with the cue words. For example, “bear” might be provided as a cue to recall “chair.” Although these are the most common types of retrieval cues, others can also be developed.

Recognition Tests

Recognition memory tests are perhaps the most popular measures of explicit memory used in cognitive psychology. There are two basic types of recognition memory tests. In a free choice or yes/no recognition memory test, participants are presented with a long list of test words and are asked to say “yes” if they recognize a word from

the study list (thus, they are free to say “yes” or “no” to each item). For example, if participants studied 100 words, they might be presented with 200 words during the test (the 100 studied words mixed in with 100 distracter words) and asked to make a yes/no response for each item. Two basic measures of recognition performance are obtained in this test: the hit rate (the probability of saying “yes” to words that were actually studied) and the false alarm rate (the probability of saying “yes” to words that were not studied). The false alarm rate can be interpreted as a measure of false recognition and can also be used to correct performance for guessing (by subtracting the false alarm rate from the hit rate). Although a yes/no recognition memory test can be thought of as a 2-point scale for judging recognition, the scale can also be expanded by asking participants to provide confidence ratings. For example, participants might be asked to judge each item according to a 6-point scale, ranging from 1 (sure the item was not studied) to 6 (sure the item was studied). Such fine-grained scales provide the researcher with more information regarding participants’ decisions during the recognition memory test.

The other primary type of recognition memory test is the forced choice recognition memory test. In a forced choice test, participants are presented with several alternatives on the test (one previously studied item embedded among several distracter or lure items) and are required to choose the item that they think was presented in the study list. For example, participants might be presented with “chair table dresser lamp” and asked to choose the item that they studied. If all of the response alternatives are equally likely to have been studied, the guessing level can be determined depending on the number of alternatives. For example, in a two-alternative test, 50% reflects chance-level performance, whereas in a three-alternative test, 33% reflects chance-level performance.

Although recognition and recall tests are both explicit measures of memory, they do not always produce the same results. As mentioned previously, although people are better at recalling high-frequency words than low-frequency words, they are better at recognizing low-frequency words than high-frequency words. As another example, when adults of different ages are compared in their performance on a free recall test, older adults typically recall less than younger adults do. However, on recognition memory tests, older adults often perform just as well as younger adults do. These dissociations illustrate that recall and recognition memory tests measure different aspects of retention and cannot be considered equivalent.

Paired Associate Learning

Another popular method of studying memory is paired associate learning. In a paired associate learning test,

participants are presented with pairs of items, such as knight—heaven, elephant—house, flower—camera, and so on. Later, they are given the left-hand member of the pair (e.g., knight) and are asked to recall the right-hand member of the pair (heaven). This type of paired associate learning test measures the forward association between the pairs of words that is formed during learning. Researchers can also investigate backward associations by providing the right-hand member (heaven) and asking participants to recall the left-hand member (knight). In general, recall of forward associations is better than recall of backward associations. Because forming associations among experiences is thought to be a basic mechanism of learning, paired associate learning has been investigated since the beginning of memory research, notably by Mary Calkins, in 1894. Note that the paired associate learning procedure can be considered a type of cued recall.

Serial Recall

Although paired associate learning has been used for over 100 years, serial recall is actually the oldest memory paradigm, first used by Francis Nipher in 1878 and by Ebbinghaus in 1885. In a serial recall test, participants are presented with a series of items (such as digits, letters, words, or pictures) and are asked to recall the items in the order in which they were presented, working from the beginning to the end of the series. Recalling a telephone number is an everyday example of a serial recall task: the digits in a telephone number must be remembered in correct sequential order. Thus, memory both for the items and for the order in which they occurred is critical. A more difficult variation on this task is backward serial recall, in which a person is presented with a sequence, such as 7923948, and is asked to recall the sequence in backward order (8493297). Backward recall is often used in memory assessment batteries, because people with brain damage, for example, show greatly impaired performance on this type of task.

Implicit Measures of Retention

In addition to the explicit measures of memory, there is an entire other class of tests, implicit memory tests; these are superficially similar to explicit tests, but measure retention indirectly. For example, consider an experiment in which some participants are presented with a list of pictures (with one being of an elephant) and other participants are presented with a list of words (the names of the pictures, so the word “elephant” is presented). Following this initial presentation phase, participants are told that they will now perform a different, unrelated task, and nothing is said about testing their memory for the list

of items. In one such test, participants are presented with word fragments (“e_e_h_n_”) and are asked to complete them (as in the game Wheel of Fortune). Some of the correct answers, such as “elephant,” were presented on the study list, whereas others are not. The difference in the ability to complete studied versus nonstudied fragments is a measure of priming, the measure of primary interest in studies of implicit memory.

In the rest of this section, two main types of implicit memory tests, perceptual tests and conceptual tests, are described.

Perceptual Implicit Memory Tests

Perceptual tests present a puzzle or challenge to the perceptual system. Participants are typically asked to identify or complete a degraded stimulus, such as identifying a briefly flashed item or completing an object presented in a fragmented format. These implicit memory tests are considered to be perceptually driven because performance on them is affected greatly by manipulations of perceptual processing and less (if at all) by manipulations of meaning-based processing. Several examples are considered in the following discussions.

Word Fragment Completion

In a word fragment completion test, individuals are presented with word fragments and are asked to complete them, which is difficult if the correct answer has not been recently primed and much easier if it has been primed. In a typical word fragment completion experiment, the probability of completing a fragment that was not primed is about 0.30, and the probability of completing fragments after studying a list of words is about 0.60 (a 30% priming effect). However, after studying a series of pictures (such as a picture of an elephant), negligible priming effects are observed (0–5%), which indicates that even though the concept (elephant) may be primed, performance on a word fragment completion test depends on priming specific perceptual representations. In contrast, on explicit memory tests such as recall or recognition, pictures are remembered better than words are, a finding known as the “picture superiority effect.” Changes in presentation modality (i.e., auditory or visual) also affect priming in word fragment completion. Visual presentation of words produces the greatest amount of priming, whereas auditory presentation produces reduced levels of priming. The effects of presentation modality on word fragment completion provide additional evidence that it is a perceptually driven test.

Word Stem Completion

In a word stem completion test, individuals are presented with the first three letters of a word (“ele_____”) and are asked to complete the stem with the first word that comes

to mind. This test differs from word fragment completion because participants could potentially produce several different words from the same stem (“element, elegant, elevate, eleven,” etc.). Priming in a word stem completion test is measured as the difference between the ability to complete primed word stems versus those that were not primed. Like word fragment completion tests, performance on word stem completion tests is also affected by perceptual manipulations.

Word Identification

Priming can also be measured in a word identification test. In a typical word identification test, participants are asked to identify briefly presented words, and priming is measured as the difference between identifying previously studied versus nonstudied words. Priming in word identification tests can also be measured under auditory presentation conditions, in which participants might be asked to identify words presented against a background of noise.

Other Perceptual Tests

There are several other implicit memory tests that are perceptual in nature. For example, participants might be presented with picture fragments and, following the same logic presented previously, asked to guess the identity of the picture. Likewise, there are several auditory implicit memory tests, in which test words are presented in noise or with portions of the words deleted. Because these tests are also affected greatly by manipulations of perceptual processing during encoding, they are classified as perceptual implicit memory tests.

Conceptual Implicit Tests

In conceptual implicit memory tests, participants are provided with cues that are conceptually related to primed items. Whereas perceptual tests are affected by manipulations of perceptual processing, conceptual tests are not affected by perceptual manipulations but, instead, are affected by manipulating conceptual (meaning-based) processing. Three examples are category association, word association, and general knowledge tests.

Category Association

In category association tests, participants are presented with lists of items (such as “elephant”) during an initial phase and are later asked to generate as many instances from a category (such as “animals”) as they can during a brief testing period (lasting 30–60 seconds). Priming is measured as the greater probability of producing words that had been presented earlier than words that were not presented. In category association and other conceptually driven tests, priming is increased when the words are initially encoded in a way that emphasizes their meaning

rather than other aspects of the words (such as the surface features or sound of the words).

Word Association

Word association tests are very similar to category association tests. However, the retrieval cue in a word association test is an associate of the target word (such as “tusk”), rather than the name of a category. Priming in word association tests is also affected by manipulations of conceptual processing during encoding.

General Knowledge Tests

As the name implies, general knowledge tests require participants to answer general knowledge questions. For example, they might be asked, “What animal aided the general Hannibal in his attack on Rome?” Participants who had previously been presented with the word “elephant” will be more likely to produce the correct answer to this question, compared to participants who had not been primed with the correct answer. Once again, priming on this test is not affected by manipulating perceptual processing of the studied words (e.g., modality of presentation) but is affected by manipulating conceptual processing.

Other Measures of Memory

In addition to the measures of learning and memory already discussed, there are many more ways to test memory. Several tests have been designed to measure working memory capacity, which is the ability to hold information in mind and resist interfering information. One popular measure of working memory capacity is the operation span task, in which test participants are presented with a series of math problems followed by target words (for example, “ $12 \times 8 = 96$, WINE”). Participants must read the problem out loud, say whether it is true or false, and then read the target word. After a series of 2 to 10 operations such as these, participants are asked to recall all of the target words in the order in which they were presented. The average length of the lists that are recalled in correct serial order is the participant’s operation span. Measures of working memory capacity such as the operation span task are correlated with measures of general fluid intelligence and also predict performance on a wide variety of other cognitive tasks.

Other memory tests have been designed to measure autobiographical memory, which is a person’s memory for their own life history. One popular technique for measuring autobiographical memory is the Galton–Crovitz cue word method, in which participants are presented with a word or phrase naming a common object or activity and are asked to recollect an experience from their lives related to this cue. For example, a person who is presented with the cue “nurse” may recall an event

from when they were 5 years old in which they went to the hospital and were frightened by a scary nurse. One finding from research using this technique is that people in later life (50 years and older) most frequently retrieve memories from the period of their life lasting from late adolescence to young adulthood (roughly ages 16 to 25). Experiences from these formative years seem especially likely to come to mind.

There are also several standardized measures of memory used in educational testing and neuropsychological testing (for example, to assess whether a person with brain damage has memory impairments). The Wechsler Memory Scale and the California Verbal Learning Test are two widely used standardized memory tests. Tests such as the Scholastic Assessment Test (SAT) or even different measures of intelligence can also be considered as tests that, in part, measure recall of information learned during a lifetime (similar to the general knowledge tests).

Concluding Remarks

Although measuring human learning and memory may seem to be a straightforward enterprise at first blush, there is no single correct method of measuring retention. Instead, several diverse measures are used for different purposes to assess various aspects of a person's memory. Most importantly, different methods of testing memory for the same experiences can be completely uncorrelated or even negatively correlated with each other. These findings have important implications for our conceptualization of memory. Memory does not refer to a single, unitary property of the mind, and dissociations among measures of retention indicate that several different memory processes and systems work together to produce the complexity of human memory.

Libraries

John Carlo Bertot

Florida State University, Tallahassee, Florida, USA

J. T. Snead

Florida State University, Tallahassee, Florida, USA

Glossary

activities The library services/resources (e.g., licensed resources availability, story hours, training sessions) actually generated by inputs.

evaluation The process of determining or setting a value or amount.

evaluation approach The framework or methodology used for evaluative purposes.

indicators Also known as performance indicators or performance measures; used to measure the effectiveness and efficiency of library resources and services.

inputs The resources that libraries invest (e.g., money, staff, workstations, and on-line commercial databases).

outcomes The benefits from and/or changes in knowledge, skills, or behavior that library users gain after involvement with library resources, services, or programs.

outputs The number of services/resources generated from library investments (e.g., number of public-access workstations, number of databases licensed, and print material purchased).

service quality The evaluation of how well a library provides a service or program.

Social measurement in libraries involves the collection of evaluation data through social science methods. The goal is to determine the extent to which resources utilized in the management, planning, and presentation of collected sources of information, programs, and services by libraries meet the specific needs of a broad range of library users.

Introduction

Libraries in the 21st century exist within a complex and rapidly changing environment. Library services and resources are shifting increasingly from the traditional brick-and-mortar setting to one that includes network-based services, creating a hybrid library operating environment. This new environment includes services such as material lending, interlibrary loan, reference, and instruction. It also includes programs delivered and available via the Web and other Internet-based technologies; the creation of digital collections; access to on-line databases, books, and other content; and services such as digital reference.

With the growing use of technology in the development of library services and resources, patrons use libraries in what has been coined as an “anytime, anywhere” atmosphere. Access to and availability of library resources and services has changed from the limiting hours of operation within a traditional setting to anytime of the day and from anywhere a patron has access to a library’s on-line presence. The trend within libraries today is a steady increase in the volume of resources available electronically from within the library and from geographically dispersed locations. At the same time, however, libraries continue to provide building-based services and resources. This dual operation mode creates an evaluation environment in which libraries need to assess both their traditional and their networked resources and services from multiple perspectives. Indeed, though libraries have a long tradition of planning and evaluation initiatives that employ multiple techniques and strategies, the networked environment requires librarians to learn

new ways to apply traditional evaluative strategies and to develop new, specific approaches to assess network-based resources and services.

A key issue facing researchers, library managers, and others in this context is the determination of the extent to which library services, resources, or programs meet the information needs of a wide range of library users, including on-site and remote users. Libraries have a history of evaluating library activities through a number of research methods (surveys, focus groups, interviews, and systems-based data collection involving circulation records). In using such methods, librarians and researchers adopt a number of evaluation frameworks to assess whether library services/resources meet user information needs and expectations. In the following discussions, the ways in which libraries evaluate library services, resources, and programs are explored.

Social Change in Libraries

Historically, the primary role of the library has been to function as an information collection center for dissemination and use purposes. Materials have been typically collected and services developed for use by patrons and for archival or historical purposes. Essentially, librarians (1) determined what materials to collect and archive within these collections and how to do so; (2) were responsible for providing the expertise and guidance for use of these collections by patrons; (3) were instrumental in developing structures for the presentation and ordering of the materials; and (4) developed services for the delivery of materials, for training, and for managing the collections. During the past three decades, however, many changes have occurred within the library environment. The following changes have affected how librarians function in this collection and development process for the presentation of materials and services:

- Development of user-centered evaluative strategies within the research community.
- Development of professional librarian degree programs that focus on delivering user-based library services and resources.
- Evolution of information-seeking behavior of users to reflect a diversity of information resources and services from a number of access points.
- Increased availability and use of technology, development of a networked environment, and increased impact of the Internet, which has affected the information-seeking behavior of users.

Additionally, each of these areas is interrelated, creating a cumulative impact on libraries, their resources and services, and the communities that they serve.

Changing Role of Libraries

During the 1970s, evaluation within libraries underwent a shift in perspective. Understanding libraries from the library point of view shifted to understanding libraries from the user perspective. In 1973, Douglas Zweizig conducted a study that focused on the role of libraries in the lives of adult users. This study evaluated how library resources and services affected the users of the resources and services—the patrons. The results of this study and others like it led to the recognition by a growing number of researchers of the need for the development of user-centered evaluation strategies of library collections and services from a user perspective, as well as from the library's perspective.

Prior to 1980, most of the complex research conducted within a library setting was conducted by librarians and a select few professional researchers. Library staff members acted as intermediaries for library users and directed and instructed these users in the use of the library's resources and services. Patrons were generally dependent on libraries and their staff for the fulfillment of more complex research needs, particularly for access to exclusive and expensive databases. During the 1980s and continuing into the 1990s, however, the introduction of personal computers and the digitization of resources changed the way patrons could access information within the library setting. Patrons learned to use digitized resources to conduct research, and their dependency on library staff decreased over time as users developed personal skills in the use of technology to access information directly. The evolution of the Internet throughout the 1990s expanded access to information for library patrons by providing access from a growing number of access mechanisms and locations. Patrons no longer needed to go to a library or to consult as often with a librarian to access many of the library's resources. This change in access to resources also signaled a change in the information-seeking behavior of patrons.

Technology and the Development of Resources

With the development of the Internet, library web sites began to include remote resources developed and located outside the library's primary collections, along with links to other sources of information available via the Internet. Libraries made the following changes:

- Formed consortiums with other libraries to share databases and other resources in an effort to control costs of maintaining and developing collections.
- Subscribed to databases maintained outside the library's collections and maintained by vendors.
- Expanded Internet access for their patrons by increasing the number of workstations.

- Expanded the scope and use of their web sites as portals to other sources of information, such as federal, state, and local government web sites.
- Expanded access to a variety of information resources and services available via the Internet for many library patrons.

Technology and the development of the Internet have served to enhance information dissemination by creating a medium that effectively and efficiently delivers resources to library patrons located within libraries and from remote locations.

Challenges Faced by Libraries due to Changing Roles and Technology

Operating in a dual environment in which many of the traditional physical services and resources are offered alongside Web-based services and resources, 21st century librarians find themselves in need of reevaluating their role as a central repository for information services, resources, and programs. As the roles of libraries change, new challenges arise for librarians. These challenges include the presentation of traditional and Web-based collections, services, and programs by means of a web page; the need for software that integrates multiple databases and applications; the need to balance expenditures between physical resources and services and digital resources and services; the development of various policies, such as privacy and security, created by the on-line environment; and changes in the behavior of patrons due to the development of a dual environment—the traditional and the networked. Librarians recognize these challenges and attempt to meet many of them through the use of planning and evaluation efforts.

Planning, managing, and implementing collections, services, and programs may also be affected by other factors as well, such as meeting the needs of multiple stakeholders; weighing quality of resources and services against quantity; addressing issues of accountability to staff, library volunteers, patrons, boards of directors, and in some instances organizations offering funding; and developing evaluative measures and approaches to understand the effects of planning, managing, and implementing collections, services, and programs. Together, these challenges form the basis for library evaluation activities through a number of methods and approaches.

Evaluative Strategies in Libraries

Libraries use a variety of approaches for the collection of data and statistics, and various data standards have been created and agreed on for the collection of a number of the usage-based statistics. For example, the National Information Standards Organization (NISO) has the NISO

Z39.7 *Library Statistics* standard that provides data elements and definitions for U.S. libraries. The International Standards Organization (ISO) has the *ISO Standard on Library Statistics* (ISO 2789) and the *Standard on Library Performance Indicators* (ISO 11620). Also, individual library organizations such as the Association of Research Libraries (ARL), or state or national library agencies, agree to a number of library use statistics to collect and report on an annual basis. Use of these approaches alone, however, is not sufficient to offer all the needed answers regarding library services and resources in general, and the management of such resources and services in particular. Michael Buckland suggests that library administrators must identify problems or decisions that need solutions and prioritize them; determine what areas within a library are affected; determine if research is the answer to the problem or decision; determine what research needs to be done to provide potential solutions to the problems and the potential effectiveness of the research; and link what they want to know with specific evaluative approaches.

Today's libraries are often faced with decisions that require timely results; issues of accountability in the use of diminishing funding are ever present, and simply conducting more research is not always the answer. Managing and planning evaluation have become imperative in a rapidly changing technological environment, and identifying areas that need evaluation has become the real challenge. The traditional approach of turning to research when problems arise or when there is a need to make decisions is still a viable approach. The addition of planning and developing an overall evaluative scheme, however, enhances the evaluative process. Identifying the focus from specific perspectives in this process recognizes the need to understand a complex environment. Approaching evaluation as an overall process is not new either. An evaluative process that encompasses many areas of a library's functions describes the evaluative evolution that has already occurred within libraries over the past three decades. Incorporating a management plan into the evaluative approaches enhances evaluation efforts.

Evaluation

The primary purpose of conducting research using evaluative approaches in a library setting is twofold: (1) to understand user interaction with library resources and services and (2) to capture data that inform the planning, management, and implementation of library resources and services. Integrated research, evaluation, and planning efforts, through various measurement approaches and methods, can assist libraries in efficiently and effectively developing, implementing, and changing resources and services that meet user information needs over time.

They can also provide an understanding of the broader social context of libraries from a user perspective.

Evaluative Approaches

Evaluative approaches are difficult to define or even to standardize. Each evaluative approach typically offers potential information, based on collected data, particular to a specific area of focus within a library. The area of focus may be broad in scope or defined narrowly for a specific task within a specific setting. Also, evaluative approaches tend to be tailored to particular needs of an organization; to be linked to available time and funding; to be limited by scope and breadth of application due to funding, planning, etc.; and to be determined by direction that ranges from what libraries collect historically to immediate learning needs regarding library services, resources, and programs. Data and statistics captured due to the evaluative effort of an approach may be qualitative or quantitative, descriptive, anecdotal or definitive, collected using traditional manual methods, or tabulated electronically. Whatever approach is used, the guiding principle for researchers is to answer questions such as “what do libraries need or want to know?” through an evaluation planning process within a library setting.

Library evaluation activities can be complex and include a number of factors throughout the process. In general, however, library evaluation centers on three key components (see Fig. 1):

1. **Inputs.** These are the resources that libraries invest (e.g., money, staff, workstations, on-line commercial databases).
2. **Activities.** These are the library services/resources that the inputs actually generate (e.g., licensed resources availability, story hours, training sessions).

3. **Outputs.** These are the number of services/resources generated from library investments (e.g., number of workstations, number of databases licensed, print material purchased, number of training sessions).

These three components form the basis for essentially all library evaluation strategies, because they provide vital baseline data regarding costs, investments, services, and resources.

Types of Evaluative Approaches

There are many approaches used to evaluate library resources and services from multiple perspectives, and the approaches may be library-centered or user-centered. Each approach is part of an evaluative process that includes planning, data collection, and evaluation as components of the evaluation. For purposes of this discussion, evaluative approaches are briefly presented within four broad areas based on the inputs, activities, and outputs: outputs assessment, performance measures, service quality, and outcomes assessment (see Table I). Each of these areas represents multiple approaches. The application of an approach may be broad in coverage or limited and specific. The approaches are malleable. Researchers modify each to fit specific needs and to answer questions based on decision-making needs, in the presentation of resources or services, and on particular perspectives. Library-centered approaches evaluate the presentation of resources and services with an emphasis on efficiency and effectiveness. User-centered approaches evaluate the quality of the presentation of resources and services and the inclusion of the needs of users (or patrons) in accessing resources and services, and may include the library community in general within the approach or may target specific stakeholder groups.

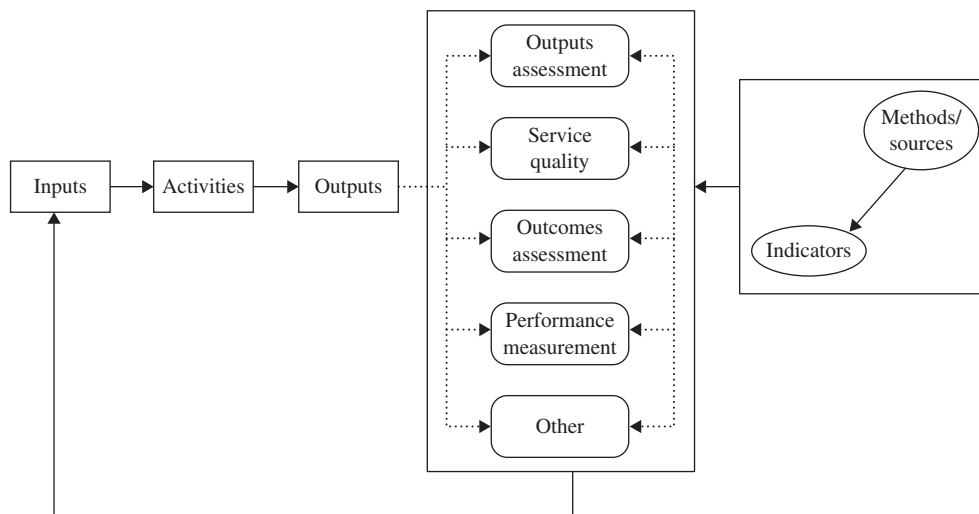

Figure 1 Library services and assessment frameworks.

Table I Overview of Four Broad Areas of Evaluative Approaches

<i>Evaluation approach</i>	<i>Description</i>	<i>Examples of evaluative practices</i>	<i>Applications</i>
Outputs assessment	Collection of counts from use of resources, services, or programming	<ol style="list-style-type: none"> 1. Collection of traditional counts, e.g., reference, circulation, etc. 2. Focus groups 3. Interviews 	<ol style="list-style-type: none"> 1. Evaluation of resources, services, and programs 2. Planning
Performance measures	Developed for evaluating the presentation and/or delivery of specific library resources, services, or programs	<ol style="list-style-type: none"> 1. Availability studies 2. Usability studies 3. Web page analysis 4. Content analysis 5. Functionality analysis 	<ol style="list-style-type: none"> 1. Usability of resources, services, or programs 2. Availability of resources 3. Determine efficiency or effectiveness of presentation of resources, services, or programs, etc.
Service quality	Developed to determine the overall quality of both traditional and network-based resources and services	<ol style="list-style-type: none"> 1. ServQual 2. LibQual+ 3. Balanced scorecard 4. Best practices 5. Benchmarking 	<ol style="list-style-type: none"> 1. User satisfaction with library services 2. Library staff/management appraisal and/or desired level of service provision
Outcomes assessment	Developed to assess the effects of programming on patrons in terms of benefits to patrons	<ol style="list-style-type: none"> 1. Outcomes as a product of programming 2. Outcomes as the effect of programming 	<ol style="list-style-type: none"> 1. As a product, initial measurable affect of programs on patrons 2. As an effect, initial to long-term evaluation of measurable benefits for patrons based on specific programming

Outputs Evaluation

Outputs assessments typically involve the identification of the number of library activities in which patrons engage (e.g., number of database sessions, number of database items examined, and number of training sessions conducted). They may also, however, include data that are qualitative in nature, such as the results of focus groups and interviews. Outputs are collected to determine the usage of library resources and services and as part of a library's planning process. [Table II](#) includes examples of outputs evaluation techniques.

Traditionally, libraries have collected output data in many forms from reference and circulation departments, facility usage, etc. With the advent of networked resources and services, however, outputs today include usage statistics of the networked environment that include data and usage statistics from digital reference services, database article downloads, remote visits to library web sites, and others. Typically, these on-line data and usage statistics are collected using electronic means. Electronic means of collection include data from log files that track and document the information-seeking behavior of users; network traffic statistics that offer data on where users originate, the browsers used, the files accessed, and other

data; and use of databases that can be tracked from statistics gathered directly from library-developed databases and from statistics supplied by vendors of databases. As technology continues to evolve, the development of electronic means to collect outputs will evolve as well.

Performance Measures

Performance measures (also known as performance indicators) have a long history within the tradition of library research. They are used to measure the effectiveness and efficiency of library resources and services from both the library and the user perspectives. These forms of measures are versatile and changeable, determine efficiency and effectiveness, offer measures of satisfaction, and are used to determine needs of users (see [Table III](#)). Performance measures include availability and usability studies and studies utilizing focus groups and interviews; with the evolution of electronic presentations, they also include content analysis, web page analysis, and functionality testing. Performance measures developed for measuring impacts of physical resources and services are often adaptable to the networked environment and may be inclusive of outputs evaluation counts and approaches. Examples of performance measures include cost per item circulated,

Table II Overview of Outputs Evaluative Approaches

<i>Evaluation approaches</i>	<i>Description</i>	<i>Examples of types of data collected</i>	<i>Applications</i>
Tradition counts	Counts collected by physical means	1. Reference statistics 2. Circulation statistics 3. Library patron counts	Used to determine usage of library resources and services
Focus groups and interviews	Typically consists of 1–10 individuals and used to collect information in the form of opinions, perceptions, concerns, and experiences	1. Qualitative data 2. Anecdotal data 3. Quantitative data	1. Planning 2. Exploration 3. Evaluation 4. Assessment 5. Description
Network statistics	Counts collected electronically	1. Web log file statistics 2. Network traffic statistics 3. Database use statistics 4. Vendor statistics	Used to determine usage of library electronic resources and services

Table III Overview of Performance Measures

<i>Evaluation approach</i>	<i>Description</i>	<i>Examples of types of data collected</i>	<i>Applications</i>
Performance measures	Developed for evaluating the presentation and/or delivery of specific library resources, services, or programs	1. User-centered 2. Library-centered statistics 3. Technology related statistics	1. Usability of resources, services, or programs 2. Availability of resources 3. Determine efficiency or effectiveness of presentation of resources, services, or programs, etc. 4. Identify needs, strengths, and weaknesses of resources and services

items downloaded per registered borrower, and correct answer fill rate.

Service Quality

In general, service quality is an evaluation of how well a library provides a service, resource, or program. Service quality approaches include evaluation from the library and user perspectives, of libraries as a field, and of the library as an institution (see [Table IV](#)). Approaches used to determine service quality saw rapid growth during the 1980s with the shift to user-centered research and with the development of electronic resources and services. Approaches developed in the business environment such as best practices, benchmarking, customer satisfaction assessment tools (e.g., ServQual), and others were adapted for use in a library environment in the measuring of service quality. ServQual was developed specifically to measure quality of business services based on perceptions, desires, and a minimal level of expectation of consumers. LibQual+ was developed specifically to measure satisfaction in the quality of library services based on

perceptions, desires, and a minimal level of expectation of users.

More recently, libraries have applied the balanced-scorecard approach to evaluating library services. The balanced-scorecard method determines overall organizational performance along four dimensions—financial, customer, internal, and innovation/learning dimensions. This approach provides libraries with an overall assessment technique that involves the multiple evaluation frameworks of outputs, service quality, and outcomes.

Outcomes Assessment

Outcomes assessment is relatively new to library evaluation. This evaluation approach seeks to determine the impact of library resources and services on the users of library resources and services. In particular, outcomes assessment seeks to determine the benefits or changes in knowledge or skill level, behavior, attitudes, or any change that may be seen as a benefit for the participants. As a product, outcomes are immediate measurable benefits for users with potential long-term effects. As an evaluative approach, a large body of work is available from the

Table IV Overview of Service Quality Evaluative Approaches

<i>Evaluation approaches</i>	<i>Description</i>	<i>Examples of types of data collected</i>	<i>Applications</i>
Service quality (ServQual)	Library-centered approach developed to determine library service quality or effectiveness in the presentation and/or delivery of specific library resources, services, or programs	Quantitative data of library performance based on patrons' perceptions, desires, and minimum expectations of five ServQual dimensions: 1. Tangibles 2. Reliability 3. Responsiveness 4. Assurance 5. Empathy	1. Strategic analysis 2. Gap Analysis 3. Input analysis 4. Production capability 5. Determine efficiency of resources, services, and programs
Library quality (LibQual+)	User-centered approach developed to determine library service quality or effectiveness in the development, presentation, and/or delivery of specific library resources, services, or programs based on the wants and needs of users	Quantitative data of user-centered wants and needs of library performance based on patrons' perceptions, desires, and minimum expectations	1. Output analysis 2. Outcomes analysis (where outcomes are measurable results) 3. Results targeted for benchmarking 4. Long-range planning
Balanced scorecard	Developed to balance past measures of success with future measures of success based on four dimensions—financial, customer, internal, and innovation/learning dimensions	Qualitative and quantitative data collected by means of performance measures and outputs	1. Planning for future services or programs 2. Financial, customer, internal, and innovation/learning dimensions 3. Strategic planning at an organizational level
Best practice and benchmarking	The process of initiating industry best practices in developing standards or benchmarks to gauge future developments or practices	Qualitative and quantitative data collected from products, processes, programs, etc.	1. Improve efficiency and effectiveness of services and programs 2. Future strategic planning 3. Identify user-centered quality programs and services

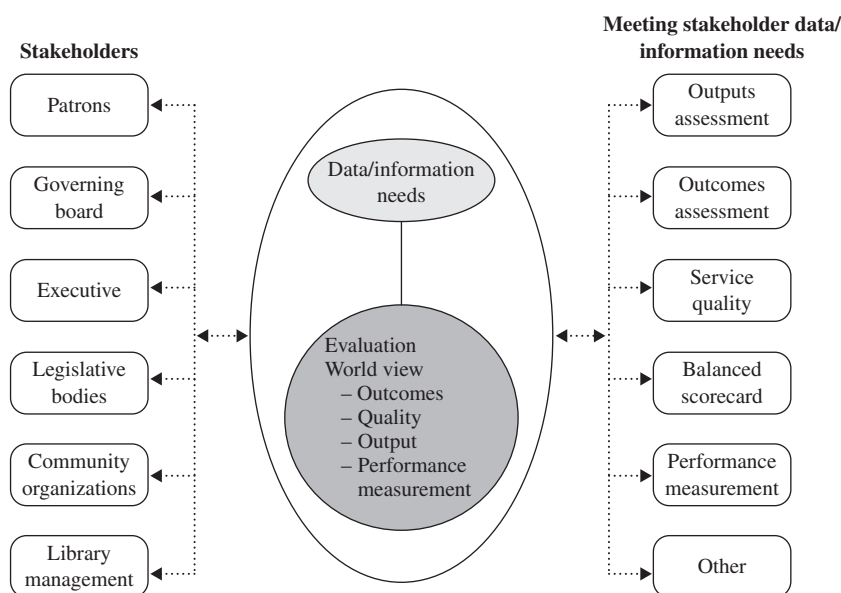

fields of education and sociology in which outcomes are typically measurable results of interventions or programs. Table V presents selected examples of outcomes assessment strategies. When viewed as an effect, the measurable change is part of the assessment process in determining the initial to long-term impact of specifically developed programs on participants of the programs. Developed programs are designed in terms of institution goals or standards to create benefits for participants, and performance measures are used within the programs to measure the differences produced by the programs.

Summary of Evaluative Approaches

Evaluative approaches are developed to answer the questions of what libraries need or want to know regarding their resources and services (see Fig. 2). A library's need/desire to know may be influenced by a number of factors, including internal and external stakeholders such as library management, governing boards, or other community-based stakeholders. To meet these data needs, evaluation activities within libraries often use multiple assessment strategies and approaches, because no single approach is likely to

Table V Overview of Outcomes Assessment

**Figure 2** Needs-driven evaluation strategies.

provide all the answers for library management and decision-making purposes. The approaches are versatile and, as presented here within four broad categories, often overlap and may serve multiple purposes. Performance measures may use aspects of outputs approaches within the evaluative scheme and the results may serve as indicators of service quality. Approaches developed for physical settings are adapted and utilized in the networked environments.

As researchers of library environments continue to develop evaluative schemes, more complex approaches to evaluation are beginning to appear. For example, evaluative schemes can include the collection of traditional and networked data and statistics, combined with the use of performance measures in understanding service quality or outcomes. Researchers and practitioners in library settings are aware of the need to develop evaluative strategies that include multiple approaches, methods, and

evaluation frameworks to gain a better understanding of a complex library environment and are working to develop approaches to address this need.

Challenges of a Networked Environment

Although the fundamentals of evaluation efforts and the measurement frameworks and paradigms in which evaluation activities reside remain essentially constant, the networked environment continues to usher in a whole host of new library resource and service use measures. At present, these measures occur in essentially two areas: (1) resource/service availability, related to the number of items available (e.g., full-text titles, e-books, digitized images), instruction tools, and digital references, and

(2) user actions, related to the items examined and/or downloaded, the number of searches conducted, the number of digital reference questions submitted, etc. As of this writing, libraries are only in the early stages of considering service quality and outcomes assessment for networked services. Moreover, the “what,” “how much,” and “how often” questions in the networked environment will be in a continual development cycle as new technologies and capabilities enable a variety of networked library resources and services.

Future of Evaluation in Libraries

Libraries will continue to evaluate their resources and services and how users interact with and engage in those resources and services. The core of these evaluation strategies—inputs, activities, and outputs—will likely remain the same. Differing internal and external factors and library situational factors, however, will influence the assessment strategies that libraries employ and methodologies that enable useful data collection for decision-making and research purposes. For example, an external program evaluation paradigm, such as institutional accreditation in higher education for academic libraries or results-oriented government in public libraries, can drive the assessment activities within a library. Indeed, this serves as the impetus for outcomes assessment in academic and public libraries. Also, user behavior and expectations for library services continue to evolve. Thus, user expectations, the library’s situational context, and program reporting requirements combine to influence library evaluation activities of the present and future.

Likert Scale Analysis

Ira H. Bernstein

University of Texas, Arlington, Arlington, Texas, USA

Glossary

bipolar domain Dimensions that have meaningful and opposite extremes, such as good vs. bad.

congeneric (test) model Tests that have the following properties: (1) their true components are linearly related and (2) their error components are unrelated across respondents.

error component The latent (unobservable) part of an observed score that is independent of the actual trait of interest.

Likert scales of agreement Scales that allow the respondent to express degrees of agreement (like) vs. disagreement (dislike), for example, “Strongly agree,” “Agree,” “Agree somewhat,” “Disagree somewhat,” “Disagree,” and “Strongly disagree.”

Likert scaling An approach to scaling that treats ordinal (ordered) alternatives as if they are equally spaced. For example, “Strongly agree,” “Agree,” “Agree somewhat,” “Disagree somewhat,” “Disagree,” and “Strongly disagree” would be coded 1–6. This scaling principal is not limited to Likert scales of agreement.

observed score The score a person is assigned on a test or test item.

parallel (test) model Two congeneric tests that have the following properties: (1) their true components are identical and (2) their true and error components are the same across respondents.

systematic (true) component The latent (unobservable) part of an observed score that measures the actual trait of interest.

Likert scales are named after Rensis Likert (1903–1981) and are also known as summated rating scales because the scale score is a simple sum of responses over items. They are perhaps best known from items that allow respondents to express degrees of agreement, such as “Strongly agree,”

“Agree,” “Agree somewhat,” “Disagree somewhat,” “Disagree,” and “Strongly disagree” rather than a simple choice between agreement and disagreement. However, Likert scales contain a second element that Likert actually stressed more in his original article. This involves using equally spaced integral scale values, most simply, 1, 2, 3, . . . , to scale items with ordinal response categories instead of a more formal algorithm. Consequently, the logic he used in his classic 1932 paper applies to any ordinal multicategory rating scale, which includes estimates of frequency, anchored scales, and confidence ratings. This entry is concerned with the issues that surround their analysis. The terms Likert scales of agreement and Likert scaling thus describe Likert items in their familiar application and the use of equally spaced scale values, respectively, noting that the former is a special case of the latter.

Likert's Basic Idea

Thurstone proposed a method of scaling responses to ordered multicategory items that was designed to transform the categories to points on an equal-interval scale. This sigma method assumed that the latent scale values could be inferred from the response proportions in the various categories. Likert presents an example using proportions of 0.13, 0.43, 0.21, 0.13, and 0.10 in five categories. Thurstone's method generates cited values of -1.63 , -0.43 , $+0.43$, $+0.99$, and $+1.76$, using a simplified algorithm described in Thurstone's original article. A close approximation to these values may be obtained by (1) adding the proportion of observations below a given interval and one-half the proportion within the given interval and (2) converting this sum of proportions to a z score. In the case of the second interval, the result

is the z score corresponding to $0.13 + 0.5 \times 0.43$ or 0.345, which is -0.40 .

Likert's scaling method was simpler—give unit scores to the categories. As anyone who has ever used a Likert scale of agreement knows, this simply means assigning weights such as 1, 2, 3, 4, and 5 (or -2 , -1 , 0, $+1$, and $+2$) with a five-category scale. This simplification was extremely useful before computers became widely available, but it ran counter to the apparent precision of Thurstone's method. However, Likert showed that the reliabilities and validities of scales scored with his method were at least as high, and often were higher, than those scored with Thurstone's method, even with fewer items. Unlike Thurstone's many other contributions, which are still used, his method of constructing equal intervals from multicategory scales is now rarely employed.

Many, however, still question the interval assumptions underlying Likert's scaling method, as seen by the frequency of related questions in various Internet discussion groups. Of course, perhaps the majority of critics have not read his original justification. Likert's scaling method employs *a priori* weights, so it avoids the tendency of Thurstone's category estimates to contain a lot of sampling error.

Allen Edwards was among the first to support Likert's approach, although he was concerned about the issue of a middle category failing to differentiate true neutrality or lack of concern with ambivalence. This point emerges periodically; indeed I was once briefly involved in the topic. Of interest is the fact that at that time Edwards and others were exploring a variety of scale-construction procedures such as Guttman scales. Guttman scales are now rarely used, but were an important precursor of item response theory.

There is a direct link between Likert's scaling logic and what Kaiser and, later, Wainer referred to as the "It don't make no nevermind principle," which notes that simplified weightings in multivariate applications such as factor analysis and multiple regression are often more robust than "exact" values. Wainer later modified his conclusions somewhat, but the gist of the story is that little, if anything, is gained by using complex weighting schemes with multicategory items in classical multivariate applications.

Likert's scaling model may be pursued more formally. One way to do so is to assume that the categorized overt responses to individual items are a product of implicit responses that are available internally along a continuum (there are also decision threshold models that assume that even the implicit response is categorical, but these are not considered here). The present theory consists of two models: (1) the implicit model, which generates the latent responses and (2) the categorization model, which can be used to categorize these latent responses into overt responses.

The Implicit Model

One way to state Likert's scaling model is as follows, following classical psychometric theory. Assume that asking any question, such as attitudes toward a commercial product, evokes a latent response, λ_{ij} , where i denotes the subject (out of n subjects) and j denotes the response (out of k items defining the scale). Next, assume that λ_{ij} is a weighted combination of a systematic (true) component (τ_{ij}) and an error component (ϵ_{ij}), as defined by the following general model:

$$\lambda_{ij} = \beta_i \tau_{ij} + \gamma_i \epsilon_{ij} \quad (1)$$

where both the true and error components are standard normal random variables, β_i is the weight allocated to that true score, and γ_i is the weight allocated the error term for that item. As a result, all that is assumed at this point is that the true and error scores are independent (uncorrelated) and that they combine linearly. Further, assume that the error scores for different items are also uncorrelated. The scalings of the two weights can reflect the assumption that they are also definable as standard normal variables. Because even nonlinear relations are often approximated by linear ones and the very meanings of the terms "true score" and "error" imply independence, only one point is controversial. That is the view that the absolute magnitude of the response is the critical variable. This is generally regarded as a good assumption in such areas as intellectual functioning (the smarter you are, the better you perform). However, in many attitudinal areas, an unfolding model using distances from an ideal point may be more relevant; for example, a candidate may be either too liberal or too conservative to be preferred optimally by a given voter.

In addition, even this model is far too general. One common assumption is that the implicit responses are normally distributed, which we assume here for its illustrative value; however, Micceri has made a well-stated objection to this Gaussian model. More critically, an important class of restrictions is often made that lead to the congeneric (i.e., measuring the same thing) test model:

1. True score components across items are linearly related to one another for a given respondent.
2. Errors are independent over items and respondents.

The parallel test model is even more restrictive. It further assumes that:

1. True score components for a given respondent across items are the same.
2. Their weighting is the same across items.

This leads to:

$$\lambda_i = \beta\tau_i + (1 - \beta^2)^{0.5}\varepsilon_{ij} \quad (2)$$

Because of the first parallelism assumption, the item subscript can be dropped for a given respondent, and because of the second parallelism assumption, the item subscript can be dropped from the item weighting. The second congeneric assumption allows the same weight to be applied to each error observation. It can be shown that letting the γ_i of Eq. (1) equal $(1 - \beta^2)^{0.5}$ simply standardizes the values of λ_i . Given this standardization, it makes sense to define β as the item reliability. Finally, if we simply keep in mind that respondents inherently vary, their subscript can be eliminated, giving rise to:

$$\lambda = \beta\tau + (1 - \beta^2)^{0.5}\varepsilon_j \quad (3)$$

As strong as this model is, it probably fits quite well when items are sampled from a homogeneous pool (domain sampling). That is the case, for example, in an abilities test that requires respondents to add randomly selected pairs of three-digit numbers, in which the pool (domain) consists of the numbers 000, 001, . . . , 999. The concept of domain sampling may not apply to an unselected set of attitudinal items, but may at least be approximately true of a scale following item analysis in which the items have similar item/total correlations. The demonstrations that follow assume parallelism for simplicity.

The Categorization Model

Assume that a latent response is classified into one of m response categories using a series of $m - 1$ cut-offs. This follows the standard logic of signal detection theory, which also traces back to Thurstone. In other words, let c_j ($j = 1, 2, \dots, k - 1$) and the response to a given item be assigned to overt category C_i if $\lambda > c_i - 1$ and $\lambda \leq c_i$. In other words, if standardized data are dichotomized symmetrically ($c_1 = 0$), then $C_i = 1$ if $\lambda < 0$ and $C_i = 2$ if $\lambda \geq 0$. Of course, these can be transformed linearly to -1 and $+1$ or any other pair of distinct values.

Note that there are at least two potential ways to justify Likert's assumption of equality. The first is to assume that the cut-offs partition responses into equal proportions of observations over respondents. For example, cut-offs of -0.675 , 0 , and $+0.675$ will divide normally distributed observations into equal quartiles. The alternative is to assume that the intervals themselves are equal. This is meaningless if we assume the continuum extends from $-\infty$ to $+\infty$; but if, say, we assume it only extends from -3 to $+3$, the cut-offs can be -1.5 , 0 , and $+1.5$. However, neither seems exceptionally plausible in general because response distributions are usually demonstrably unequal, and there is little to justify a rectangular distribution of observations.

Likert Scaling and Cohen's Dictum

Jacob Cohen noted that we pay an extremely high price in loss of power when we dichotomize, which is referred to here as Cohen's dictum. This is not limited to the present situation; it also occurs when we discard, say, continuous information contained in age as a variable and replaces it with "Young" vs. "Old." Specifically, he estimated that a value of r^2 obtained with two continuous, normally distributed variables would shrink by a factor of 0.65 when one variable is dichotomized and by a factor of 0.41 when both are dichotomized. This implies losses in power of 38% and 60% —the equivalent of discarding the respective numbers of cases. Often this dichotomization is done because investigators are familiar with the analysis of variance but not with more general forms of regression. Of course, there are techniques such as biserial r and tetrachoric r that are designed to offset the reduction in r^2 produced by categorization, but these statistics have much greater sampling errors than ordinary Pearson r , can lead to anomalous results in procedures such as factor analysis, and make little sense when the original continuous variables are available in the first place. Cohen's dictum applies to Type II errors for dichotomized data in null hypothesis testing (which, as an incidental point, he was actually opposed to), as well as such things as confidence intervals (which he supported). Cohen's general focus on statistical inference contrasts somewhat with this entry's emphasis on description, particularly with regard to internal consistency. However, we would normally expect increases in reliability to reduce Type II errors.

Several have looked at Type I and Type II error rates as a function of the number of categories that data are placed into. In 1987, Gregoire and Driver performed an extensive series of computer simulations and concluded that the results for Type I error even with five-point scales were unsatisfactory. In 1989, Rasmussen argued that their conclusion reflected an erroneous assumption about the mean used to test the various confidence intervals. When they corrected this assumption, Type I error rates were in accord with expectation. In 1977, Jenkins and Taber also showed that problems that arise with a dichotomization do not arise when a five-point scale is used. This is consistent with Likert's scaling assumption.

Multicategory Scales and Coefficient α

Consider how using multiple categories affects coefficient α reliability for a set of k parallel test items. This is done

here in terms of the simple latent variable model for parallel items already discussed.

The cut-offs were chosen to yield equal population item frequencies at three levels of categorization, 2, 4, and 8. As result, the cut-offs were (1) 0, (2) -0.675 , 0, and $+0.675$, and (3) -1.15 , -0.675 , -0.32 , 0, $+0.32$, $+0.675$, and $+1.15$. These were combined with three values of β (0.4, 0.6, and 0.8) and three test lengths (5, 10, and 20 items) on 10,000 replications/simulation. Figures 1–3 contain the coefficients α for 5, 10, and 20 items, respectively, across number of categories (including the latent data), with β as the parameter.

The three figures collectively illustrate how coefficient α is a joint function of scale length, item intercorrelation, and number of categories, but also they indicate that these effects are clearly not linear. It is perhaps useful to examine these differences in the light of the commonly suggested (but arbitrary) standards of 0.8 and 0.9 for tests used to measure group differences and tests used for individual classification, respectively. The five-item data in Fig. 1 indicate that an item reliability of 0.8 is required to meet the standard for group discrimination using dichotomized data, but this level of item reliability produces a value of coefficient α that nearly meets the individual standards with eight-category data. The 10-item data in Fig. 2 indicate that the individual-level criterion is reached at an item reliability of 0.6 and four or eight categories or at an item reliability of 0.8 regardless of the number of categories. Indeed, the latter scale almost meets the individual-level criterion. Finally, the 20-item data in Fig. 3 indicate that dichotomized data and an item reliability of at least 0.6 are satisfactory for group-level discrimination and dichotomized data and an item reliability of 0.8 are satisfactory for individual-level discrimination, regardless of the number of categories. Note that

the lowest level of item discrimination does not lead to a satisfactory group-level discrimination, let alone an individual-level scale, with the parameters studied. Further analysis, not detailed here, suggests that dichotomized data with an item reliability of 0.4 requires at least 40 items for group-level discrimination and at least 70 items for individual-level discrimination, which may not be practical. This was improved only slightly to roughly 30 and 60 items using four categories, which differed but marginally from the eight-category results. In other words, although using as few as four categories can make a substantial difference for scales of at least moderate ($\beta = 0.6$ in the present case) item reliability, nothing can save a scale made up of low ($\beta = 0.4$) item reliability items. At the same time, the group-level criterion is met

Figure 2 Values of coefficient α as a function of the number of categories into which latent observations are categorized for a hypothetical parallel 10-item scale; the parameter is the item reliability, β (simulated data).

Figure 1 Values of coefficient α as a function of the number of categories into which latent observations are categorized for a hypothetical parallel five-item scale; the parameter is the item reliability, β (simulated data).

Figure 3 Values of coefficient α as a function of the number of categories into which latent observations are categorized for a hypothetical parallel 20-item scale; the parameter is the item reliability, β (simulated data).

with four-category data and an item reliability of 0.6 with only 10 items and the individual-level criterion is met with 20 items. Thus, the ability of multiple categories to save a scale requires at least moderate item reliability. In general, the effect of going from four to eight categories was marginal. These results are in accord with Jenkins and Taber's more extensive simulations.

The choice of items with the same distribution may be a bit extreme because it is often desirable to obtain a spread of item difficulties so that further simulations along these lines may be of interest. However, the choice of cut-offs that make the response frequencies equal provides a best-case scenario over the effects of categorization. The more extreme the difference in response frequencies for the various categories (as in scales that assess rare symptoms), the less dramatic the advantage of any multicategory format becomes.

Effects of Item Reliability on Inter-Item Correlations

Table I contain the correlation between items 1 and 2 (r_{12}) as a joint function of the number of categories, the number of items, and the item reliability ($\beta = 0.4, 0.6, \text{ and } 0.8$). Holding the number of categories and item reliabilities constant, the r_{12} is identical across scale lengths because the first five items employed identical data (likewise, the first 10 item responses were identical in the 10- and 20-item data, again holding number of categories and item reliabilities constant). As we expect from the coefficients α data, the effects of increasing the number of categories are minimal with an item reliability of 0.4, but increase as the item

reliability increases; with $\beta = 0.8$, there is considerable attenuation in r_{12} with dichotomized data compared to the latent data, but relatively little with eight-category data.

Effects of Item Reliability on the Factor Structure

Bernstein and Teng noted that the effects of using multicategory scales are as we might expect with older exploratory methods, but can lead to some surprising outcomes with inferences derived from newer maximum likelihood-based methods.

Table I also contains the first and second eigenvalues (λ_1 and λ_2) obtained from analyzing the 20-item data for $\beta = 0.4, 0.6, \text{ and } 0.8$, respectively. Recognizing the limitations of the Kaiser-Guttman criterion (the number of components whose eigenvalues are less than 1) for the number of factors, these results are consistent with a single-factor solution. Moreover, all other common criteria for the number of factors (parallel analysis and minimum average partial) lead to the same conclusion. Specifically, parallel analysis (factoring null matrices based on 10,000 observations and 20 variables) generated mean values λ_1 and λ_2 values of 1.08 and 1.06 with 20 variables. The obtained λ_1 is clearly larger and the obtained λ_2 is clearly smaller than these values with all degrees of categorization. However, also note that λ_1 becomes larger and, accordingly, λ_2 becomes smaller as the number of categories increases from 2 to ∞ . The same held true with the shorter scales, although with a smaller magnitude of difference.

Table I Values of the Correlation between Items 1 and 2 (r_{12}) and the First Two Eigenvalues, λ_1 and λ_2 ^a

Number of categories	Number of items	$\beta = 0.4$			$\beta = 0.6$			$\beta = 0.8$		
		r_{12}	λ_1	λ_2	r_{12}	λ_1	λ_2	r_{12}	λ_1	λ_2

∞	20	0.15	4.00	0.91	0.35	7.77	0.69	0.63	13.10	0.39

^a Eigenvalues obtained from factoring scales varying in number of categories (2, 4, 8, and ∞), number of items (5, 10, and 20) and item reliability (β).

Exploratory maximum likelihood solutions for 5, 10, and 20 items were based on 10, 45, and 190 df in testing the null hypothesis that at least one factor was present and on 5, 35, and 170 df in testing the null hypothesis that the residual from a single-factor solution was nonsignificant. There was never any issue of a single factor being present nor, in my experience, is this ever the case with any reasonable number of variables. However, the value of the χ^2 statistic used to test for the presence of a single factor does increase with the number of categories with the difference between two and four categories being much larger than that between four and eight, which, in turn, is larger than that between eight and ∞ .

More interesting and complex results are found in looking at the test for residual variance, which are consistent with Bernstein and Teng's results. Table II contains the values of χ^2 as a joint function of number of categories, number of items, and item reliabilities.

The key point to note is that the minimum value of χ^2 for a test of the residual is *not* necessarily reached with the latent (∞) data, in general, because these values were actually lower with the four- and, especially, eight-category Likert scales when the item reliability was low. Even worse is the problem that longer scales made up of more reliable items lead to significant residuals and that this tendency increases rather than decreases with number of categories (the latent data conformed to theoretical expectations throughout). What happens is that the more reliable Likert data make the effects of categorization more (rather than less) apparent. In other words, using Likert scales may increase (rather than decrease) the probability of falsely concluding a unidimensional scale is multidimensional

Table II Values of χ^2 Associated with the Null Hypothesis^a

Number of categories	Number of items	β		
		0.4	0.6	0.8
2	5	6.15	8.54	0.66
4	5	1.25	2.42	3.98
8	5	0.79	2.38	1.83
∞	5	2.04	2.05	2.06

^a H_0 : One factor is sufficient to explain the data as a function of number of categories (2, 4, 8, and ∞), number of items (5, 10, and 20), and item reliability (β) = 0.4, 0.6, or 0.8).

* $p < 0.05$.

** $p < 0.01$.

when inferential criteria are used, at least those based on maximum likelihood tests!

Effects on Item Response Theory Parameters

An alternative way to look at the data is in terms of item response theory. In particular, the data for the $\beta = 0.6$ for 10-item dichotomous data and $\beta = 0.6$ for 10-item eight-category data were fit to rating scale models (in the case of the dichotomous data, this led to the same outcome as a one-parameter model). The results of greatest interest are the test information functions. The higher the value of this function, the more precise the statement about small differences in the estimation of the latent attribute, θ , in this region in the scale. Figure 4 contains these results.

As can be seen, both functions peak at $\theta = 0$, which results from the symmetric manner in which the various distributions were constructed and the fact that the items are parallel (have the same true and error components). Note, however, that the Likert scale falls above the dichotomized data, meaning that it is more informative about the latent attribute, and that it is nearly flat from $\theta = -2$ to $\theta = +2$, whereas the function for the dichotomized data is approximately normal because it falls off fairly rapidly. This will not be the case if items vary in their means, unlike the present simulations.

Bipolar Domains

Likert scales of agreement (but not Likert scaling in general) imply an underlying bipolar continuum. For

Figure 4 Test information function for eight-category Likert and dichotomized data, assuming 10 parallel items with item reliabilities of 0.6.

example, agreement with an item such as “parents should receive vouchers from their state government to pay for private school education of their children” implies support for a conservative position and disagreement implies support for a liberal position, where conservative and liberal are poles of a single dimension.

In 1965, Green and Goldfried challenged the view that common scales such as “Good/Bad,” “Large/Small,” and “Active/Passive” are, in fact, bipolar. These bipolar dimensions are presumed to underlie the semantic differential, a once highly popular type of rating scale. Instead of having respondents employ a single bipolar dimension, they had the respondents respond to the two poles separately, for example, using separate “Good” and “Bad” scales. Whereas the bipolar view suggests that the “Good” scale ratings of a series of stimuli should have a strong negative correlation with the “Bad” scale ratings, this often did not happen. However, Bentler pointed out that these minimal correlations may have been influenced by the tendency to acquiesce (agree). When this trait was partialled out, the expected strong negative correlations between the putatively bipolar scales were in fact obtained, supporting the bipolarity assumed by Likert scales of agreement.

A related problem arises when certain items are phrased so that agreement denotes the presence of a trait and other items are phrased so that agreement denotes either the absence of the trait or its polar opposite. In other words, suppose one self-descriptive item asks, “I am presently in a good frame of mind,” and another asks, “I am presently unhappy,” (it does not matter here whether the items use Likert scales of agreement or are simply binary). Assuming we wish positive scores to reflect happiness, we would simply subtract the rating on the second question from seven (the number of categories plus 1). Conversely, if we wish positive scores to reflect unhappiness, we would apply the same transformation to the first item. Note that either of these is straightforward and neither is a matter for disagreement among experts and that your choice of measuring happiness or unhappiness leads to equivalent outcomes.

Be prepared for two items phrased positively to correlate more highly and for two items phrased negatively to correlate more highly than a positively worded item with a negatively worded item. However, this typically reflects the method rather than content variance. The history of this distinction traces back to a classical 1959 paper by Campbell and Fiske.

How Many Categories to Use?

Another common question is how many categories to employ. Part of this question involves whether to employ a neutral category. Many investigators (such as this

author) prefer to try to force a decision out of the respondent, which leads to avoiding a neutral category by incorporating an even number of categories. However, this makes no difference in some methods, such as signal detection rating scale analysis.

As for choosing the number of categories, the first point to keep in mind is that we can always condense a scale containing a larger number of categories to a smaller number. The second point is that we need to determine whether there is an optimal number of categories to use. The simulations so far suggest that there is little need for more than eight categories, but these simulations have only touched the surface of a vast literature. Indeed, rather strong assumptions were made in the simulations. Note that the limitation to “seven plus or minus two” categories, so artfully summarized by George Miller, does not really apply because this limitation applies to judgments of unidimensional stimuli such as height and weight and not the complex attributes usually scaled. However, it is good to keep in mind that respondents may not be fully able to use, say, a 100-point scale and that items with 10 or fewer categories fit nicely within many mark-sense forms.

At the same time, there are several studies that indicate that subjects can use a relatively large number of categories profitably. Bendig found that the amount of information transmitted, a type of nonmetric correlation, increased up to at least nine categories. Green and Rao, using simulated data and a multidimensional-scaling-fit criterion, found support for more rather than fewer categories. On the other hand, Komorita and Mattell and Jacoby used respondent’s ratings and found that the reliability of a scale was independent of the number of categories; Mattell and Jacoby also found that the scale’s validity was likewise unaffected by the number of categories. Moreover, Lissitz and Green, using simulated data, argued that seven categories are optimal, noting a leveling off of coefficient α and a decrease in standard deviations as the number of categories increases, holding the covariance structure constant. In 1973, Ramsay developed a maximum likelihood algorithm. Using the precision of estimation (reciprocal standard errors) as a criterion, his model predicts a leveling off at approximately seven categories. Perhaps as interesting is the finding that estimating the category boundaries from the data degraded the model’s performance considerably compared to treating them as fixed.

Note that the conclusions often differ because different investigators used different criteria (e.g., information transmitted vs. coefficient α). Although not recent, Cox provides a useful summary of the considerations relevant to this complex issue (indeed, the complexity of the issue has become so widely recognized that recent textbooks tend not to even suggest an optimal number). Perhaps it

is best to conclude this section by suggesting that each investigator consider which criteria will be used to evaluate the scale's performance and act accordingly.

Mixing Items with Different Numbers of Scale Points

Suppose we wish to combine some items scored on, say, a five-point scale with others scaled on an eight-point scale. The simplest possibility is simply to mix the two types of items without making adjustments for the difference in the numbers of categories and, therefore, item variance. A more complex procedure is to spread the five categories over an eight-point range by assigning values of 1, 2.75, 4.5, 6.25, and 8 to the five categories. In general, if we want the first category have a value of A_0 , have a total of C intervals, and have V_{\max} be the values of the highest numbered category, we let the value of category C_i be $A_0 + (V_{\max} - 1) \times (C_i - 1)/(C - 1)$. Thus, in the present example, the scale value of the second category is $1 + (8 - 1) \times (2 - 1)/(5 - 1) = 1 + 7/4 = 11/4 = 2.75$.

It is instructive to compare this with simply mixing in the two types of items with their original scalings, that is, spreading the five-category items over a five-point range and the eight-category items over an eight-point range. Consistent with Likert's scaling thesis (and those of many others who advocate scaling in the simplest manner), we will probably find the two scores correlate nearly perfectly.

The Use of Anchors

It is always a good idea to make the descriptors of the various response categories (anchors) as clear as possible. Ideally, we should also choose categories that are chosen

by respondents a reasonable percentage of the time, say at least 0.5%. A third consideration is not to bias responses, for example, by asking respondents about how much they like something and providing only positive options. Of course, the desire to achieve reasonable proportions of choice may conflict with the need to balance categories to avoid bias. It is suggested that this last consideration take precedence.

Linear Logistic Test Models

Gerhard H. Fischer

University of Vienna, Vienna, Austria

Glossary

basic parameters Parameters that are the source of differences in item difficulty; examples are parameters measuring the complexity of cognitive operations or subtasks and the effects of test conditions or treatments.

Bradley-Terry-Luce (BTL) model A probabilistic model for paired comparisons of objects or of players in a tournament.

item generation The production (typically of large numbers) of items on the basis of a formalized theory of their cognitive complexity, yielding sets of items of predefined difficulty levels.

linear Bradley-Terry-Luce (LBTL) model A BTL model in which the object parameters are linear combinations of certain basic parameters.

linear logistic test model (LLTM) A logistic test model in which the difficulty of each item is a linear combination of certain basic parameters.

linear partial credit model (LPCM) A partial credit model in which the parameters of items \times categories are linear combinations of certain basic parameters.

linear rating scale model (LRSM) A rating scale model in which the item parameters are linear combinations of certain basic parameters.

partial credit model (PCM) A model for polytomous test items in which the numbers of ordered response categories and their attractiveness parameters can vary between items.

Rasch model (RM) A model for dichotomous test items in which the probability of a right response is a logistic function of the difference between a person's ability and the item difficulty.

rating scale model (RSM) A model for polytomous test items in which both the numbers of ordered response categories and their attractiveness parameters are the same for all items.

virtual item An item that is characterized by an item parameter in a model but does not necessarily exist in reality; for example, if a real item is given under two testing conditions influencing the response probabilities, the item

is represented in the model by two virtual items with different item parameters.

This entry introduces the linear logistic test model (LLTM), which aims at explaining the difficulty of test items or tasks in terms of underlying factors such as rules, cognitive operations, treatments or training, and trend effects (e.g., development). The estimation of the model and properties of the estimators, testing of fit, hypothesis testing, relationship of the LLTM to the linear Bradley-Terry-Luce (LBTL) model, typical fields of application (analysis of the cognitive complexity of tasks, cross-cultural research, and group- and individual-centered analysis of change), a multivariate reinterpretation of the LLTM, its estimation and properties of the estimators, and hypothesis testing in multivariate LLTMs are outlined. Polytomous extensions and specialized software products are briefly mentioned.

Definition of the Linear Logistic Test Model

The linear logistic test model (LLTM) is an extension of the Rasch model (RM) assuming that the item difficulty parameters β_i , $i = 1, \dots, k$, of the RM can be linearly decomposed into a weighted sum of basic parameters α_l , $l = 1, \dots, p$, with $p \leq k - 1$. (For a list of the mathematical symbols used here, see Table I; for abbreviations, see Table II.) The motivation for this extension is the notion that, in some classes of tests, the differences between the difficulties of any two items, I_i and I_j , can be accounted for by the sum of the difficulties of the cognitive operations that are needed for item I_i but not for item I_j minus the sum of the difficulties of those cognitive operations that

Table I Mathematical Symbols

k	Number of items in a test or in an item sample
p	Number of basic parameters
β_i	Item (difficulty) parameter of item I_i
$\boldsymbol{\beta}$	Column vector of item parameters β_i , $i = 1, \dots, k$
β_i^*	Item (difficulty) parameter of virtual item I_i^*
α_l	Basic parameter no. l
$\boldsymbol{\alpha}$	Column vector of basic parameters α_l , $l = 1, \dots, p$
$\mathbf{1}_k$	A k -dimensional column vector of ones
w_{il}	Weight of basic parameter α_l in item I_i
$\mathbf{W} = ((w_{il}))$	Matrix of weights
$\mathbf{W}^+ = (\mathbf{W}, \mathbf{1}_k)$	Matrix of weights extended by a column of ones
\mathbf{V}	Asymptotic covariance matrix of basic parameter estimators
θ_v	Position of testee S_v on trait Θ (unidimensional case)
θ_{vi}	Position of testee S_v on trait Θ_i (multidimensional case)
Θ	Latent trait dimension
x_{vi}	Item score of testee S_v on item I_i
$x_{.i} = \sum_v x_{vi}$	Item marginal sum (item score)
$x_{..} = \sum_v \sum_i x_{vi}$	Total sum of item scores
$\mathbf{X} = ((x_{vi}))$	Item score matrix
\mathbf{y}	An arbitrary vector of responses to k items, with raw score r
c	Normalization constant
L_c	Conditional likelihood function
$\gamma_r(\boldsymbol{\beta})$	Elementary symmetric function of order r of parameters $\exp(-\beta_i)$
$\gamma_{r-1}^{(i)}(\boldsymbol{\beta})$	Elementary symmetric function of order $r-1$ of parameters $\exp(-\beta_1), \dots, \exp(-\beta_{i-1}), \exp(-\beta_{i+1}), \dots, \exp(-\beta_k)$
$s_l = \sum_i x_{.i} w_{il}$	Realization of sufficient statistic for α_l
$r = \sum_i x_{vi}$	Raw score of testee S_v
n_r	Number of testees with raw score r
$n = \sum_r n_r$	Testee sample size
\mathbf{r}	Column vector of raw scores of all S_v , $v = 1, \dots, n$
$\mathbf{D} = ((d_{ij}))$	Adjacency matrix of digraph D
q_{gjt}	Dosage of treatment B_j given to all $S_v \in G_g$ up to time point T_t
η_j	Effect of one dosage unit of treatment B_j
$\boldsymbol{\eta}$	Column vector of treatment effects η_j , $j = 1, \dots, p$
τ	Trend effect
ρ_{jl}	Treatment interaction effect $B_j \times B_l$
δ_v	Amount of change in testee S_v
\mathbf{M}	$p \times p'$ -dimensional matrix expressing a H_0 about $\boldsymbol{\eta}$

are required for I_j but not for I_i ; or that changes of item difficulties over time can be explained as the sum of effects of treatments, training, or information given between testing occasions. The LLTM therefore assumes, for all pairs of items, that:

$$\beta_i - \beta_j = \sum_{l=1}^p (w_{il} - w_{jl}) \alpha_l \quad (1)$$

where w_{il} denotes the weight of the basic (or effect) parameter α_l for item I_i . When the difficulty of items is analyzed in terms of their cognitive structure, w_{il} is usually defined either as the number of times cognitive operation O_l is needed to solve I_i or more simply as

$w_{il} = 1$ if O_l is needed for I_i , and $w_{il} = 0$ otherwise. The difficulties of operations needed equally for both items or not needed for either item (implying $w_{il} - w_{jl} = 0$ for $l = 1, \dots, p$) obviously do not influence the difference $\beta_i - \beta_j$ in Eq. (1). In treatment effect studies, typically the weights w_{ij} are the cumulative dosages of the treatments given prior to the testing occasions.

Formally, the LLTM is constituted by the following two equations. First, the RM is defined by:

$$P(X_{vi} = 1 \mid \theta_v, \beta_i) = \frac{\exp(\theta_v - \beta_i)}{1 + \exp(\theta_v - \beta_i)} \quad (2)$$

S_v	Testee (person) number v
T_t	Time point number t
\mathcal{T}_1	Pretest
\mathcal{T}_2	Posttest

for k items I_i , where X_{vi} is the response variable with realizations $x_{vi} = 1$ if testee S_v gives the response “+” to I_i and $x_{vi} = 0$ if S_v gives the response “−” to I_i ; θ_v is the latent ability of S_v ; and β_i the difficulty of item I_i . All item responses are assumed to be locally independent. Parameters θ_v and β_i are defined only up to a common additive normalization constant c .

Second, the following linear constraints are imposed on the β_i :

$$\beta_i = \sum_{l=1}^p w_{il} \alpha_l + c \quad (3)$$

for $i = 1, \dots, k$, with weights w_{il} , basic parameters α_l , and normalization constant c . The weights are considered to be given constants (unless explicitly stated otherwise). Inserting the item parameters according to Eq. (3) into the difference $\beta_i - \beta_j$ obviously leads to cancellation of c and thus yields Eq. (1).

Estimation of the Basic Parameters

Conditional Maximum Likelihood Estimation

The most satisfactory method for the estimation of the basic parameters α_l is the conditional maximum likelihood (CML) method. It maximizes the likelihood of the item response matrix $\mathbf{X} = ((x_{vi}))$, conditional on the testees' raw scores r_v , $v = 1, \dots, n$. This likelihood function is:

$$L_C(\boldsymbol{\beta} | \mathbf{r}) = \left(\prod_r \gamma_r(\boldsymbol{\beta})^{n_r} \right)^{-1} \prod_i \exp(-x_{.i} \beta_i) \quad (4)$$

where $\boldsymbol{\beta}$ denotes the (column) vector of item parameters β_i , \mathbf{r} the vector of testees raw scores, n_r the number of testees with raw score r , $x_{.i}$ the sum of the i th column of \mathbf{X} , that is, $x_{.i} = \sum_v x_{vi}$; and γ_r the elementary symmetric function of order r of the transformed item parameters $\exp(-\beta_i)$, $i = 1, \dots, k$. These well-known functions,

which are of fundamental importance (e.g., in algebra), are defined as:

$$\gamma_r(\boldsymbol{\beta}) = \sum_{\mathbf{y} | r} \prod_i \exp(-y_i \beta_i) \quad (5)$$

where the summation is taken over all possible response vectors \mathbf{y} that are compatible with raw score r , implying $\sum_i y_i = r$.

Inserting constraints (3) into Eq. (4) and rearranging terms:

$$L_C(\boldsymbol{\beta} | \mathbf{r}) = \left(\prod_r \gamma_r(\boldsymbol{\beta})^{n_r} \right)^{-1} \exp(-x_{..}c) \exp\left(-\sum_l s_l \alpha_l\right) \quad (6)$$

with $x_{..} = \sum_i x_{.i} = \sum_r r n_r$ and $s_l = \sum_i x_{.i} w_{il}$. The likelihood in Eq. (6) thus depends on the data only via the s_l (and the n_r , which, however, are considered fixed constants), from which it can be concluded that the s_l are realizations of jointly sufficient statistics for the parameters α_l . Note that L_C actually is independent of the normalization constant c because, by Eq. (5), it holds that $\gamma_r(\boldsymbol{\beta} - c\mathbf{1}_k) = \gamma_r(\boldsymbol{\beta}) \exp(cr)$, where $\mathbf{1}_k$ denotes a column vector of dimension k with all elements equal to 1.

Therefore, $\prod_r \gamma_r(\boldsymbol{\beta})^{n_r} = \exp(-x_{..}c) \prod_r \gamma_r(\boldsymbol{\beta} - c\mathbf{1}_k)$, so that the expression $\exp(-x_{..}c)$ cancels out of Eq. (6), yielding $L_C(\boldsymbol{\beta} - c\mathbf{1}_k | \mathbf{r}) = (\prod_r \gamma_r(\boldsymbol{\beta} - c\mathbf{1}_k)^{n_r})^{-1} \times \exp(-\sum_l s_l \alpha_l)$.

Taking partial derivatives of $\ln L_C$ in Eq. (6) with respect to the α_l , $l = 1, \dots, p$, and setting these derivatives to zero yields the CML estimation equations:

$$\sum_i w_{il} \left[x_{.i} - \sum_r n_r \frac{\gamma_{r-1}^{(i)}(\boldsymbol{\beta}) \exp(-\beta_i)}{\gamma_r(\boldsymbol{\beta})} \right] = 0 \quad (7)$$

for $l = 1, \dots, p$. The functions $\gamma_{r-1}^{(i)}(\boldsymbol{\beta})$, for $r = 1, \dots, k$, denote elementary symmetric functions of order $r-1$ of transformed item parameters $\exp(-\beta_j)$ where, however, the i th parameter $\exp(-\beta_i)$ is omitted; therefore, the arguments of these functions are $\exp(-\beta_1), \dots, \exp(-\beta_{i-1}), \exp(-\beta_{i+1}), \dots, \exp(-\beta_k)$.

A software product specifically designed for CML estimation and hypothesis testing in the LLTM and some of its extensions in LPCM-Win by Fischer and Ponocny-Seliger. It uses recursions for computing the functions γ and, as a fast iterative method for solving the CML equations, the so-called Broyden–Fletcher–Goldfarb–Shanno algorithm.

Some Properties of the Conditional Maximum Likelihood Estimators

It is noteworthy that the CML Eqs. (7) do not involve the person parameters any more; by conditioning on the observed raw scores r_v , which in any RM are realizations of sufficient statistics for the θ_v , the likelihood in Eq. (6) becomes independent of the θ_v , and hence the same holds for Eqs. (7). This property, typical for all RMs, has the consequence that the distribution of the θ_v in the given sample (or in the reference population) is irrelevant. This is only true, however, as long as the raw score distribution in the sample (i.e., the n_r) is considered fixed. There remains the problem, however, that this distribution in samples of size n *does* depend on the Θ distribution of the population from which the testees have been sampled, which influences the information in the sample with respect to the item parameters β_i (and the basic parameters α_l in the case of an LLTM).

A more exact and unequivocal formulation of these important properties of the RM and the LLTM can be based on two results: (1) the uniqueness of the CML estimator in finite samples and (2) its consistency for $n \rightarrow \infty$.

The Uniqueness of the CML Estimator in Finite Samples

For a condensed description of a fundamental property of the item score matrix \mathbf{X} of an RM, the following directed graph (or digraph) D is most serviceable. Assign one-to-one nodes (or vertices) to the k items and define the adjacency matrix $\mathbf{D} = ((d_{ij}))$ by putting $d_{ij} = 1$ if some testee S_v has given the response “+” to item I_i and the response “−” to item I_j and by putting $d_{ij} = 0$ otherwise. Each element $d_{ij} = 1$ is then represented by a directed line from node i to node j , for all $i, j = 1, \dots, k$. The crucial property of \mathbf{X} is whether D is strongly connected. (Efficient algorithms to determine strong connectedness of a digraph are standard instruments of graph theory and thus are not discussed here.)

A sufficient condition for uniqueness of the CML estimator $\hat{\boldsymbol{\alpha}}$ is the following. If D is strongly connected, then a unique (finite) CML estimate (i.e., a unique solution of the CML equations) $\hat{\boldsymbol{\alpha}}$ exists iff the rank of matrix \mathbf{W}^+ is $p+1$, where \mathbf{W}^+ is the matrix \mathbf{W} extended by a $(p+1)$ st column of 1s, $\mathbf{W}^+ = (\mathbf{W}, \mathbf{1}_k)$. If D fails to be strongly connected (i.e., has more than one strong component), the CML estimator $\hat{\boldsymbol{\alpha}}$ still may be unique because a weaker necessary and sufficient (n.s.) condition holds for uniqueness. This n.s. condition, however, is more complicated, involving a set of linear inequalities based on a partial order of the strong components of D . Further details can be found in the book *Rasch Models* by Fischer and Molenaar, Chapter 8.

In complete designs in which each person responds to each item, the probability of obtaining a strongly connected digraph D tends to 1 very fast as n increases, so in practice the uniqueness of the CML estimator depends only on the rank of the extended weight matrix \mathbf{W}^+ . LLTMs in which \mathbf{W}^+ has full column rank are therefore denoted identifiable. It should be noted, however, that in some cases of incomplete designs digraph D may necessarily have more than one strong component, so that the uniqueness question regarding the CML estimator $\hat{\alpha}$ can be decided only by means of the more complicated n.s. condition previously mentioned.

The CML Estimator's Consistency

An important asymptotic result about the CML estimator in the RM is given by Pfanzagl: it states that the normalized estimator $\hat{\beta}$ is consistent iff for $n \rightarrow \infty$,

$$\sum_{v=1}^n \exp(-|\theta_v|) \rightarrow \infty \quad (8)$$

Therefore, the CML estimator $\hat{\alpha}$ in the LLTM is also consistent iff Eq. (8) holds true and \mathbf{W}^+ has rank $p + 1$. Condition (8) rules out degenerate Θ distributions where almost all $|\theta_v|$ are infinitely large, which, by the way, would entail also the violation of the condition of strong connectedness of digraph D . Whenever Eq. (8) is satisfied, however, the particular form of the Θ distribution becomes irrelevant to the question of consistency of $\hat{\alpha}$. Then asymptotic normality of $\hat{\alpha}$ around α , with asymptotic covariance matrix $\hat{\mathbf{V}}$, taken at $\alpha = \hat{\alpha}$,

$$\mathbf{V} = - \left(\frac{\partial^2 \ln L_C}{\partial \alpha \partial \alpha'} \right)^{-1} = - \left(\mathbf{W}' \frac{\partial^2 \ln L_C}{\partial \beta \partial \beta'} \mathbf{W} \right)^{-1} \quad (9)$$

can be proved.

These results hold only, however, if the weight matrix \mathbf{W} , which represents the researcher's hypothesis about the factors causing differences of difficulties between items, is fixed and given. Bechger, Verstralen, and Verhelst point out in 2002 that LLTMs with different weight matrices and different basic parameters may be equivalent (i.e., may yield the same likelihood for any data matrix \mathbf{X} and thus be empirically indistinguishable). They prove a result that is equivalent to the following: Two identifiable LLTMs with weight matrices \mathbf{W}_1 and \mathbf{W}_2 are equivalent iff the columns of either of the matrices \mathbf{W}_1^+ and \mathbf{W}_2^+ lie within the column space of the other, which is equivalent to saying that matrix $(\mathbf{W}_1^+, \mathbf{W}_2^+)$ has rank $p + 1$.

Other Estimation Methods

Two other popular methods of estimation in item response theory (IRT) can also be employed for the LLTM. The first is the joint maximum likelihood (JML) method that maximizes the likelihood of the data as a function of both the basic and the person parameters. A program employing this method for a family of many-facet RMs (including the LLTM) is FACETS by Linacre. An advantage of this approach is its relative simplicity; its disadvantage is the lack of consistency, which, moreover, implies that nothing is known about the asymptotic properties of the estimators. The second method is the parametric marginal maximum likelihood (MML) method, which extends the IRT model by assuming a parametric population distribution of Θ . These parameters are then integrated out of the likelihood, which becomes a function of the item and distribution parameters. The software program ACER ConQuest by Wu, Adams, and Wilson uses this approach. Its advantage lies in the complexity of the models that can be handled; its disadvantage lies in the bias occurring when the unknown Θ distribution has not been specified correctly.

Testing of Fit

Testing the fit of an LLTM comprises two steps. First, it is necessary to ascertain that the RM fits the item score matrix \mathbf{X} . (A state-of-the-art account of methods for testing of fit in the RM is given by Glas and Verhelst.) If the RM does not fit at least approximately, there is no point in attempting to decompose β because then α (and its estimator) would lack an empirical meaning.

Second, if the RM has been found to fit, we may check whether the decomposition in Eq. (3) is empirically valid. In that case, the $\hat{\beta}_i^{(RM)}$ that result from fitting the RM and the $\hat{\beta}_i^{(LLTM)}$ reproduced from the LLTM via Eq. (3) should be the same except for random deviations (assuming in both cases the same normalization). A Pearson correlation can be used as a rough indicator of agreement; however, it has often been seen that such correlations can be quite high (> 0.90), even in the presence of significant model violations. Therefore, a more rigorous test of significance for the null hypothesis represented by Eq. (3) is indicated.

A global test of Eq. (3) under the assumption of the validity of the RM is easily made using (once more) the conditional likelihood function L_C , both under the LLTM (as H_0) and under the RM (as H_1). Denote the respective likelihoods as $L_C(H_0) = L_C(\hat{\alpha} | \mathbf{r}, \mathbf{W}, \mathbf{X})$ and $L_C(H_1) = L_C(\hat{\beta} | \mathbf{r}, \mathbf{X})$; then under H_0 the statistic:

$$\chi^2 = -2 \ln \left(\frac{L_C(H_0)}{L_C(H_1)} \right) \quad \text{with df} = k - 1 - p \quad (10)$$

follows a central chi-square distribution and thus can be used for a conditional likelihood ratio (CLR) test of H_0 . Moreover, there exists a Lagrange multiplier test of the LLTM by Glas and Verhelst.

This CLR test of the LLTM against the RM is quite powerful for detecting departures from the restrictions in Eq. (3). Lack of fit can be caused, for instance, by neglect of some relevant factors (e.g., p too small) or by wrong entries in matrix \mathbf{W} . Researchers may therefore wish to carry out tests of significance for particular elements of the weight matrix \mathbf{W} and, if the model does not fit sufficiently well, make improvements on these elements. Bechger, Verstralen, and Verhelst develop a test for a single element of \mathbf{W} plus a specific method to estimate it empirically. There is a simpler way, however, to achieve the same goal, completely in line with the methods previously presented.

Suppose that w_{ab} is the element of interest. Under H_0 , let $\mathbf{W}_0 = \mathbf{W}$, so that the contribution to the difficulty parameter β_a pertaining to w_{ab} , is $w_{ab}\alpha_b$. Under H_1 , w_{ab} becomes a free parameter ω . To bring the H_1 model, however, back to the form of an LLTM, we replace w_{ab} by $w_{ab}\hat{\alpha}_b + \hat{\alpha}_{p+1}$, where the new parameter α_{p+1} is a correction term. For the estimation of α_{p+1} under H_1 , the weight matrix is:

$$\mathbf{W}_1 = \begin{pmatrix} w_{11} & \dots & w_{1b} & \dots & w_{1p} & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ w_{a1} & \dots & w_{ab} & \dots & w_{ap} & 1 \\ \dots & \dots & \dots & \dots & \dots & \dots \\ w_{k1} & \dots & w_{kb} & \dots & w_{kp} & 0 \end{pmatrix} \quad (11)$$

This model is identified iff the rank of \mathbf{W}_1^+ is $p+2$. The two LLTMs with weight matrices \mathbf{W}_0 and \mathbf{W}_1 may be compared by means of a conditional likelihood ratio test as previously described. If the test is significant, the H_1 model is accepted and the unknown element ω is estimated by means of the estimator $\hat{\omega} = w_{ab} + \hat{\alpha}_{p+1}/\hat{\alpha}_b$. (This requires $\alpha_b \neq 0$, of course; but if $\alpha_b = 0$, the element ω becomes arbitrary and thus cannot be estimated.)

An obvious advantage of this approach is that it applies also to the estimation and testing of two or more independent unknown elements in different rows of \mathbf{W} . A warning to researchers, however, seems to be indicated: such methods entail a considerable danger of overfitting the model.

Relationship to the Bradley-Terry-Luce Model

It is well known that the RM can be regarded as a Bradley-Terry-Luce (BTL) model for the pairwise comparison of testees with items. This BTL model is incomplete by

design because no direct comparisons are made between testees and none between items. The LLTM therefore is also an incomplete BTL, however, with a linear structure embedded in the object parameters; hence, it is denoted linear Bradley-Terry-Luce (LBTL) model. The correspondence between LLTM and LBTL is twofold. First, the unconditional likelihood of any LLTM is the likelihood function of an incomplete LBTL. Second, it can be shown that the likelihood function of any LBTL is the conditional likelihood function of a particular incomplete LLTM, where each testee responds to only $k_v = 2$ items. This equivalence implies several useful results both for the LLTM and the LBTL. Among these are n.s. uniqueness conditions both for the maximum likelihood (ML) estimation in the LBTL and for unconditional (or joint) ML estimation in the LLTM. These n.s. conditions again involve systems of linear inequalities based on the partial order of the strong components of certain digraphs and are, for instance, weaker than the sufficient condition for the LBTL given by Bradley and El-Helbawy.

It is obvious that the LBTL can have many interesting applications both in experimental and applied (e.g., marketing and consumer) psychology. Unfortunately, the potential of this model has so far not been fully recognized in psychometrics.

Fields of Application

Analysis of the Cognitive Complexity of Tasks and Item Generation

The focus of early applications of the LLTM was on the explanation of the difficulty of test items (e.g., in matrix completion tests), of syllogisms, or of tasks from subject matters such as physics, mathematics, and statistics (in school and university education) in terms of their cognitive complexity—the kinds and numbers of cognitive operations or rules that have to be applied to solve a given task. Many references to the first decade of research using the LLTM can be found, for instance, in articles by Fischer and Formann or Spada and May. The rapid development of computer-based testing technologies, especially of adaptive testing strategies, in the last two decades has created an increasing demand for large item banks and has triggered research on item generation principles and techniques. An up-to-date description of these methods is given by Irvine and Kyllonen. Some of this research has built on the LLTM or related IRT models; however, often simpler regression techniques, which do not enjoy the advantageous statistical properties of the LLTM, have been employed.

A frequent problem in applications of the LLTM was that the model failed to fit the data; the likelihood ratio tests specified in Eq. (10) often came out significant,

especially when the LLTM was applied to existing test materials rather than to items that had been constructed strictly on the basis of an appropriate cognitive model. Nevertheless, item difficulty could often be explained at least approximately.

An exemplary early study employing matrix completion items is due to Nährer. First, the basic parameters α_i of the factors underlying item difficulty were estimated using the data of one item sample and one testee sample. Second, a new item sample was constructed and the parameters of the items were predicted based on their cognitive structures, using the estimates $\hat{\alpha}_j$ obtained from the first sample. (Let the predicted item parameters be denoted $\hat{\beta}_i^{(LLTM)}$.) Third, these new items were presented to a new testee sample, from which item parameter estimates $\hat{\beta}_i^{(RM)}$ were derived using the RM. Fourth, a comparison of both sets of estimates, $\hat{\beta}^{(LLTM)}$ and $\hat{\beta}^{(RM)}$, was made, indicating a considerable degree of correspondence. These results can be viewed as an example of a genuine prediction of the difficulty of new items in a new testee sample.

There remains, however, the unsolved question: What is a sufficient approximation of predicted item difficulty? The answer should depend in a complex way on the purpose of the particular LLTM application.

Cross-Cultural Research and Item Bias

A major strength of the LLTM lies in the consistency of the estimator $\hat{\alpha}$ irrespective of the form of the distribution of the person parameters θ_v . This implies that the researcher can carry out a rigorous comparison of the difficulty of cognitive operations or of the application of rules between different populations, such as age groups, gender groups, and cultural groups. In other words, the LLTM is very suitable for testing the generalizability of results over different person populations. Under H_0 , the basic parameters are equal in two (or more) populations of interest, $\alpha_1 = \alpha_2 = \alpha$; under H_1 , they are independent parameter vectors. Therefore, the conditional likelihood under H_0 is $L_C(H_0) = L_C(\hat{\alpha} | \mathbf{r}, \mathbf{W}, \mathbf{X})$, whereas under H_1 it is $L_C(H_1) = L_C^{(1)}(\hat{\alpha}_1 | \mathbf{r}_1, \mathbf{W}_1, \mathbf{X}_1) L_C^{(2)}(\hat{\alpha}_2 | \mathbf{r}_2, \mathbf{W}_2, \mathbf{X}_2)$ (where the indexes 1 and 2 refer to the two populations). H_0 can be tested against H_1 by means of a CLR test statistic analogous to Eq. (10), $\chi^2 = -2\ln(L_C(H_0)/L_C(H_1))$ with $df = 2p - p = p$.

A study of this kind was carried out by Formann and Piswanger already in 1979, described later in English language in an article by Fischer and Formann. A set of matrix completion items was constructed, systematically grounded on a set of rules, and was used for a comparison of the test performance of Austrian and African high school students. The application of the LLTM revealed an unexpected influence of Arabic versus Latin writing habits on the difficulty of these nonverbal

(purely graphical) items, due to their item format. This conclusion was possible irrespective of the fact that the distributions of ability Θ differed significantly between the two populations. A more recent cross-cultural study was done by Tanzer, Gittler, and Ellis.

Obviously, item bias (or differential item functioning) studies are just special cases of cross-cultural studies, as already sketched.

Group-Oriented Analysis of Change

The LLTM has been found to be very useful for the description of change within individuals and to attribute the change to causes such as treatments and training. An illustrative example is a study by Gittler and Glück on the effect of learning mechanical geometry in high school on the development of spatial abilities in male versus female students. An LLTM-based unidimensional model of change assumes that the RM defined in Eq. (2) holds, with virtual item parameters:

$$\beta_{git}^* = \beta_i + \sum_j q_{git} \eta_j + \tau \quad (12)$$

where

- β_i is the difficulty parameter of item I_i ;
- q_{git} is the cumulative dosage of treatment B_j given to individuals S_v of treatment group G_g up to the time point of testing, T_t ;
- η_j is the effect of one unit of treatment B_j (with respect to the latent dimension Θ);
- τ is the trend effect, an effect occurring in all individuals (e.g., the effect of aging or maturation); formally, the trend can be conceived as a treatment given to all individuals with same dosage 1;
- β_{git}^* is the 'virtual' difficulty parameter of item I_i for testees $S_v \in G_g$ at time T_t , which is a result of initial item difficulty β_i plus the cumulative treatment effects up to the time of the testing.

This LLTM-based model of change requires that testees be observed or tested at least twice because otherwise the item difficulty parameters β_i would not be separable from the effect parameters η_j and trend τ . This approach to analyzing change has been seen to be a flexible and powerful tool in the analysis of repeated measurement data.

Individual Change

Suppose the researcher focuses on a single individual S (the index v is omitted for simplicity), and assume that an item pool is available for which a previous calibration study has established the fit of the RM. If S is tested at some time T_1 with an item sample (test) \mathcal{T}_1 taken from that pool, the appropriate model for the item responses is the RM

in Eq. (2), for all items $I_i \in \mathcal{T}_1$. If, subsequently, S 's trait parameter θ undergoes some change (due to treatments given or to development), the appropriate model for S 's responses given to another sample of items from the pool, denoted \mathcal{T}_2 , presented at time T_2 , is still the RM with the item parameters β_i , for $I_i \in \mathcal{T}_2$, however, with person parameter $\theta + \eta$, where η denotes the amount of change in S . The latter RM can be written as:

$$\begin{aligned} P(X_i = 1 \mid \theta, \eta, \beta_i; T_2) &= \frac{\exp(\theta + \eta - \beta_i)}{1 + \exp(\theta + \eta - \beta_i)} \\ &= \frac{\exp(\theta - \beta_i^*)}{1 + \exp(\theta - \beta_i^*)} \end{aligned} \quad (13)$$

with $\beta_i^* = \beta_i - \eta$, for all $I_i \in \mathcal{T}_2$. The reparameterization in the right-hand formula of Eq. (13) has the advantage that, in spite of the change of S 's position on trait Θ , person parameter θ_v in the model is kept constant while change is projected into the virtual item parameters β_i^* . Therefore, both RMs for time points T_1 and T_2 can jointly be considered one RM with item parameters β_i for $I_i \in \mathcal{T}_1$ and $\beta_i^* = \beta_i + \eta$ for $I_i \in \mathcal{T}_2$, with a fixed person parameters θ_v . Clearly, this is a special LLTM.

Assuming that the item parameters β_i have previously been estimated based on a calibration sample of sufficient size, they can now be treated as known constants, so that the model involves only one unknown parameter η (in addition to θ). The person parameter θ can again be conditioned out and η estimated via the CML method, one- or two-sided uniformly most accurate confidence intervals can be computed, and uniformly most powerful unbiased statistical tests can be made (e.g., of the $H_0: \eta = 0$ of no change). Moreover, if pretest \mathcal{T}_1 and posttest \mathcal{T}_2 are presented to many testees, it makes sense to tabulate significance probabilities for all possible score combinations (r_1, r_2) and to use that table without further computations in each individual case. Such tables have been published, for example, in the manual for the Progressive Matrices test by Raven, Raven, and Court.

Reinterpretation as a Multidimensional Model

A Multidimensional Linear Logistic Test Model of Change

A multidimensional reinterpretation of the unidimensional LLTM of change is possible by setting, in Eq. (2), $\theta_v - \beta_i = \theta_{vi}$ and treating these θ_{vi} as multidimensional trait parameters, so that θ_{vi} can be understood as S_v 's position on latent trait Θ_i , $i = 1, \dots, k$. No assumptions are made about whether the k dimensions Θ_i are functionally related, correlated, or independent. Owing to this weakness of assumptions about the underlying

dimensions, the model has been denoted "linear logistic model with relaxed assumptions" (LLRA). Avoiding to specify the true dimensionality is possible because, by virtue of conditional inference methods, estimation and hypothesis testing become independent of the true values of the person parameters θ_{vi} . Under the assumption that the same set of items, I_1, \dots, I_k , is presented to the testees at two time points, T_1 and T_2 , the model can be defined by:

$$P(X_{vi1} = 1 \mid S_v, I_i, T_1) = \frac{\exp(\theta_{vi})}{1 + \exp(\theta_{vi})} \quad \text{for } T_1 \quad (14)$$

$$P(X_{vi1} = 1 \mid S_v, I_i, T_2) = \frac{\exp(\theta_{vi} + \delta_v)}{1 + \exp(\theta_{vi} + \delta_v)} \quad \text{for } T_2 \quad (15)$$

$$\delta_v = \sum_{j=1}^p q_{vj} \eta_j + \tau + \sum_{j < l} q_{vj} q_{vl} \rho_{jl} \quad (16)$$

where

δ_v denotes the amount of change of S_v under the treatment(s) given,

η_j denotes the effect of one dosage unit of treatment B_j ,

q_{vj} denotes the dosage of B_j given to S_v ,

τ denotes a trend effect that is independent of the treatment(s),

ρ_{jl} denotes a treatment interaction effect $B_j \times B_l$.

Eq. (16) can be rewritten without loss of generality as:

$$\delta_v = \sum_{j=1}^{p^*} q_{vj} \eta_j \quad (17)$$

This is possible because the right-hand side of Eq. (16) is a linear function of the effect parameters η_j , τ , and ρ_{jl} : all these $p^* = p + 1 + \binom{p}{2}$ parameters can be denoted by η_j , $j = 1, \dots, p^*$, with accordingly redefined weights q_{vj} , so that Eq. (17) results immediately. The latter is notationally more convenient.

The conditional likelihood function of the two response matrices \mathbf{X}_1 and \mathbf{X}_2 can be shown to be:

$$\begin{aligned} \ln L_C &= \sum_v \sum_i (x_{vi1} - x_{vi2})^2 \\ &\times \left[x_{vi2} \sum_j q_{vj} \eta_j - \ln \left(1 + \exp \left(\sum_j q_{vj} \eta_j \right) \right) \right] \end{aligned} \quad (18)$$

Differentiating this with respect to η_a , $a = 1, \dots, p^*$, and setting the derivatives to zero yields the CML equations:

$$\sum_v q_{va} \sum_i (x_{vi1} - x_{vi2})^2 \left[x_{vi2} - \frac{\exp(\sum_j q_{vj} \eta_j)}{1 + \exp(\sum_j q_{vj} \eta_j)} \right] = 0 \quad (19)$$

for $a = 1, \dots, p^*$. Similarly, the second-order partial derivatives are:

$$\frac{\partial^2 \ln L_C}{\partial \eta_a \partial \eta_b} = - \sum_v q_{va} q_{vb} \sum_i (x_{vi1} - x_{vi2})^2 \times \frac{\exp\left(\sum_j q_{vj} \eta_j\right)}{\left(1 + \exp\left(\sum_j q_{vj} \eta_j\right)\right)^2} \quad (20)$$

which are needed, for instance, to solve Eq. (19) by means of the Newton-Raphson algorithm or to compute the asymptotic information matrix. Both the likelihood function and the estimation equations can be seen to be special cases of those for the LLTM.

Some Properties of the Multidimensional Model of Change

In spite of the multidimensionality of the latent traits Θ_i and, consequently, the large number of person parameters, the CML approach allows us to eliminate all the nk parameters θ_{vi} and thus enables a statistically stable and consistent estimation of the (treatment) effect parameters η_j . Consider, for instance, a clinical depression scale comprising 15 items (psychopathological symptoms) that cannot be meaningfully modeled by means of a unidimensional IRT approach. Suppose further a study design with three treatments and three treatment groups plus a control group. Such a design obviously does not permit us to estimate treatment interactions, so only three treatment effect parameters $\eta_j, j = 1, 2, 3$, and one trend parameter τ are estimable. If the treatment groups as well as the control group consist of 30 patients each, the model comprises $n \times k = 120 \times 15 = 1800$ person parameters plus four effect parameters. It would be hopeless to try to estimate these 1804 parameters jointly, whereas it is a statistically meaningful and feasible enterprise to estimate, by means of the CML method, the four effect parameters alone and to test hypotheses on them.

The price to be paid for this, however, is that, by conditioning on all $r_{vi} = x_{vi1} + x_{vi2}$, all response combinations with $x_{vi1} + x_{vi2} = 2$ or 0 become uninformative (because the respective conditional probability of such pairs of responses is trivially equal to 1) and cancel out the likelihood function. Technically, this is achieved by means of the term $(x_{vi1} - x_{vi2})^2$ in Eqs. (18) and (19), which filters out the uninformative score combinations. Their elimination implies a considerable loss of statistical information, but at the same time drastically reduces the number of parameters to be estimated and on which hypotheses are to be tested.

Conditioning the θ_{vi} out yields also another equally important advantage: for a multidimensional model (e.g., with 15 latent dimensions), it is practically

impossible to ascertain whether a sample of testees (or patients) is representative of a specified population. The present conditional method, however, is not sensitive to the nonrepresentativeness of the sample because the estimator $\hat{\eta}$ is consistent independently of the distribution of the θ_{vi} parameters (again except for certain degenerate distributions). This more than compensates for the disadvantage of the loss of part of the information.

Hypothesis Tests

The main goal in applications of the LLRA is the testing of hypotheses on change or on treatment effects. A general tool for the construction of such tests is the CLR statistic that compares the conditional likelihoods under H_0 and H_1 , assuming that H_1 is true. Consider null hypotheses of the form:

$$\eta = M\alpha \quad (21)$$

where $\eta = (\eta_1, \dots, \eta_p)'$ is the column vector of effect parameters under H_1 ; $\alpha = (\alpha_1, \dots, \alpha_{p'})'$, with $p' < p$, is a column vector of effect parameters under H_0 ; and M is a $p \times p'$ matrix of full column rank. Then asymptotically:

$$\chi^2 = -2 \ln \left(\frac{L_C(H_0)}{L_C(H_1)} \right), \quad \text{with } df = p - p' \quad (22)$$

is a centrally chi-square distributed statistic for testing H_0 against H_1 .

Typical null hypotheses are that (1) a particular treatment effect parameter (or trend) is zero, (2) two or more effect parameters are equal, (3) some or all effect parameters generalize over all items or over certain subgroups of items, and (4) some or all effect parameters generalize over certain subgroups of persons. A software program specifically designed for the analysis of treatment effects using the powerful conditional likelihood approach is LPCM-Win by Fischer and Ponocny-Seliger.

Polytomous Extensions

The models discussed here have been generalized also to polytomous items with ordered response categories. Two cases must be distinguished: (1) if all items have the same categories, then the basic model is a rating scale model (RSM) with a linear structure imposed on the item parameters and (b) if different items may have different response categories, then the basic model is a partial credit model (PCM) with a linear structure embedded in the item \times category parameters. A description of these "linear rating scale models" (LRSMs) and "linear partial credit models" (LPCMs) is given in the book *Rasch Models* by Fischer and Molenaar, Chapter 19, and in more

detailed form in the LPCM-Win manual by Fischer and Ponocny-Seliger. Related models have been suggested by Wilson and Adams as well as by Meiser. Further programs capable of estimating multidimensional LRSMs and LPCMs are FACETS by Linacre and Acer ConQest by Adams, Wu, and Wilson.

Linear Models, Problems

John Fox

McMaster University, Hamilton, Ontario, Canada

Glossary

added-variable plot A diagnostic graph for showing leverage and influence of observations on a regression coefficient.

Breusch–Pagan test A score test for nonconstant error variance (heteroscedasticity).

collinearity (multicollinearity) Strong linear relationships among the columns of the model matrix in a linear model, reducing the precision of coefficient estimates.

component-plus-residual plot A diagnostic graph for non-linearity, plotting partial residuals against an explanatory variable.

Durbin–Watson statistics Test statistics for serial correlation of the errors in a time-series regression.

heteroscedastic-consistent covariance matrix An estimate of the covariance matrix of the least-squares regression coefficients that is consistent even when the error variance is not constant.

high-leverage observation An observation that can exert substantial influence on the least-squares estimates by virtue of its unusual combination of values of the explanatory variables; hat-values are measures of leverage.

influential observation An observation that, when removed, substantially changes the regression coefficients; dfbeta, dfbetas, and Cook's distances are measures of influence.

outlier In a linear model, a value of the response variable that is conditionally unusual, given the values of the explanatory variables; studentized residuals may be used to locate outliers.

variance-inflation factor (VIF) A measure of the impact of collinearity on the precision of estimation of a coefficient.

Despite its broad direct applicability, the normal linear model makes strong assumptions about the structure of the data. If these assumptions are not satisfied, data analysis based on the linear model may be suboptimal or even wholly misleading. The use of linear models in data

analysis should therefore be accompanied by diagnostic techniques meant to reveal inadequacies in the model or weaknesses in the data. In favorable instances, diagnostics that reveal such problems also point toward their solution. Problems that can afflict linear models and least-squares estimation include unusual data, non-normal errors, non-constant error variance, nonindependent errors, non-linear relationships, collinearity, and measurement error in the explanatory variables.

The Normal Linear Model: Structure and Assumptions

Most of applied statistics is based, directly or indirectly, on the normal linear model fit by least squares: linear models for simple and multiple regression, analysis of variance, and analysis of covariance (dummy regression) have broad direct application. Various extensions and generalizations of the linear model—for example, generalized linear models (logistic regression, Poisson regression, etc.), robust regression, additive regression, Cox regression for survival data, linear structural-equation models, linear models fit by generalized least squares—retain central features of the normal linear model. Finally, many kinds of statistical models are fit by adaptations of linear least squares, such as the method of iteratively reweighted least squares (IRLS) commonly employed to fit generalized linear models. In this article, the terms “linear model” and “regression” are used more or less interchangeably.

The normal linear model may be written in matrix form as

$$\begin{aligned} \mathbf{y} &= \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \\ \boldsymbol{\varepsilon} &\sim \mathbf{N}_n(\mathbf{0}, \sigma^2 \mathbf{I}_n). \end{aligned} \quad (1)$$

The variables in Eq. (1) have the following meanings:

- $\mathbf{y} = (y_1, y_2, \dots, y_n)^T$ is a column vector of observations on the response variable.
- $\mathbf{X} = \{x_{ij}\}$ is an $n \times p$ model (or design) matrix of regressors. The regressors comprising the columns of \mathbf{X} may be quantitative explanatory variables, transformations of quantitative explanatory variables, polynomial terms, dummy regressors or other contrasts representing categorical explanatory variables, interaction regressors, and so on.
- $\boldsymbol{\beta} = (\beta_1, \beta_2, \dots, \beta_p)^T$ is a column vector of regression coefficients. Usually, β_1 is a constant or intercept term, in which case $x_{i1} = 1$.
- $\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)^T$ is a column vector of errors. The errors are assumed to be normally and independently distributed, with zero expectations and common variance σ^2 .
- \mathbf{N}_n is the n -variable multivariate-normal distribution.
- $\mathbf{0}$ is a column vector of n zeroes.
- \mathbf{I}_n is the order- n identity matrix.

If the x values are random rather than fixed, then the errors are additionally assumed to be independent of the x values, and the x values are assumed to be measured without error. Fixed values of x occur in experimental research, because the explanatory variables are under the direct control of the researcher; in observational research, the x values are usually construed as random. Assuming that random x values are independent of the errors implies that omitted explanatory variables (which are components of the errors) are independent (or somewhat more weakly, uncorrelated) with the explanatory variables that appear explicitly in the model.

The central task of linear-model analysis is to estimate the parameters of the model—that is, the regression coefficients (the β values) and the error variance (σ^2). Under the model, including the assumption of normality, the least-squares estimate of $\boldsymbol{\beta}$, $\mathbf{b} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$, has a variety of desirable and even optimal properties. This solution implies that the model matrix \mathbf{X} is of full column rank p ; otherwise, the least-squares coefficients \mathbf{b} are not unique. The least-squares residuals are $\mathbf{e} = \mathbf{y} - \mathbf{X}\mathbf{b}$, and an unbiased estimate of the error variance is $s^2 = \mathbf{e}^T \mathbf{e} / (n - p)$.

Diagnostics and Remedies

As mentioned, the normal linear model incorporates strong assumptions about the data, including assumptions of linearity, constant error variance (homoscedasticity), normality, and independence. Linearity follows from the assumption that the average error is zero, for then $E(\mathbf{y}) = \mathbf{X}\boldsymbol{\beta}$. The assumption of linearity is to be broadly construed,

because through transformations, polynomial regressors, and so on, the linear model may incorporate what are conventionally thought of as nonlinear partial relationships. That is, the linear model is linear in the parameters but not necessarily in the explanatory variables.

Not all of the assumptions of the model are checkable. For example, when \mathbf{X} is random, it is assumed that it is independent of the errors $\boldsymbol{\varepsilon}$, but because the least-squares residuals \mathbf{e} are necessarily uncorrelated with \mathbf{X} , the assumption is partly reflected in the estimated model. Certain departures from the assumptions can be detected (such as certain forms of nonlinearity, nonconstant error variance, nonnormality, or serial correlation of the errors), but not a correlation between the errors and a particular column of \mathbf{X} , for example, induced by an omitted (confounding or lurking) explanatory variable. Although there are tests for omitted explanatory variables (such as Ramsey's RESET test), these necessarily make assumptions about the nature of the omission. Likewise, except when there are replicated observations at each unique row of \mathbf{X} , possible departures from linearity are so diverse as to preclude effective, fully general, methods for detecting them.

The consequences of violating the assumptions of the normal linear model range in seriousness from benign to fatal. For example, depending partly on the configuration of the model matrix, moderate violation of the assumption of constant error variance may have only a minor impact on the efficiency of estimation. In contrast, substantial violation of the assumption of linearity suggests that the wrong mean function is fit to the data, rendering the results of the analysis entirely meaningless. Diagnostic methods, which are the focus here, are designed to discover violations of the assumptions of the model and data conditions that threaten the integrity of the analysis. Two general approaches to linear-model problems are numerical diagnostics, including statistical hypothesis tests, and graphical diagnostics. Tests determine, for example, whether there is evidence in the data to reject one or another assumption of the model, or to determine whether there is evidence that particular observations do not belong with the others. Graphical methods seek to reveal patterns that are indicative of problems with either the model or the data, and often are useful in suggesting ways to improve the data analysis, for example, by transformation of the variables or other respecification of the model. The two approaches, numerical diagnostics and graphs, are often complementary—for example, using a test to check a pattern discerned in a graph, or drawing a graph to display numerical diagnostics. The emphasis here is on graphical displays; more information on tests may be found in the literature.

With a few exceptions, space considerations preclude the presentation of examples in this article. Likewise,

the presentation is limited to basic and widely available methods, excluding some newer and more advanced techniques, and the generalization of diagnostics to other kinds of statistical models. Examples, advanced methods, and generalizations are copiously available in the sources cited at the end of this article.

Unusual Data

Least-squares estimates, and other statistics associated with them, such as coefficient standard errors, correlation coefficients, and the regression standard error (standard deviation of the residuals), can be seriously influenced by unusual data. It is useful to distinguish among outliers, high-leverage observations, and influential observations. In the context of a linear model, an outlier is an observation for which the y value is unusual, conditional on the x values. (Thus, a univariate outlier on y or an x need not be a regression outlier.) A high-leverage observation, in contrast, is one that has an unusual combination of x values. Observations that combine outlyingness and leverage influence the values of the least-squares coefficients, in the sense that the removal of such observations changes the coefficients substantially. Other regression quantities, however, can be strongly affected under other circumstances. For example, a high-leverage, in-line observation decreases the standard errors of (some of) the regression coefficients; such an observation may in certain circumstances be regarded as a source of precision in estimation and in other circumstances as providing an illusion of precision. Similarly, an outlying observation at a low-leverage point will not affect the coefficients much, but will decrease the correlation, increase the residual standard error, and increase the standard errors of the coefficients.

Standard numerical diagnostics for outliers, leverage, and influence, along with a graphical method for examining leverage and influence on the coefficients are described in the follow subsections.

Leverage: Hat-Values

The fitted values $\hat{\mathbf{y}}$ in linear least-squares regression are a linear transformation of the observed response variable: $\hat{\mathbf{y}} = \mathbf{X}\mathbf{b} = \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y} = \mathbf{H}\mathbf{y}$, where $\mathbf{H} = \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$ is called the hat-matrix (because it transforms \mathbf{y} to $\hat{\mathbf{y}}$). The matrix \mathbf{H} is symmetric ($\mathbf{H} = \mathbf{H}^T$) and idempotent ($\mathbf{H} = \mathbf{H}^2$), and thus its i th diagonal entry, h_{ii} , gives the sum of squared entries in its i th row or column. Because the i th row of \mathbf{H} represents the weight associated with the i th observed response in determining each of the fitted values, $h_i = h_{ii}$, called the hat-value, summarizes the potential contribution of observation i to the fitted values

collectively, and is a suitable measure of the leverage of this observation in the least-squares fit.

Because \mathbf{H} is a projection matrix (projecting \mathbf{y} orthogonally onto the subspace spanned by the columns of \mathbf{X}), the average hat-value is p/n . By rule of thumb, hat-values are considered noteworthy when they exceed twice (or in small samples, three times) the average value. It is best, however, to examine hat-values graphically—for example, in an index plot (a scatterplot with hat-values on the vertical axis and observation indices on the horizontal axis)—using the numerical cutoffs to aid interpretation of the graph.

Outliers: Studentized Residuals

Although residuals are regarded as estimates of the errors, and although the residuals are the key to outlying observations, it is a sad fact that even when the standard assumptions hold, the least-squares residuals, though normally distributed, are dependent and heteroscedastic: $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - \mathbf{H}\mathbf{y} = (\mathbf{I}_n - \mathbf{H})\mathbf{y}$. In most circumstances, the diagonal entries of \mathbf{H} are unequal and the off-diagonal entries are nonzero. One approach is to standardize the residuals, as $e_i^* = e_i/[s\sqrt{(1-h_i)}]$, but the standardized residuals do not have a simple distribution. The more useful studentized residuals, however, are each t -distributed (under the model) with $n - p - 1$ degrees of freedom: $\text{rstudent}_i = e_i/[s_{(-i)}\sqrt{(1-h_i)}]$, where $s_{(-i)}$ is the estimated standard deviation of the errors computed from a regression with observation i deleted. (There are efficient computational formulas for the studentized residuals that do not require refitting the model, removing each observation in turn.)

Although the studentized residuals are each distributed as t , different studentized residuals are correlated, and there is, moreover, a problem of simultaneous inference when, as is usually the case, attention is drawn to the largest $|\text{rstudent}_i|$. A solution is to employ a Bonferroni adjustment for the outlier test, multiplying the usual two-sided p -value for the biggest absolute studentized residual by the number of observations. It is also helpful in this context to examine plots of the studentized residuals (see Non-Normal Errors, below).

Influence: dfbeta, dfbetas, and Cook's Distances

Although, as noted previously, unusual data can exert influence on all regression outputs, the focus here is on the coefficient estimates. A straightforward approach to the influence of individual observations is to ask how much the coefficients change when an observation is deleted. The change in the regression coefficients attending

the deletion of observation i can be computed without literally refitting the model: $\text{dfbeta}_i = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{x}_i e_i / (1 - h_i)$, where \mathbf{x}_i is the i th row of the model matrix (written as a column vector); dfbeta_{ij} gives the influence of observation i on coefficient j . A standardized version of this statistic, called dfbetas_{ij} , simply divides dfbeta_{ij} by the standard error of b_j .

There are $n \times p$ of each of dfbeta_{ij} and dfbetas_{ij} , and so their examination can be tedious, even in graphs such as index plots. Several similar measures have been proposed to examine the influence of individual observations on the vector of coefficient estimates. The most popular such measure is Cook's distance, $D_i = (\mathbf{b} - \mathbf{b}_{(-i)})^T \mathbf{X}^T \mathbf{X} (\mathbf{b} - \mathbf{b}_{(-i)}) / ps^2$, where \mathbf{b} is the least-squares coefficient vector computed on the full data set and $\mathbf{b}_{(-i)}$ is the coefficient vector with observation i omitted. As in the case of $rstudent$ and dfbeta , Cook's D can be calculated without refitting the model. Cook's distance is invariant with respect to rescaling of columns of \mathbf{X} , and can be conveniently viewed in a graphical display such as an index plot.

Joint Influence: Added-Variable Plots

Single-observation deletion statistics such as dfbeta , dfbetas , and Cook's distances can fail to detect observations that are jointly influential. A good graphical diagnostic that works in such instances, and more generally, is the added-variable plot, also called a partial-regression plot. One such plot is constructed for each coefficient in the model. The collection of p added-variable plots represents projections of the $p - 1$ dimensional regression surface onto a series of planes.

For example, for b_2 , begin by regressing y on all columns of the model matrix excluding the second, $\mathbf{X}_{(-2)}$, obtaining residuals $\mathbf{y}_{(2)}^* = \mathbf{y} - \mathbf{X}_{(-2)}^T (\mathbf{X}_{(-2)}^T \mathbf{X}_{(-2)})^{-1} \mathbf{X}_{(-2)}^T \mathbf{y}$. Then compute residuals for the regression of the second column, $\mathbf{x}_{(2)}$, on the others: $\mathbf{x}_{(2)}^* = \mathbf{x}_{(2)} - \mathbf{X}_{(-2)}^T (\mathbf{X}_{(-2)}^T \mathbf{X}_{(-2)})^{-1} \mathbf{X}_{(-2)}^T \mathbf{x}_{(2)}$ (skipping over the first column of the model matrix, because it is typically a column of ones, representing the regression constant; it is possible to construct an added-variable plot for the constant, but the other coefficients are almost always of greater interest). The added-variable plot graphs $\mathbf{y}_{(2)}^*$, on the vertical axis, against $\mathbf{x}_{(2)}^*$, on the horizontal axis. The least-squares slope corresponding to this scatterplot is the coefficient b_2 from the original least-squares fit, the residuals are the original least-squares residuals e_i , and the standard error of the slope for the simple regression of $\mathbf{y}_{(2)}^*$ on $\mathbf{x}_{(2)}^*$ is (except for degrees of freedom) the standard error of the coefficient b_2 in the original model. The added-variable plot therefore shows the leverage and influence of the observations in determining b_2 , along with the precision of the estimate b_2 . An example is shown in Fig. 1.

Figure 1 Added-variable plot for income in the regression of occupational prestige on the income and educational levels of occupations. This regression has been employed by Duncan (1961) in the construction of a prestige scale for occupations. The two labeled observations, ministers and railroad conductors, serve to decrease the income slope. The least-squares line on the plot represents the regression plane in the direction of income controlling for education.

Non-Normal Errors

Violations of the assumption of normally distributed errors can threaten the efficiency of estimation (for example, in the case of heavy-tailed error distributions) or can compromise the interpretability of the least-squares fit, which estimates the conditional mean of y as a function of the x values (for example, in the case of skewed errors). As explained in the preceding section, least-squares residuals and the errors have some different properties; nevertheless, examining the distribution of the residuals can be informative about the distribution of the errors. Quantile-comparison plots of studentized residuals help in focusing on the tails of the distribution. Such plots graph ordered residuals (usually on the vertical axis) against approximate expected quantiles of a reference distribution—either the normal distribution or the t distribution with $n - p - 1$ degrees of freedom. If the residuals follow the reference distribution, then the plot will be approximately linear. Systematic nonlinear patterns are indicative, for example, of skewed residuals or heavy-tailed residuals. Enhancing the plot with a bootstrapped confidence envelope, computed assuming the truth of the fitted model, provides a visual guide to the extremity of departures from normality; this is illustrated in Fig. 2.

There are several methods for testing departures from normality. One approach is to embed the normal linear model in a more general model that indexes

Figure 2 A t quantile-comparison plot for the studentized residuals from Duncan's occupational-prestige regression. The dashed lines represent a pointwise bootstrapped 95% confidence envelope. The residual distribution looks heavy tailed in comparison with the t -distribution, and one observation (minister) is slightly outside the confidence envelope.

non-normality by one or more parameters. Consider, for example, the Box–Cox regression model:

$$y_i^{(\lambda)} = \beta_1 x_{i1} + \beta_2 x_{i2} + \cdots + \beta_p x_{ip} + \varepsilon_i, \\ \varepsilon_i \sim \text{NID}(0, \sigma^2),$$

where

$$y_i^{(\lambda)} = \begin{cases} (y_i^\lambda - 1)/\lambda & \text{for } \lambda \neq 0, \\ \log_e y_i & \text{for } \lambda = 0, \end{cases}$$

is a modified power transformation (and the y_i are all positive). This model, with parameters $\beta_1, \beta_2, \dots, \beta_p, \sigma^2$, and λ , is estimated by the method of maximum likelihood. A value of $\hat{\lambda}$ significantly different from 1 is indicative of non-normal errors (corrected by the Box–Cox transformation).

Nonconstant Error Variance

Nonconstant error variance (or heteroscedasticity) also threatens the efficiency of least-squares estimation as well as the validity of statistical inference. In principle, it is possible to examine the spread of residuals around the fitted regression surface, but because this usually is a high-dimensional surface, it is, except in the simplest cases, impractical to do so. An alternative is to look for common patterns of nonconstant residual variation. One such pattern is a tendency for residual spread to increase with the level of the response, a pattern that may be discernible in a plot of residuals (for example, rstudent_i or $|\text{rstudent}_i|$) against fitted values (\hat{y}_i).

A simple score test for the dependence of spread on level (called the Breusch–Pagan test, but independently developed by Cook and Weisberg) is to regress squared standardized residuals, $e_i^2/\hat{\sigma}^2$, on the fitted values, where $\hat{\sigma}^2 = \mathbf{e}^T \mathbf{e}/n$ is the maximum-likelihood estimator of the error variance. Half of the regression sum of squares from this auxiliary regression is distributed as chi square with one degree of freedom under the null hypothesis of constant error variance. The test can be extended to other, more general, models for the error variance.

Once discovered, nonconstant error variance can often be corrected by transformation of the response variable. In other instances, weighted-least-squares (WLS) estimation can be employed to obtain efficient coefficient estimates and accurate standard errors. Finally, it is possible to correct the standard errors of the ordinary least-squares estimates for unmodeled heteroscedasticity. A commonly employed approach estimates the covariance matrix of the least-squares coefficients consistently even in the presence of heteroscedasticity:

$$\tilde{\mathbf{V}}(\mathbf{b}) = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}' \tilde{\Sigma} \mathbf{X} (\mathbf{X}'\mathbf{X})^{-1},$$

where $\tilde{\Sigma} = \text{diag}(e_i^2)$. The estimator $\tilde{\mathbf{V}}(\mathbf{b})$ is used in place of the usual $\hat{\mathbf{V}}(\mathbf{b}) = s^2(\mathbf{X}'\mathbf{X})^{-1}$. Discovering the form of nonconstant error variance and taking it into account is advantageous, however, because doing so improves the efficiency of estimation.

Nonindependence

The potential ill effects of nonindependent errors are similar to those of nonconstant error variance. Departures from independence can occur in a variety of ways. Usually, the assumption of independence must be justified by the method of data collection. Common sources of nonindependence include clustered data (for example, hierarchical data, such as data collected on children within schools), longitudinal data collected on individuals over time, and time-series data.

How nonindependence is ascertained depends on the structure of the data. In time-series regression, for example, it is common to examine the autocorrelations of the residuals, where the autocorrelation at lag t is $r_t = \sum_{i=t+1}^n e_i e_{i-t} / \sum_{i=1}^n e_i^2$. Tests for serial correlation in the errors may be based on the Durbin–Watson statistics $D_t = \sum_{i=t+1}^n (e_i - e_{i-t})^2 / \sum_{i=1}^n e_i^2$. The D_t values have a complex sampling distribution that depends on the configuration of the model matrix for the regression, but there are good approximations available for the p -values, which may also be estimated by bootstrapping. Remedies for nonindependence depend on its source. For example, serial correlation of errors in time-series regression may be handled by generalized least-squares

estimation. Likewise, linear and nonlinear mixed-effects models provide efficient estimates for clustered and longitudinal data.

Nonlinearity

Nonlinearity is in a sense the most serious violation of the assumptions of the linear model, because it implies that the wrong equation is being fit to the data. As employed here, “nonlinearity” encompasses all departures from the specified functional form of the model; as mentioned, the linear model of Eq. (1) encompasses specifications that are nonlinear in the explanatory variables but linear in the parameters, such as polynomial regression models, models including interactions, models with dummy regressors, and so on. As with the other problems that have been discussed here, however, nonlinearity can vary in degree from trivial to serious. If there are one or two explanatory variables, nonlinearity can be discerned directly, in a smoothed two- or three-dimensional scatterplot of the data, but the higher dimensional problem is much less tractable.

If combinations of values of the explanatory variables are replicated in the data, then lack of fit can be tested for by contrasting the model fit to the data with a model that simply partitions the observations according to the unique rows of the model matrix. This strategy can be adapted as an approximation in other cases by partitioning the space of the explanatory variables into regions. An alternative general approach is to look for nonlinearity of a particular form, such as a nonlinear partial relationship between the response and each explanatory variable. This approach can be implemented both in graphical diagnostics and in tests.

A frequently useful graphical diagnostic is the component-plus-residual (or partial residual) plot. Suppose that the coefficient β_1 in the linear model is a regression constant, and focus on the partial relationship between y and x_2 conditional on the other x values. The partial residual associated with x_2 is $\mathbf{e}_{2|3,\dots,p} = b_2\mathbf{x}_2 + \mathbf{e}$, where \mathbf{e} is the vector of least-squares residuals and \mathbf{x}_2 is the second column of the model matrix. The component-plus-residual plot is a scatterplot of the partial residuals, on the vertical axis, against the values of x_2 , on the horizontal axis. Smoothing the plot with a nonparametric-regression line aids interpretation. Once the nature of a nonlinear partial relationship between the response and a particular predictor x_j is discerned, it is possible to determine how to model it—for example, by a transformation of x_j or by a polynomial in x_j . An illustrative component-plus-residual plot appears in Fig. 3.

When there are strong nonlinear relationships among the explanatory variables, component-plus-residuals plots can prove misleading. More sophisticated versions of

Figure 3 Component-plus-residual plot for the percentage of women in the regression of occupational prestige on the income level, education level, and percentage of women in 102 Canadian occupations. The dashed line in the plot represents the edge of the regression hyperplane, which is nearly horizontal in the direction of percentage of women. The solid line is for a nonparametric-regression smooth, which suggests a weak quadratic partial relationship.

these diagnostics based on polynomial or nonparametric regression are more robust. Nonlinearity can be tested for in a partial relationship by embedding the linear model in a more general model. For example, the Box–Tidwell regression model includes parameters for the power transformation of one or more predictors. In a similar spirit, the linear model can be replaced with a semi-parametric additive model in which certain terms are modeled nonparametrically, contrasting the fit of this model with the linear model by an approximate incremental F -test. Likewise, if an explanatory variable is discrete, it can be treated as a set of dummy regressors, contrasting the resulting fit with the original linear model.

Collinearity and Other Sources of Imprecision

Consider fitting a linear model in which β_1 is the regression constant. The sampling variance of the least-squares estimate b_2 of β_2 is

$$V(b_2) = \frac{\sigma^2}{(n-1)s_2^2} \times \frac{1}{1-R_2^2}, \quad (2)$$

where σ^2 is the error variance (estimated by s^2 in a application), n is the sample size, s_2^2 is the sample variance of x_2 , and R_2^2 is the squared multiple correlation from the regression of x_2 on the other x variables. Thus, imprecise estimates are the product of large error

variance, small samples, homogeneous explanatory variables, and strong linear relationships among (some of) the explanatory variables, termed collinearity or multicollinearity. The second factor in Eq. (2), $1/(1-R_2^2)$, called the variance-inflation factor (VIF), expresses the harm produced by collinearity. The square root of the VIF is the expansion of the size of the confidence interval for β_2 due to collinearity.

Variance-inflation factors are applicable to one-degree-of-freedom effects, but not, for example, to sets of related dummy regressors or polynomial terms. Write the linear model as follows:

$$y = \beta_1 \mathbf{1} + \mathbf{X}_2 \beta_2 + \mathbf{X}_3 \beta_3 + \varepsilon,$$

where $\mathbf{1}$ is a vector of ones, \mathbf{X}_2 contains the columns of the model matrix pertaining to a particular multiple-degree-of-freedom effect, and \mathbf{X}_3 contains the remaining columns of the model matrix. Then the generalized variance-inflation factor is $\text{GVIF} = \det \mathbf{R}_{22} \det \mathbf{R}_{33} / \det \mathbf{R}$, where \mathbf{R}_{22} is the correlation matrix among the columns of \mathbf{X}_2 , \mathbf{R}_{33} is the correlation matrix among the columns of \mathbf{X}_3 , \mathbf{R} is the correlation matrix for $[\mathbf{X}_2, \mathbf{X}_3]$ (i.e., the full model matrix, omitting the constant regressor), and \det stands for the determinant. The GVIF gives the inflation in the squared (hyper)volume of the joint confidence region for the coefficients in β_2 due to collinearity between the columns of \mathbf{X}_2 and \mathbf{X}_3 .

There are other diagnostics for collinearity (based, for example, on eigenvalue–eigenvector or singular-value decompositions of the model matrix or of the cross-products or correlations among the columns of the model matrix), but variance-inflation factors are particularly easy to interpret. Once collinear relationships are located, they can be explored by regressing one column (or set of columns) of the model matrix on the others. What to do about collinearity is a thornier issue. Unlike most of the other problems discussed in this article, collinearity is usually best understood as a problem with the data rather than with the model: because of strong correlations among the x variables, the data are uninformative about certain partial relationships between the response and explanatory variables. Common approaches to collinearity, such as variable selection and biased estimation, make the problem *seem* to disappear by (often surreptitiously) altering the questions asked of the data.

Measurement Error in the Explanatory Variables

Consider the following regression model:

$$y_i = \beta_1 \xi_i + \beta_2 x_{i2} + \varepsilon_i,$$

where the “latent” explanatory variable ξ is not directly observed (hence the Greek letter); x_2 is directly observed and measured without error; and the regression error ε behaves according to the usual assumptions—in particular, $E(\varepsilon_i) = 0$, and the errors are uncorrelated with each other and with the explanatory variables. To simplify the exposition, but without loss of generality, suppose that all of the variables, y , ξ , and x_2 (along with ε), have means of 0, eliminating the regression constant from the model. Imagine that we have a fallible observable indicator x_1 of ξ ,

$$x_{i1} = \xi_i + \delta_i,$$

where δ is the measurement-error component of x_1 . Suppose further that the measurement errors are “well behaved”: $E(\delta) = 0$; $E(\xi\delta) = 0$ (the measurement errors and “true scores” are uncorrelated); $E(x_2\delta) = 0$ (the measurement errors in x_1 are uncorrelated with the other explanatory variable); and $E(\varepsilon\delta) = 0$ (the measurement and regression errors are uncorrelated).

Under these circumstances, it is not hard to show that

$$\begin{aligned} \beta_1 &= \frac{\sigma_{y1}\sigma_2^2 - \sigma_{12}\sigma_{y2}}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2 - \sigma_\delta^2\sigma_2^2}, \\ \beta_2 &= \frac{\sigma_{y2}\sigma_1^2 - \sigma_{12}\sigma_{y1}}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2} - \frac{\beta_1\sigma_{12}\sigma_\delta^2}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2}, \end{aligned} \quad (3)$$

but that the population analogues of the least-squares coefficients (i.e., the quantities that the least-squares coefficients estimate) are

$$\begin{aligned} \beta'_1 &= \frac{\sigma_{y1}\sigma_2^2 - \sigma_{12}\sigma_{y2}}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2}, \\ \beta'_2 &= \frac{\sigma_{y2}\sigma_1^2 - \sigma_{12}\sigma_{y1}}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2}. \end{aligned} \quad (4)$$

In these equations, the σ values are variances and covariances: for example, σ_{y1} is the covariance of y and x_1 , σ_1^2 is the variance of x_1 , and σ_δ^2 is the measurement-error variance (which supposedly is nonzero). Comparing Eqs. (3) and (4) reveals that the least-squares coefficients are biased as estimators of β_1 and β_2 : because the denominator of β_1 in Eq. (3) must be positive, and $-\sigma_\delta^2\sigma_2^2$ is necessarily negative, the least-squares estimand β'_1 is “attenuated” toward zero.

The bias in β'_2 has a different (and more interesting) characterization: Write $\beta'_2 = \beta_2 + \text{bias}$, where

$$\text{bias} = \frac{\beta_1\sigma_{12}\sigma_\delta^2}{\sigma_1^2\sigma_2^2 - \sigma_{12}^2}.$$

The bias can be in either direction, but as the measurement-error variance σ_δ^2 grows, the least-squares estimand β'_2 is driven toward σ_{y2}/σ_2^2 , which is the population analogue of the least-squares coefficient for the regression of y on x_2 alone. That is, a large measurement-error component in x_1 makes it a weak

statistical control, in effect removing it from the regression equation. Of course, when there are several explanatory variables, all subject to measurement error, the effects are more complex.

What can be done about measurement error in the predictors? Under certain circumstances—for example, when there are multiple indicators of latent explanatory variables—it is possible to derive unbiased estimators that take account of the measurement errors.

Linguistics

Gail R. Benjamin

University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Glossary

dialect A variety of a language, spoken by an identifiable group of speakers or in identifiable circumstances.

ethnography A description of the thought and behavior of a cultural group.

grammar The (finite set of) rules for formulating/describing the (infinite) set of sentences of a given language.

lexicon The set of meaningful units of a language; words, but also smaller and larger units.

phonology The set of sounds and sound categories of a language, and the rules for combining them into words or larger units.

register A variety of language usage patterns, confined to identifiable situations.

Language as observed in action, rather than as patterns divorced from usage, has been of interest as an insight into the nature of language, and also as an insight into social structure, culture, and individual psychology. How language use varies between groups of speakers and in different situations, how it functions in power relationships, and how it changes are studied to gain cultural and psychological perspectives. Social structures can be understood by examining how language is involved in social constructs and how it relates to achieving social coherence.

Individual/Social Nature of Language

Language appears to analysts in two guises: innate knowledge and speech. Language seems to be something that individuals “know” and to suggest an internal,

psychological structuring of knowledge that is self-contained in an individual. Ferdinand DeSaussure, in lecture notes from 1906 to 1911 collected by his students, formulated the distinction between language as the object of study of linguistics, and speech, as behavior in social settings, subject to study by sociologists, historians, and anthropologists. Language is the human faculty to use a particular semiological system, “a system of distinct signs corresponding to distinct ideas Language exists in the form of a sum of impressions deposited in the brain of each member of a community, almost like a dictionary of which identical copies have been distributed to each individual. Language exists in each individual, yet is common to all.” Speech, on the other hand, is behavior, not a faculty. It is characterized by individual will, imperfection, and variation, and is subject to many (linguistically) extraneous social, cultural, physical, and other vagaries.

Many important insights into the structure and nature of languages were gained using this perspective, and the practical work of writing grammars, dictionaries, translations, and teaching materials in numerous languages was made possible by the working assumption that one, or a very few, speakers could provide linguists with a complete sample of the structures of a language, and that all other speakers would be able to understand performance based on the competence-derived grammars of one or a few speakers. This was the traditional approach to the task of gaining knowledge of previously unknown languages, too. One teacher could teach a learner a language.

But the second guise of language is intensely social, and the social nature of language seems to many linguists to pervade all the questions of a linguistics of pure language and languages. Many linguists have found the data of linguistic performance, in all its messiness, to be the only evidence for linguistic competence, the language faculty, and essential to understanding the structure of

language and languages, as those abstract entities are used in the world, and in people's minds. The functions of language, in this view, are a necessary focus for understanding the structure of language and languages.

The nonsocial criterion for sharing knowledge of a language is agreement on what strings, or sentences, are grammatical strings of the language. Thus English speakers are expected to share common judgments of the grammaticality of strings such as *Colorless green ideas sleep furiously* and *Furiously ideas colorless sleep green*. Sharing judgments of grammaticality in this way means that two speakers speak the same language. Many linguists adopt the view that writing a grammar means specifying the rules for isolated grammatical strings. The social criterion for sharing knowledge of a language is mutual intelligibility. In this framework, the ability of speakers mutually to understand strings such as *He didn't give me anything* and *He dint give me nothin'* means that both forms have to be accepted as grammatical strings of the language in question, and the formulation of the rules, or knowledge, of the language must encompass the possibility of both strings, just as the rules must include both *Do you want coffee?* and *Would you like some coffee?* In both cases, social and discourse factors play a role in the formulation of the strings, in their comprehension, and in their acceptability.

Patterned, shared variations in the performance of linguistic features, such as vowel systems, may reduce users' sense of comprehension. Thus American English, in any of its varied forms, may have a vowel system essentially the same as Australian English, but both Australian and American speakers will experience some sense of diminished comprehension when first experiencing the other performance. If language users are able to learn to interpret the different patterns as readily as American and Australian speakers do, then the communities are said to share high levels of mutual intelligibility. A common writing system increases the sense of mutual intelligibility, of the "same language." A number of situations have been observed in which chains of linguistic variation have resulted in intelligibility between near neighbors, but an accumulation of differences prevents intelligibility between far distant communities. Within one geographical community, one social group may claim that another's language is mutually intelligible with theirs, but this claim may be denied by the second group. When they act "as if" they do not understand others, it is difficult to dispute their assertion. In other cases, members of one part of a "monolingual" language community may be able to adjust their linguistic performance so that it is either easily understood by people from a different segment of the community, or so that it is understood with great difficulty, or perhaps not at all.

Beyond the recognition of variables in the feelings of degrees of intelligibility between language communities,

or language users, little work has been done trying to quantify intelligibility, or to evaluate the relative impact of different linguistic factors in contributing to intelligibility or the lack thereof. And anecdotally, speakers have sometimes reported high degrees of comprehension in language communication with other people without any basis for linguistic comprehension at all. If language is considered as the major component of a human communication system, then observing its use in social contexts is an essential method of discovering its communicative resources and structures. Questions of interest to linguists and the social science techniques that have been used to approach each follow.

How Does Language Use Vary between Groups of Speakers?

The earliest modern interest in language variation arose in conjunction with the interest in historical linguistics, the attempts to trace "family trees" of languages and their evolutionary origins. Regional differences were salient and noticeable to the linguists doing this work, and the methods used were targeted surveys of usage in different regions. The preferred sources of data were the oldest, least educated, least mobile speakers that could be found, usually males. There was an emotional tension in scholars between the feeling that newer forms were somehow degenerations from purer forms, and the sense that newer, better, more advanced standard forms were inevitable.

It is generally recognized that regional variations in language use can be found in phonology, lexicon, grammar, and semantics, but it is easiest to collect data about phonological and lexical differences. A few minutes of talk will reveal almost all of the phonetic variation in vowel and consonant systems, especially with a few questions calculated to highlight "interesting" questions: in American English, for example, does a speaker use different vowels in *pin/pen*, *caught/cot*, *merry/Mary/marry*? Are the initial consonants of "we'll" and "wheel" different? Using a word list can quickly elicit words used for common objects. Much more data is needed to establish grammatical and semantic differences. Again, in American English, "any-more" and "whenever" have different meanings in different regions, and the use of multiple modals, "might could," for example, is regionally bounded. These variations could well be absent from short samples of speech.

The notion of dialect has been associated with the social characteristics of the informants providing dialect data: in early research, dialect indicated language use patterns that were nonstandard, provincial, uneducated, and less modern. Both in Europe and the United States, social class and education differences in language use were apparent to

everyone, but these were generally treated as either “good” or “bad” French, English, German, etc.

Studies of a wide variety of speakers in a given region, and in a wide variety of social circumstances, have caused a reformulation of the meaning of the term “dialect.” No longer is it seen as a question of identifying speakers who speak a dialect. Rather, dialect is seen as a tool of speech performance that speakers can use strategically in interactions, both to establish self-identities in interactions, and to manipulate the nature of interactions. Speaking “casually” is part of what makes a situation casual; a sense of self in interaction is signaled by speech performance variables. Situational or identity-marking variation in speech performance is sometimes referred to as register variation, to differentiate it from regional dialect, some aspects of which may be less malleable and less available for strategic interactional use than a speaker’s repertoire of registers.

One of the nonregional factors that correlates with variables in speech performance is gender. Investigations of male and female speech behaviors have endeavored to document differences in the behaviors of males and females, the ages at which they are acquired, the situations in which they are apparent, the implications for the linguistic competence of males and females, and the causes for differences. Do females speak in forms that de-emphasize self-assertion because they are females, or because they usually find themselves in situations in which they have lesser power, and de-emphasis of self is the gender-neutral speech response to such situations? What are the costs and benefits for using male/female speech patterns?

Sociolinguists have focused attention on correlations between ethnicity, class, and linguistic variables; they have been interested in social analysis and the discovery of the role of language behavior in social behavior, as well as implications for understandings of language per se. Linguistic and social constraints on code switching, moving from one language to another, or one marked dialect to another, in the course of the same discourse or the same sentence, have been investigated. When collecting data in more extended formats than word lists, from people who attach social and emotional meanings to speech variations, who are found to vary speech patterns in different interactions and social settings, who are not indifferent to others’ speech, or to their own, the observer effect becomes an evident problem. Mechanically recording speech behavior without the knowledge and consent of the recorded is usually unethical and often illegal.

Various techniques for recording “natural” speech have been developed. First, of course, is the practice of being alert to speech patterns of interest, and writing down instances of their use as they occur in the investigator’s presence. This is feasible if the investigator is present in the community for a long time. A Pittsburgh resident can collect uses of the “it needs painted” construction over

a period of months or years, to determine the scope of the use in grammatical and social terms of this regional variation. Because it is stigmatized in its local environment, recording would usually be done after the interaction.

William Labov, in *Sociolinguistic Patterns*, interested in the distribution of a New York City dialect feature, the omission of “r” in postvocalic positions (“park,” “car,” “guard”), elicited performances of “fourth floor” from a socially stratified sample of New Yorkers by asking employees of (socially stratified) department stores for the location of something Labov knew to be found on the fourth floor. He asked for a repetition of the answer. After each encounter, he recorded the gender, approximate age, and job of the speaker, along with the responses, which could contain from zero to four occurrences of “r.” His report on findings fails to indicate anything about his own speech (New York dialect or not?) or appearance, often taken to indicate class membership. But insofar as the store employees can be assumed in this instance to be speaking with little self-consciousness, the data can be used as “natural” speech.

Another study of New York City speech by Labov was designed to collect large samples of speech from a stratified random sample of New York City speakers, in a wide range of speech styles. Interviews, which were identified as part of an American Language Survey, were conducted at people’s homes. As part of the interview, Labov asked informants to read a six-paragraph story highlighting the linguistic variables he had chosen to measure and to provide quantitative data on linguistic variables. He also asked them to recite “jump-rope” rhymes from their childhood, to tell about a time in their life when they felt they might die, and to read a second story containing words that are distinctive in many American dialects but not always in New York City speech (e.g., dark/dock, source/sauce, chalk/chocolate). Then he asked them to read lists of these pairs of words and to discuss whether the words were the same or not, showing by reading the lists again how they sounded in very careful pronunciation. These tasks were expected to provide some speech samples of careful self-conscious speech, and others of less self-conscious speech. Because the interviews were lengthy and conducted in homes, there were usually interruptions, and talk occurred that was not part of the interview. Telephone calls were made and received, neighbors and children came in and out, and interviewers were offered refreshments and accompanying chitchat.

The overall impression of the quality of talk in all these situations was that each speaker exhibited a wide variety of speech patterns, and much of it seemed very spontaneous and vernacular. Quantitative measurements of speech variables confirmed the impressions. These interviews could not provide samples of the full range of the repertoire of speech performances of any individual speaker, but they did show that recording in itself,

even when it was announced that the subject of interest was the speaker's speech, does not contaminate behavior beyond usefulness.

How Does Language Use Vary in Different Situations?

Ethnography of communication, associated with Dell Hymes and other anthropologists, emphasizes the competence to communicate and interact, involving much more than the formulation of isolated grammatical sentences. The approach also calls into question a narrow understanding of which features of speech performance fall within the scope of analysis. Linguists working in this tradition have looked at socially defined situations, social actions, and the speech performance patterns associated with them. Examples include greetings, narratives, question/answer sequences, prayers, testimonies, riddles, curing rituals, examinations, medical interviews, lectures, compliments, ritual insult duels, political debates, and trials. A complete list of situations and tasks would amount to a complete ethnography of a group. Nonwritten communication has been emphasized, but the approach is also fully compatible with the analysis of written genres.

Hymes formulated a mnemonic for fieldwork, the **SPEAKING** framework, that emphasizes the difference in the research agenda for this approach and for a grammatical strings approach. Communication and language behavior take place in **Settings**, the time and physical attributes of which often influence the behaviors involved. The **Participants** in a communicative event may be present, in different roles (speaker and listener, teacher and student, performer and audience, etc.), or not all co-present (as in the case of the recipient of a letter). Communicative events have **Ends**, both as goals of interactors and as results of interactions. What is communicated has both form and content, and both aspects of these **Acts** should be considered. The overall tone or manner of an interaction is indicated by the term **Key**, whether the event is mock or serious, perfunctory or full, or humorous or not, and similar variations. **Instrumentalities** refer to the channels used (face-to-face speaking, writing, telephone talk, silence, code or open signaling, singing, chanting, whispering, etc.) and to the forms selected from the speaker's repertoire of languages, dialects, registers, and varieties. **Norms** of interaction refer to expected ways of carrying out communicative events and are often detected by reactions when the norms are not followed. Finally, **Genre** refers to emically recognized types of communicative events in the speech community being studied.

The primary method for gathering data for an ethnography of communication is participant observation recorded in written field notes, tape recording, and video recording. Video recording seems the most obtrusive,

but may still be mostly ignored by participants who are caught up in the interaction being recorded. It also provides more data than can be easily analyzed. Sampling problems also must be faced. How many "events," selected on what bases, are needed to describe in order to talk about events in general? What about the numbers and types of members of a speech community who need to be studied in order to talk about the community in general? These issues tend to be dealt with on *ad hoc* bases, in each study or research project. Usually, extensive event-related observation of participants is carried out before tape or video recording is done, so that the ethnographer has a sense of what is normal for such an event and what might be significantly unique in the recorded interaction.

It should be noted theoretically that, in narrow terms, just as a language can be defined as an infinite set of grammatical strings, generated by a limited set of units and rules for combining them, such that ungrammatical strings can be identified but grammatical ones cannot be predicted or exhaustively listed, so communicative competence will lead to communicative performances that are unique, unpredictable, and "grammatical." Thus, a small sample of speakers/actors/events should be sufficient. (Though ethnographers who take the communication competence approach tend to be very wary of the "one or a few" speakers who suffice for grammatical studies, in the narrow sense.) Often, published descriptions present one representative event (or a few) or a composite representation of a type of event.

What Do Users Accomplish through Language?

Conversational analysis, first widely publicized by Harvey Sacks, Emanuel Schegloff, and Gail Jefferson, building on phenomenological approaches to social analysis by Erving Goffman and others, took conversational interaction as a way to understand social order at the most basic microlevel. They took "conversation" as one of the most common, least specified forms of social interaction available for inspection, and considered how participants accomplish this interaction. Their focus was on speech, or language accompanied with the messiness of performance: hesitations, false starts, interruptions, volume changes, speed variations, overlaps, and mistakes. They regarded these as all potentially useful tools in the "construction" of conversational interaction. They also focused attention on the phonological, grammatical, and semantic relations of utterances to preceding ones in interaction. One feature of their approach which differs from the ethnography of communication orientation is that they see themselves as formulating universal understandings of social interaction, and base their analysis as little as possible on individual (social) identities of the interactors,

or cultural variations. They are interested in the competence exhibited by anyone participating in social interaction. This orientation has proved difficult to adhere to; there seem not to be many “anyones” in the social world.

Conversational analysts use two tactics. One is to identify some general (language) interactional activity, such as greetings, ending conversations, asking questions, etc., and to look for the contexts in which these take place, and at what is accomplished, with what language/speech tools. Given the assumption that the competences of interest are very general and very widespread, data is often found in transcribed or recorded interactions originally collected for other purposes. This addresses to some degree the bias that might be introduced by purposive recording of speech interaction. Again, for the competences of interest in this framework, it does not matter who is interacting or being recorded.

The second entrée for conversational analysis is to choose some microphenomenon that recurs in speech, such as the use of proper names or laughter, then to look for its contexts and reasonable explanations of the function, or “work” of the phenomenon. A classic example is Gail Jefferson’s article, “A Case of Precision Timing: Overlapped Tag-Positioned Address Terms in Closing Sequences.” This article first points out that sometimes names or other address terms (“Joe,” “honey,” “sir”) are added to the ends of sentences in English. This use is always optional; it is never required by rules of English grammar. Second, when these forms of address are used, the speech of the addressee often overlaps them; the addressee starts talking before the speaker is finished. And third, such events often happen during the closings of conversations. Jefferson states these as simple general observations, and they seem plausible enough. She then establishes that such overlaps could be either deliberate, and not just the result of quick-paced talk, or accidental. By looking at transcripts of interruptions in speech, she shows that interruptions are not randomly placed, and at least sometimes take place just after the first syllable at which a listener could be sure of the information being conveyed by a speaker in a turn; precision timing is an available tool for talkers. She then offers the following example, a sequence of six turns at the end of a telephone conversation, containing two instances of names attached to the end of utterances, overlapped by the following speech of the addressee:

- Jean: Okay.
 Mel: Okeydoke.
 Jean: Thank you Mel.
 Mel: Thank you Jean.
 Jean: Bye bye.
 Mel: Bye.

Jefferson’s analysis posits that tag-positioned address terms are likely to be overlapped because they are optional

and unpredictable, and because the precise timing of a next turn that follows a completed turn, with no empty time, is one way for interactors to show that they are fully attending to an interaction and thus know when to take their own turn. But address terms are important signals of the relationship between interactors in any situation, given that any individual may be accurately addressed with many different terms. If an address term is used in interaction, it is often (usually?) followed by a responding address term, here validating or questioning the term first used. If an addressee does not hear or ignores the use of an address term, here “Mel,” the understanding of the ongoing relationship offered by the speaker who used it may have been rejected, leaving the user in some doubt about the appropriateness of its use. Or, because it was overlapped, it may just not have been heard. A use of a responding term in the tag position, hear “Jean,” is equally vulnerable to overlapping, as in this case. Jefferson even suggests that not overlapping it, and leaving a potentially silent time, just in case it might be used, would draw undue attention to its (potential) absence. Here, however, Jean’s use of the two-syllable “bye bye” in effect signals that she has heard Mel’s end tag, “Jean,” in spite of its occurring during her own speech, because using two syllables instead of one gives Mel a chance to make his one syllable “bye” match hers, thus achieving the preferred simultaneous ending of conversation. Similarly, Mel’s use of “okeydoke” accomplished the task of establishing that the next turn at the beginning of this excerpt should be Jean’s, because Mel finished last, even though they began simultaneously. What these two conversationalists have accomplished, in this excerpt, is a mutually attentive simultaneous closing incorporating reciprocal namings—not the namings they employed at the beginning of the conversation—and the tools they have employed, from the range offered by their language competence, include precision timing of speech. Conversations, as well as other consequential interactions—interviews, trials, medical examinations, contracts—in this sociological framework are “work” accomplished by speech interaction, and the study of language in use and the structure of language has both linguistic and sociological import.

Penelope Brown and Steven Levinson (in their 1978 *Language Universals: Politeness Phenomena*) have looked at how language use varies as speakers accomplish face-threatening acts (FTAs). Their analysis is both sociological, in defining FTAs and in providing a framework for interactors’ evaluation of FTAs, and linguistic, in looking at the many ways of saying the same thing that natural languages offer. They define “face” as the competing desires of people to be left alone and unimpeded in pursuit of their wants, and to be liked and admired. FTAs occur when one person wants or needs to threaten the “face wants” of another, in making requests or demands, in acknowledging the other or ignoring them,

for instance. Nearly any utterance can be construed as an FTA, even simple statements.

Though most things can be FTAs, not all FTAs are equal. They are distinguished, in Brown and Levinson's framework, by the power relationships of the interactors, by the "social distance" relationship, and by the ranking of the imposition. Some method of measuring each of these is assumed to be collected into a score for the composite FTA, and each score is associated with a set of linguistic devices for appropriately accomplishing the FTA. The following approaches are examples of FTAs:

- *What time is it?*[?] (bald, on record, no mitigating actions).
- *Do you have the time?*[?] (conventional indirectness, literal answer not expected, assumes nice addressee).
- *Pardon me, could you tell me what time it is?*[?] (imposition recognized, past tense distances the action, conventional indirectness in question, assumes cooperation).
- *Excuse me, my watch doesn't seem to be working; could you just tell me what time it is?*[?] (imposition recognized, excuse offered, request minimized (*just*), past tense, conventional question form).
- *How come they don't have any clocks in this building?*[?] (off-record request could be denied, blame for imposition placed on impersonal others, assumption of ability and willingness of hearer to identify need and respond).

Finally, people may decide not to attempt the FTA at all.

Though communicative competence may belong to everyone, observation of the distribution of speech variables strongly suggests that variation in performance is a key to establishing "who" is interacting. To the extent that individuals are involved in ongoing and relatively unchanging social relationships with others, their use of appropriate speech variations may come to be part of their identity and self-identity. What is required to establish this phenomenon is observation of many individuals in one role, and one individual in a number of roles. One outstanding example of work in this vein is Leslie Milroy's Belfast work, reported in 1980 in *Language and Social Networks*. After collecting recorded speech samples from casual conversations in natural settings from an undisclosed number of speakers, Milroy chose the speech of 23 men and 23 women, from three communities, and two age groups each, for careful analysis of a correlation of speech variables with social variables. (This is a small sample in sociological practice, but a large sample in sociolinguistic/linguistic practice.) The eight linguistic variables chosen for analysis were each cast in terms that were amenable to quantitative analysis. For variations in vowel quality, a continuum was established between two extremes of variation, and a speaker's performance was placed at a point on the continuum; three to five point

scales were used. For features that are more or less dichotomous, percentage scores were used (e.g., to indicate how often lip rounding was used in monosyllables containing the vowel [ʌ], as in *hut*, *mud*). Linguistic variables are commonly quantified in these ways, but care must be taken with specifying the linguistic context.

In Milroy's case, the sociological variables of interest were gender, age, community, and social network. Milroy was able to establish a six-point scale for network multiplexity and density for all of the 46 individuals. (One point was given for each of the following variables: membership of a high-density, territorially based cluster; kinship ties in the neighborhood; working at the same place as at least two others from the same area; working at the same place as at least two others of the same sex from the area; and voluntary association with workmates in leisure hours.) Individual scores covered the full range of the scale. Each speaker's performance could be correlated, for eight variables, with gender, age, community, and network score. The findings of significant associations showed that different variables were associated with different features of social identity, some with gender, some with age, some with community, and some with network scores. In one community, for instance, though men were found overall, compared to women, to use more vernacular forms, they also had higher network scores compared to women overall, but women's use of vernacular forms also correlated with their network scores.

Milroy suggests that the use of these variables (assumed to be under speakers' control, if not in their awareness) by individuals is best understood as tools for signaling different aspects of social identity: women in one community, for instance, may use vernacular forms less often than men do, this difference being a gender marker, but the women still use some forms that differentiate their community from others, exhibiting community loyalty. The particular vernacular forms that are correlated with network scores may vary from community to community. Milroy's work suggests, as does work by other sociologists and linguists, that dense, multiplex networks operate as norm enforcement mechanisms. A speaker's choices from variables exhibits social identity features and enacts social identity roles, an explanation for the persistence of nonstandard stigmatized forms. What speakers accomplish through the use of language can thus be seen to encompass both short-term social interactions, such as conversations and FTAs, and long-term social roles, identities, and relationships.

How Does Language Function in Power Relationships?

Ethnography of communication and conversational analysis tends to exhibit an orientation to language use as

individually motivated, and as a cooperative enterprise of those involved in a speech situation, but it is also possible to view the conventions and practices of language usage as much less benign and more coercive. Instead of seeing an interview as a joint elicitation/production of information sharing, it is possible to see the interview as antagonistic efforts to shape or manipulate the information that forms the basis for following action. Thus the interview becomes an occasion and an instance of a power relationship, not a cooperative one. Conversations or narratives or question/answer sequences, or curing rituals or trials or any other speech events, can be similarly construed.

Looking at interactions between people who are clearly unequal in power—questioning of suspects or witnesses in legal disputes, talk between doctors and patients, discussions directed by teachers—shows how the power to accept or reject replies or information offered by the powerless, to shape the flow of information, culminates in events that usually reaffirm the prevailing power relationships and ideology. Because there is no one-to-one relationship between linguistic formulations and the real world, choosing formulations is an attempt to manipulate perceptions of the world and actions, available in principle to all language users and demonstrably used by both the powerful and the powerless (*My jacket got lost; The computer crashed; I'm in a bad mood*). But the powerful have more power to coerce compliance with their formulations, and their formulations are used to enhance their power. The more powerful speaker often interrupts, cuts off talk by the other, rephrases contributions of the less powerful, proceeds as though the less powerful had accepted the offered interpretation of events or information, or coerces agreement under threat, open or implied. The methodology used here, as in much of linguistic analysis, is to look at events of language usage (or transcriptions more or less rich), and to ask of each element of the event what set of alternatives it was chosen from, then to set forth the effects or results of the particular choices made, validated by comparison with the effects in other instances of use.

How Does Language Structure Enable Users to Achieve Coherence?

Language is used for sharing both intellectual (*There is a herd of deer over the next hill*) and phatic/social (*Dr. White, how are you?*) meaning. There are formidable barriers to communication in both spheres, stemming from the nonexistent one-to-one relationship between world states and talk about the world, and from issues of intentions of speakers and listeners. Linguistic utterances proceed in a one-after-another fashion, and incorporate structures to facilitate all parties attending to the

same world states and phatic/social states during a linguistic interaction. Analysis that looks for the phonological, grammatical, and semantic features that play a role in this coordination commonly adopts two strategies.

Sometimes a set of linguistic exchanges is searched to catalog the occurrences, and a rationale is sought for their appearances in those places. Thus in *Discourse Markers*, Deborah Schiffrin's investigation of the word "oh" in American conversation began with proposed identifications of contexts for "oh." One such identification was that "oh" is used when one speaker requests clarification from another of something contained in a previous turn. This is the use in Val's first utterance:

- Freda: Sometimes he got a notice for staying out past curfew. Recently. In August, that was.
 Val: Oh curfew? What's curfew?
 Freda: A certain time that children have to be in.
 Val: Oh your children. Oh I see. Oh it's personal. Oh I . . . I thought there might be police or something.

In Val's second utterance she signals with "oh" each element of her understanding of the clarification offered by Freda, and her own new understandings of the situation Freda is talking about. Such enumeration of new understandings enables both parties to continue with relative assurance that mutual comprehension is available as the basis for further talk. Counts of the occurrences of "oh" in the large corpus studied show that it occurred in 11% of environments analogous to Val's first use (so it is not the only device available for this task), that it never occurred in contexts like Freda's response, and that it occurred in 41% of contexts like Val's last utterance. Similar specification of contexts proceeds until there are no more anomalous occurrences of the item under investigation.

The range of variations that can be studied this way is large. Examples are changes in language or register, use of particular grammatical forms (passives or other rhetorical devices), changes in voice quality, use of feedback or echoing devices, repetitions of previous speakers' talk, puns, manipulation of deictic markers, proverbs, and conventional summaries.

Alternatively, an environment is specified, and data are searched to find different devices used. Thus, one speaker's questions may be the environment, and it can then be determined what follows the questions (usually, but not always, an answer, not always in the same forms).

How Do Users Employ Language to Construct Social Structures?

Talk about the real world is subject to many manipulations outside the truth/falsity framework. In talk, the answers

to questions concerning whether a reference to the world will be made now, what aspects of the world will be mentioned, what kind of reference will be made, and what recipients will do with it will be made in the context of the current state of interaction, and will in turn influence the subsequent states and talk. That talk then becomes a feature of the interactional world within which speakers act.

William Hanks, in *Referential Practice: Language and Lived Space among the Maya*, has provided a linguistically and anthropologically complex analysis of everyday and ritual speech patterns that reflect and enact sociocultural realities. Deictic features in languages are the ones that establish interactors and referents in time and space, absolutely and with regard to each other. They are pervasive and unobtrusive. Tenses, pronouns, and demonstratives are included in this category. One interaction analyzed by Hanks is given here:

tiʔ e kàanal k-im-b'èetik aʔ → káʔa p'ée sùurko kén u-b'i seh →
 "In this ditch I'm making two rows it will take,

ump'é téʔel a → ump'éé téé bey aʔ →
 one right here (pointing), one like this here (pointing).

káʔa øol pak'aál kén in-ǵááeh
 Two rows of plants will I put (there)."

This talk was produced by DP when DP, VC, and WH were engaged in digging an irrigation ditch. WH was loosening soil with a pickax, VC was shoveling the dirt out of the way, and DP was sitting on the ground watching them. Nevertheless, it is DP who uses the first-person singular pronoun "I" in "I'm making" and "I will put." He is the father of VC, the leader of the work team and of all economic activity they undertake together, and it is appropriate for him to use this form about an activity being carried out by others. But it would not have been inappropriate for him to use "this ditch you're making" or "this ditch we're making" either. Though the content of the three forms is different, each is an acceptable one (no one objected, or even particularly noticed) only in the context of a set of social understandings that validates DP's ownership of work done by others, and his position as the focal point of the collectivity he heads. In other contexts, he is also treated in this way: an inquiry about "how is DP?" on another occasion produced information about various people in DP's homestead.

The Maya language includes a number of terms that translate into English as "here" and "there." In this talk, DP had available two appropriate forms, "téʔel a" and "téʔel o," both used in shared perceptual, spatial, and actional frames. But "téʔel a" is better used for information that is not shared by all participants, and the information was new to WH, though not to VC. DP thus claims the information as his, and indicates that it is addressed

to WH, not VC, though VC is also a full participant in the work and the talk about it. A little later, DP was standing very close to VC, watching him dig a hole for a bush. He pointed to the side of the hole and told VC to enlarge the hole:

tían téé xčík'in oʔ →
 "There's where it is there on the west."

Here DP uses a nonimmediate deictic, "there," even though what he is indicating is closer to him and to VC than the referent of "here" in the previous example. (Note also the cardinal direction used, "on the west" for a point about a meter from the speaker and addressee.) This utterance also includes the particle, "tían," which indicates previous mention of the referent, the hole, though it was not talked about in the immediately preceding exchanges. The utterance thus places the activity in VC's space, nonimmediate to DP, but also acknowledges the shared background knowledge about the activity common to VC and DP. The very ordinarieness of these exchanges emphasizes the nature of the real-world situation as a creation of interactors, speakers in ongoing talk. Deictic features are a general feature of all human languages, and nowhere is their use any more straightforward than in these examples.

George Lakoff's work, notably in *Women, Fire and Dangerous Things*, has shown that metaphor is among the most pervasive ways of structuring information in talk (and thought), and the use of cohesive devices in talk strengthens its role. Cohesive devices for demonstrating comprehension of ongoing talk include repetitions and extensions of a metaphor in following talk. These lead to more and more talk adopting the same line of thought, reinforcing the metaphor. An example from English concerns the conceptions of time. Lakoff contends that talk (and thought) in English incorporates two underlying notions of the nature of time. One is that time is a thing—it is formally a noun and can be used with active verbs—that it is in front of us, and that it is moving toward us. English habitually treats things in front of us as having a face, and as facing us, as people most commonly do in conversation. Thus if a person, a ball, and a table are in a row, English speakers will most often say that the ball is in front of the table, not behind the table, as though the table were "facing" the speaker. This is not the habitual formulation of speakers from speech communities who ordinarily do not converse face to face, but commonly talk side by side, looking in the same direction. For them, the ball would be characterized as behind the table, because the table is "facing" the same direction as the speaker.

Because time is facing English speakers, it is moving toward the speaker. It is this pervasive metaphorical framework that makes English speakers accept formulations such as "we look ahead to the next season,"

“it’s behind us now,” “in the following weeks,” “in the preceding months,” and so on. When speakers participate, over and over, in ongoing talk utilizing this metaphorical set, the argument goes, they come to conceptualize time in this way. They may also entertain other frameworks, such as the cyclical one of “thank God it’s Friday” or “every summer we go to the beach,” or the time travel framework of science fiction, and when these are invoked, speakers also structure subsequent talk and thought. Thus both the social world and the real world in which it exists are structured for speakers by forms of talk about them.

How Do Language Use and Language Change?

Two modern insights have provided linguistics with a way to deal with language changes. First is the notion of rule change emphasized in Chomsky’s linguistics. Thus the set of changes exemplified in the correspondences between *pater/father*, *tres/three*, *canus/hound*, where in each case, a stop in Latin (p, t, k) corresponds to a fricative in English (f, th, h), can be accounted for if we posit a rule change that says “change a stop (in specified contexts) to a fricative at the same point of articulation.” (This rule change must have happened before English began borrowing words from Latin, at some point when the Germanic languages as a whole diverged from Proto Indo-European in a different way than the Latin family developed.) Rule changes are internal to a speaker’s language competence, and can account for changes in language behavior in a holistic and plausible way. The alternative is to imagine whole communities somehow “missing the target” of their ideal notion of a large set of words in their performance. Especially because English (Germanic) retained “p” in other contexts, this is not a very convincing picture. The question remains as to why would anyone, or any community, come up with such a rule change. Language change, in general, imposes costs in communication, between generations and between communities, so there would seem to be strong pressures to minimize change. In terms of linguistic competence, or the language faculty, nothing is gained by language change (except for vocabulary enlargement).

A groundbreaking study by William Labov (in *Sociolinguistic Patterns*) showed how linguistic change could be observed in a time period amenable to observation, and provided a motivation for a rule change. Labov noticed that speakers living on Martha’s Vineyard, an island off the coast of Massachusetts, were using a different vowel in certain contexts than had been recorded only 30 to 40 years earlier in a dialect survey. The vowel change involved the diphthongs /ai/ and /au/,

as in the words “knife” and “life” and “about” “house.” In each case, the first part of the diphthong was centralized, starting at a position closer to /ə/ than to /a/. The change can be specified in linguistic terms as a rule change, operating in certain environments. The costs of the rule change in terms of intelligibility are small; English speakers tolerate wide variations in the realization of vowels, but it is noticeable. It is not evenly distributed over the whole population of Martha’s Vineyard speakers. The speakers who showed the sound change were among those who most strongly held as part of their personal identity a sense of themselves as Vineyarders, different from other Massachusetts residents, or other Americans. These others were typically encountered in the form of rich vacationers who summer on the island, and until recently they tended to come from Boston. When dialect data from the 1940s were collected in New England, Boston speakers widely used the rule calling for deletion of the postvocalic “r.” Martha’s Vineyarders did not use this rule, and were linguistically distinct in this way from other New Englanders. Over the course of 30 years, Bostonians, like other “r” deleters in the United States, were influenced by nonlocal prestige speech patterns to abandon this rule, to become “r”-speakers. This made their speech less different from that of Vineyarders. Labov proposed that the vowel change he observed was adopted to preserve a linguistic distinction by those Vineyarders who did not want to be absorbed into a larger sociolinguistic entity. He also observed that a personal decision to be a Vineyarder entailed a decision to remain poor, to forgo the economic benefits that came from leaving the island community. Thus “prestige,” if it is to be invoked as a motivation for linguistic modeling, must be construed in local, nonobvious forms.

Variation is now seen as either a change in progress or as a manifestation of sustained diversity within a speech community. Increasing social complexity is expected to be accompanied by increasing linguistic diversity, and universal movement to “standard” forms of a language is no longer expected. The explanations of language change are both linguistic and sociological in nature.

Literacy, Mathematical

Jan de Lange

Utrecht University, Utrecht, The Netherlands

Glossary

assessment (educational) A method for determining how well students are learning; provides feedback to students, educators, parents, policymakers, and the public about the effectiveness of educational services.

competencies (mathematical) Processes that students apply as they (attempt to) solve problems. Aspects of mathematical competencies are organization of knowledge, problem representation, connecting the real world with mathematics (mathematization), metacognition, use of different strategies, and contributions to group problem-solving, but also knowledge of basic facts, mathematical language, and procedures.

context The specific setting, within a situation, of an assessment item. An important aspect in measuring mathematical literacy is inclusion of a variety of situations.

mathematical literacy An individual's capacity to identify and understand the role that mathematics plays in the world, to make well-founded judgments, and to engage in mathematics in ways that meet the needs of that individual's current and future life as a constructive, concerned, and reflective citizen.

mathematics The science of structure, order, patterns, and relations that has evolved from the practices of counting, measuring, and describing the shapes of objects.

Mathematical literacy has evolved as a subject for discussion because of a growing awareness that we are increasingly surrounded by numbers and data, but that we fail to reason and think about these in a sensible way. Fundamental questions about this subject concern identifying the ingredients of mathematical literacy, how the capacity to be literate is related to mathematics, the essential competencies needed to be mathematically literate, the role of literacy in real-world contexts, and how to measure mathematical literacy, especially in large-scale assessments.

Introduction

According to a widely accepted definition, mathematical literacy is an individual's capacity to identify and understand the role that mathematics plays in the world, to make well-founded judgments, and to engage in mathematics in ways that meet the needs of that individual's current and future life as a constructive, concerned, and reflective citizen. This definition is widely accepted, in part because it comes from the Organization for Economic Cooperation and Development/Program for International Student Assessment (OECD/PISA) study in 2003, which was supported by the 29 OECD countries and by a number of other countries, and in part because the definition is quite comprehensive.

Innumeracy, or the inability to handle numbers and data correctly and to evaluate statements regarding problems and situations that invite mental processing and estimating, is a greater problem than our society generally recognizes. "Fixing" this problem, however, requires dealing with several issues: from a mathematical perspective, how do we define literacy? Does literacy relate to mathematics (and to what kind of mathematics)? What kind of competencies are we looking for? And how do we measure mathematical literacy?

Mathematical Literacy

Before trying to understand what knowledge of mathematics is important, it seems wise first to look at a "comfortable" definition of quantitative literacy (QL). Lynn Arthur Steen pointed out that there are small but important differences in the several existing definitions and, although he did not suggest the phrase as a definition, referred to QL as the "capacity to deal effectively with

the quantitative aspects of life.” Indeed, most existing definitions Steen mentioned give explicit attention to numbers, arithmetic, and quantitative situations, either in a rather narrow way, as in the National Adult Literacy Survey, or more broadly, as in the International Life Skills Survey. The National Adult Literacy Survey, conducted by the National Center for Education Statistics (NCES), narrowly defines QL as “the knowledge and skills required in applying arithmetic operations, either alone or sequentially, using numbers embedded in printed material (e.g., balancing a checkbook, completing an order form).” The International Life Skills Survey (ILSS) broader definition of QL is “an aggregate of skills, knowledge, beliefs, dispositions, habits of mind, communication capabilities, and problem solving skills that people need in order to engage effectively in quantitative situations arising in life and work.”

These definitions emphasize quantity. Mathematical literacy is not restricted to the ability to apply quantitative aspects of mathematics, but also involves knowledge of mathematics in the broadest sense. Spatial literacy can also be defined—it deals with aspects such as map reading and interpretation; spatial awareness; “grasping space;” and understanding a range of things, such as great circle routes, plans for a new house, patterns, distances, scale, symmetry, and so on. All kinds of visualization of data belong also to the literacy aspect of mathematics and constitute an absolutely essential component for literacy.

Against this background of varying perspectives, the most recent and widely spread definition of mathematical literacy is broad but also rather “mathematical.” As stated in the OECD/PISA 2003 assessment, “Mathematics literacy is an individual’s capacity to identify and understand the role that mathematics plays in the world, to make well-founded judgments, and to engage in mathematics in ways that meet the needs of that individual’s current and future life as a constructive, concerned and reflective citizen.” This definition was developed by the Expert Group for Mathematics of PISA. There is some confusion, as indicated previously, about the boundaries of the definitions. For instance, some equate numeracy with quantitative literacy, whereas others equate quantitative and mathematical literacy. It is thus helpful to discriminate between different aspects of literacy in relation to mathematics, i.e., spatial literacy, numeracy, quantitative literacy, and mathematical literacy:

1. Spatial literacy (SL) is the simplest and most neglected aspect of literacy in relation to mathematics. SL supports our understanding of the (three-dimensional) world in which we live and move. To deal with what surrounds us, we must understand properties of objects, the relative positions of objects, and the effect thereof on our visual perception; this involves the creation of all kinds of two- and three-dimensional paths and

routes, navigational practices, shadows—even the art of Escher.

2. The next obvious literacy is numeracy (N), fitting as it does directly into quantity. Most definitions stress the ability to handle numbers and data and to evaluate statements regarding problems and situations that invite mental processing and estimating in real-world contexts.

3. When we look at quantitative literacy, we are actually looking at literacy dealing with a cluster of phenomenological categories: quantity, change and relationships, and uncertainty. These categories stress understanding of, and mathematical abilities concerned with, certainties (quantity), uncertainties (quantity as well as uncertainty), and relations (types of, recognition of, changes in, and reasons for those changes).

4. We think of mathematical literacy (ML) as the overarching literacy comprising all others.

It goes without saying that every definition of mathematical literacy will have its shortcomings and that different scholars put different emphasis on the aspects of mathematical literacy. Some, for instance, stress the fact that an approach to mathematical literacy must never lead logically to the conclusion that only the expert can be mathematical literate: it is an obvious condition of mathematical literacy, and literacy in general, that it be directed toward and attainable by the greater part of society. This seems certainly a valid observation for the aforementioned OECD study.

Discussion

In an interview in *Mathematics and Democracy*, Peter T. Ewell was asked the following question: “*The Case for Quantitative Literacy* argues that quantitative literacy (QL) is not merely a euphemism for mathematics but is something significantly different—less formal and more intuitive, less abstract and more contextual, less symbolic and more concrete. Is this a legitimate and helpful distinction?” Ewell answered that indeed this distinction is meaningful and powerful. The answer to this question, however, depends in large part on the interpretation of what constitutes good mathematics. We can guess that in Ewell’s perception, mathematics is formal, abstract, and symbolic—a picture of mathematics still widely held. Ewell continued to say that literacy implies an integrated ability to function seamlessly within a given community of practice. Functionality is surely a key point, both in itself and in relation to a community of practice, which includes the community of mathematicians. Focusing on functionality gives us better opportunity to bridge gaps or identify overlaps. In the same volume, Alan H. Schoenfeld observed that in the past, literacy and what is learned in mathematics

classes were largely disjointed. Now, however, they should be thought of as largely overlapping and taught as largely overlapping. In this approach, which takes into consideration the changing perception of what constitutes mathematics, mathematics and mathematical literacy are positively not disjointed.

For Schoenfeld, the distinction most likely lies in the fact that, as a student, he never encountered problem-solving situations, that he studied only “pure” mathematics and, finally, that he never saw or worked with real data. Each of these real-world approaches is absolutely essential for literate citizenship, but none even hints at defining what mathematics is needed for ML, at least not in the traditional school mathematics curricula descriptions of arithmetic, algebra, geometry, and so on. Again, in *Mathematics and Democracy*, Wade Ellis, Jr. observed that many algebra teachers provide instruction that constricts rather than expands student thinking. He discovered that students leaving an elementary algebra course could solve fewer real-world problems after the course than before it: after completing the course, they thought that they had to use symbols to solve problems they had previously solved using only simple reasoning and arithmetic. It may come as no surprise that Ellis promotes a new kind of common sense, i.e., a quantitative common sense based on mathematical concepts, skills, and know-how. Despite their differences, however, Schoenfeld and Ellis seem to share Treffers’ observation that innumeracy might be caused by a flaw in the structural design of instruction.

These several observers seem to agree that, in comparison with traditional school mathematics, ML is less formal and more intuitive, less abstract and more contextual, and less symbolic and more concrete. ML also focuses on reasoning, thinking, and interpreting, as well as on other very mathematical competencies. To get a better picture of what is involved in this distinction, it is first necessary to describe the “elements” needed for ML. With a working definition of ML and an understanding of the elements (or “competencies,” as they are described in the PISA framework) needed for ML, we might come closer to answering the original question (what mathematics is important?) or formulating a better one.

What Is Mathematics in Relation to Mathematical Literacy?

To provide a clearer picture of literacy in mathematics, it seems wise to reflect for a moment on what constitutes mathematics. There is no intention here to offer a deep philosophical treatment—there are many good publications around—but it is not unlikely that many readers might think of school mathematics as representing mathematics as a science. Several authors in *Mathematics and*

Democracy clearly pointed this out quite often, based on their own experiences (Schoenfeld, Schneider, Kennedy, and Ellis, among others). Lynn Steen (observed in *On the Shoulders of Giants: New Approaches to Numeracy*) that traditional school mathematics picks a very few strands (e.g., arithmetic, algebra, and geometry) and arranges them horizontally to form the curriculum: first arithmetic, then simple algebra, then geometry, then more algebra, and, finally, as if it were the epitome of mathematical knowledge, calculus. Each course seems designed primarily to prepare for the next. These courses give a distorted view of mathematics as a science, do not seem to be related to the educational experience of children, and bear no relevance for society. A result of this is that the informal development of intuition along the multiple roots of mathematics, a key characteristic in the development of ML, is effectively prevented. To overcome this misimpression about the nature of mathematics created by such courses, we will try to sketch how we see mathematics and, subsequently, what the consequences can be for mathematics education.

Mathematical concepts, structures, and ideas have been invented as tools to organize phenomena in the natural, social, and mental worlds. In the real world, the phenomena that lend themselves to mathematical treatment do not come organized as they are in school curriculum structures. Rarely do real-life problems arise in ways and contexts that allow their understanding and solutions to be achieved through an application of knowledge from a single content strand. If mathematics is viewed as a science that helps solve real problems, it makes sense to use a phenomenological approach to describe mathematical concepts, structures, and ideas. This approach has been followed by Freudenthal and by others, such as Steen. They state that if mathematics curricula featured multiple parallel strands, each grounded in appropriate childhood experiences, the collective effect would be to develop among children diverse mathematical insight into the many different roots of mathematics. Steen then suggested that we should seek inspiration in the developmental power of five deep mathematical ideas: dimension, quantity, uncertainty, shape, and change. The OECD/PISA mathematics expert group has adapted these, creating four phenomenological categories to describe what constitutes mathematics: (1) quantity/space, (2) shape/change, (3) relationships, and (4) uncertainty. Using these four categories, mathematics content can be organized into a sufficient number of areas to help ensure a spread of items across the curriculum, but also a small enough number to avoid an excessively fine division, which would work against a focus on problems based in real-life situations. Each phenomenological category is an encompassing set of phenomena and concepts that make sense together and may be encountered within and across a multitude of quite different situations. By their very

nature, each idea can be perceived as a general notion dealing with a generalized content dimension. This implies that the categories or ideas cannot be sharply delineated vis-à-vis one another. Rather, each represents a certain perspective, or point of view, which can be thought of as possessing a core, a center of gravity, and a somewhat blurred penumbra that allow intersection with other ideas. In principle, any idea can intersect with any other idea.

Competencies Needed for ML

The competencies that form the heart of the ML description in PISA seem, for the most part, well in line with the elements proposed by Steen. The following list of eight competencies rely on the work of Mogens Niss and his Danish colleagues, but similar formulations can be found in the work of many others representing different countries:

1. Mathematical thinking and reasoning. Posing questions characteristic of mathematics, knowing the kinds of answers that mathematics offers and distinguishing among different kinds of statements, and understanding and handling the extent and limits of mathematical concepts.

2. Mathematical argumentation. Knowing what proofs are, knowing how proofs differ from other forms of mathematical reasoning, following and assessing chains of arguments, having a feel for heuristics, and creating and expressing mathematical arguments.

3. Mathematical communication. Expressing oneself in a variety of ways in oral, written, and other visual form and understanding someone else's work.

4. Modeling. Structuring the field to be modeled; translating reality into mathematical structures; interpreting mathematical models in terms of context or reality; working with models; validating models; reflecting, analyzing, and offering critiques of models or solutions; and reflecting on the modeling process.

5. Problem posing and solving. Posing, formulating, defining, and solving problems in a variety of ways.

6. Representation. Decoding, encoding, translating, distinguishing between, and interpreting different forms of representations of mathematical objects and situations as well as understanding the relationship among different representations.

7. Symbols. Using symbolic, formal, and technical language and operations.

8. Tools and technology. Using aids and tools, including technology when appropriate.

To be mathematically literate, individuals need all these competencies to varying degrees, but they also need confidence in their own ability to use mathematics

and need to be comfortable with quantitative ideas. An appreciation of mathematics from historical, philosophical, and societal points of view is also desirable. This list of competencies is just one example. Other studies have chosen, instead of emphasizing competencies, to question what it means to be successful in mathematics. Recognizing that no term completely captures all aspects of expertise, competence, knowledge, and facility in mathematics, the study *Adding It Up* has chosen to identify five strands for mathematical proficiency:

1. Understanding. Comprehending mathematical concepts, operations, and relations, i.e., knowing what mathematical symbols, diagrams, and procedures mean.

2. Computing. Carrying out mathematical procedures, such as adding, subtracting, multiplying, and dividing numbers flexibility, accurately, efficiently, and appropriately.

3. Applying. Being able to formulate problems mathematically and to devise strategies for solving them using concepts and procedures appropriately.

4. Reasoning. Using logic to explain and justify a solution to a problem or to extend from something known to something not yet known.

5. Engaging. Seeing mathematics as sensible, useful, and doable (if effort is exerted) and being willing to do the work.

Kilpatrick and Ball, the authors of *Adding It Up*, stress that students are open to mathematics, and all students can and should be mathematically proficient.

Without comparing the competencies and strands of proficiency in detail, it is clear that there are some similarities, albeit that the emphasis is placed somewhat differently. If the five strands are reordered as computing, applying and reasoning, and understanding, we come very close to the clustering of competencies as used for the PISA study. This will be discussed next.

Competency Clustering

PISA defines three competency clusters for mathematical literacy. The “reproduction” cluster involves reproduction and recall of practiced knowledge, common problem representations, recognition of equivalents, recall of familiar mathematical objects and properties, routine procedures, and carrying out standard computations. The “connections” cluster addresses competencies needed to plan for solving problems by drawing connections from different mathematical content strands. The competencies include students’ abilities to combine and integrate information in order to solve problems. They also include the ability of students to interpret the meaning of a solution and to check the validity and meaning of their work. The “reflection” cluster activities include the ability to reflect on the processes needed to solve

a problem. They relate to the students' abilities to plan solution strategies and implement them in more complex problem settings. Items measuring the competencies of this cluster should reflect students' abilities to analyze. In other words, they must be able to interpret, to reflect, to explain, and to present mathematical generalizations, arguments, and proofs.

Context and Situations

An important part of mathematical literacy is using, doing, and recognizing mathematics in a variety of situations. In dealing with issues that lend themselves to a mathematical treatment, the choice of mathematical methods and representations often depends on the situations in which the problems are presented. Teachers of mathematics often complain that students have difficulty applying the mathematics they have learned in different contexts. Students who do not excel in science often dislike contexts involving physics applications in mathematics, because they do not understand the physics. Building from this, it seems necessary to examine the wisdom of confronting nonscience students with mathematics applications that need specific science literacy at a nonbasic level. As has been pointed out before, to transfer their knowledge effectively from one area of application to another, students need experience solving problems in many different situations and contexts. Making competencies a central emphasis facilitates this process: competencies are independent of the area of application. Students should be offered real-world situations that they recognize as relevant. This can be either real-world situations that will help them to function as informed and intelligent citizens, or real-world situations that are relevant to their areas of interest, either professionally or educationally.

The term "situation" is used here in the context of the part of the student's world in which a certain problem is embedded. It is very convenient and relevant to the art of teaching for ML to see situations as having certain distances in relation to the student. The closest distance is the student's personal life; next is school (educational) life, then work (occupational) and leisure, followed by the local community and society as encountered in daily life. Furthest away are scientific situations. It might be desirable to enlarge the distance domain as the age of the students increases, but not in a strict way. Steen itemized an impressive list of expressions of numeracy, most of which can be seen as having a certain "distance" from citizens. "Personal life" includes, depending on age, games, daily scheduling, sports, shopping, saving, interpersonal relations, finances, voting, reading maps, reading tables, health, insurance, and so on. School life relates to understanding the role of mathematics in society and school events (e.g., sports, teams, scheduling) and

understanding data, computers, and so on. Work and leisure involve reasoning and understanding data, statistics, finances, taxes, risks, rates, samples, scheduling, geometric patterns, two- and three-dimensional representations, budgets, visualizations, and so on. In the local community, the intelligent citizen makes appropriate judgments and decisions, evaluates conclusions, gathers data and makes inferences, and in general adopts a critical attitude, i.e., sees the reasoning behind decisions.

Last, we come to science situations. To function as an intelligent citizen, individuals need to be literate in many fields, not only in mathematics. The use of scientific situations or contexts in mathematics classes should not be avoided per se, but some care must be taken. If we try to teach students the right competencies but use the wrong context, we are creating a problem, not solving it. A good but rather unscientific example concerns work with middle-school students in the United States. The designed lesson sequence had archeology as a context. Archeologists sometimes use rather straightforward but quite unexpected and rather "subjective" mathematical methods in their research—just the kind of mathematics middle-school students can handle. The question, therefore, was not whether the students could do the mathematics but whether the context was engaging enough in this short-attention-span society. Without giving the specifics, the students were highly engaged because of the unexpectedness of what they were learning and the relevance of the methods used. In this instance, it was learned that connecting to the students' real world can be a complex but highly rewarding journey.

It has become clear in dealing with mathematics in context over the past 25 years that making mathematics relevant by teaching it in context is quite possible and very rewarding, despite the many pitfalls. Much more experience and research are needed, but based on previous experiences it appears that teaching both mathematical literacy and relevant mathematics at almost the same time might very well prove feasible.

Items and Assessment Structure

In general, mathematical literacy will be measured by an assessment system consisting of restricted-time written tests. For literacy, context or a real-world situation is an essential part of any item designed to measure mathematical literacy. This implies that typically an item will consist of some stimulus material or information, an introduction, and the actual question. In addition, for non-multiple-choice items, a detailed coding scheme will be developed to enable trained markers. It goes without saying that there is an inherent tension between the traditional choice of item formats, usually with very

restricted time limits (1–2 minutes per item), and the rather ambitious definitions of what constitutes mathematical literacy. It still has to be proved that, in this respect, tests such as PISA (and many others) are valid in the sense that they really measure mathematical literacy. But it is also clear that much progress has been made in the past 40 years on the quality and especially the authenticity of items used in ML studies. Authenticity is especially important when measuring ML, meaning here that tasks represent one of a variety of real-world situations, and that they have a context for which the use of mathematics to solve the problem that is authentic.

Although experts do not completely agree on the subject, careful observations make clear that items requiring competencies that go beyond mere reproduction and basic skills are quite difficult to operationalize with items of the multiple-choice format. Closed-constructed response items and open-constructed response question are often used to operationalize these competencies (see Fig. 1). For items in these formats, guessing is not likely to be a concern, and the provision of distracters (which influence the construct that is being assessed) is not necessary. Open-constructed response items differ from closed-constructed response in that they require a more extended response, and the process of producing the answer requires often higher order cognitive activities.

The assessment structure that is popular when measuring ML is the rotating test design. Items are clustered in a number-cluster of items, with each item-cluster representing a fixed amount of time. The item-clusters will be placed in booklets according to the rotated test design. In order to ensure reliable scoring, detailed guidelines have been developed for the scoring guides, the training materials to recruit scorers, and the workshop materials used for training national scorers. For each test item, the intent of the question is described, and how to code the student's response to each item. This description allows for giving partial credit. Also included is a system of double-digit coding, allowing not only for correctness of the answer but also for identifying strategies or misconceptions. In order to examine the consistency of the marking process, an interscorer reliability study has to be carried out.

Methodological Aspects

The 2003 PISA is, by any measure, the largest study yet in the area of mathematical literacy (in the 2003 study, mathematics is the main study subject). Some technical aspects of this study are summarized here. PISA developed quality standards, procedures, instruments, and verification mechanisms to ensure that national samples yielded comparable data. The data quality standards required minimum participation rates for educational institutions as

In the diagram below, you see the pattern of a certain lighthouse. The light flashes alternate with dark periods. It is a regular pattern. After some time the pattern repeats itself. The time taken by one complete cycle of a pattern, before it starts to repeat, is called the period. When you find the period of a pattern, it is easy to extend the diagram for the next seconds or minutes or even hours.

In the diagram below, make a graph of a possible pattern of light flashes of a lighthouse that sends out light flashes for 30 seconds per minute. The period of this pattern must be equal to 6 seconds.

Figure 1 The type of problem that was used in the PISA 2003 Assessment Framework. The wording of the description (A) and of the instruction (B) indicates the openness of the problem (note the use of the word “possible”). The problem presents a challenge to students to construct or design a solution. This challenge to express mathematical competency in an active and underived manner is an important aspect of mathematical literacy. There are two conditions to solving the problem: there must be equal amounts of light and dark in a 1-minute period, and each period must last for a specified time (6 seconds). These conditions require comprehension on a conceptual level, indicating that the students are being confronted with the “reflection” competency cluster. Adapted from Organization for Economic Cooperation and Development (OECD) (2003).

well as for students. The minimum participation rate had to be met at a national level, not necessarily for each participating country (details of the quality assurance report are contained in the 2003 OECD publication). PISA used item response theory (IRT) methods to produce scale scores that summarized the achievement results. The model (mixed-coefficients multinomial logit IRT) used to produce the test results is similar to the more familiar two-parameter IRT model. With this method, the performance of a sample of students is a subject area or subarea can be summarized on a single scale or a series of scales, even when different students do different items. IRT scaling provides estimates of item parameters (such as difficulty and discrimination) that define relationships

between items and underlying variables measured by the test. Parameters of the IRT model are estimated for each test question, with an overall scale being established as well as scales for each predefined content area.

One of the key problems of a study that deals with a matter as complex as measuring mathematical literacy, on such a large international scale, is the problem of keeping the burden for students as low as possible, and obtaining results that are accurate nevertheless. In the PISA study, because so few items were done by students, it was impossible to produce accurate content-related scale scores for each student. To account for this, the plausible-value theory can be applied. For example, PISA administered few assessment items to each student and generated five possible scale scores for each student. The five scale scores represented selections from the distribution of scale scores of students with similar backgrounds who answered the items in the same way. In this way, PISA used the plausible-values methodology to represent what the true performance of an individual might have been, had it been observed, using a small number of random draws from an empirically derived distribution of score values based on the student's observed responses to assessment items and on background variables. Because of this plausible-values approach, secondary researchers can use the data to carry out a wide range of analysis.

Developments and Studies on Mathematical Literacy

Some of the publications in the field of mathematical literacy have had a proven impact. In 1977, the Education Department of Western Australia published a policy paper on literacy and numeracy, stating that the "term 'numerate' is understood to mean mathematical literacy. A person is considered to be literate and numerate when he has acquired the skills and concepts that enable him to function effectively in his group and community, and when his attainment in reading, writing and mathematics make it possible for him to continue to use these skills to further his own and his community's development." The report stresses a more traditional view by emphasizing mastery of number facts, competence in operations, skills in estimation, skills in interpreting graphs, etc.

A noteworthy publication in the United Kingdom, Cockcroft's *Mathematics Counts*, contained David Stringer's survey *Make It Count*. The survey mentioned that "there are many adults in Britain—not just the unintelligent and uneducated—that are hopeless in arithmetic and they want to do something about it... Functional innumeracy is far more widespread than anyone has cared to believe." The entire Cockcroft report was an important source of information and especially was moti-

vation to rethink mathematics education in many countries, especially the United States and Australia. One part of this report stated that "it is important to have the feeling for number, which permits sensible estimation and approximation and which enables straightforward mental calculation to be accomplished. Most important of all is the need to have sufficient confidence to make effective use of whatever mathematical skill and understanding is possessed, whether this be little or much."

In 1989, the United States followed the UK report *Make It Count* with the report *Everybody Counts*. In this report, it was stated that "numeracy requires more than just familiarity with numbers. To cope confidently with the demands of today's society, one must be able to grasp the implications of many mathematical concepts—for example, chance, logic, and graphs—that permeate daily news and routine decisions." Almost at the same time, the National Council of Teachers in Mathematics (NCTM) published its *Standards*. In this publication, the authors refer to mathematical literacy and recognize its importance. This was again emphasized in the more recent revised edition of the *Standards*. Literacy is not only a Western world problem. On the contrary, the push for literacy in general started with the work of Paulo Freire. His pleas for literacy for all were reflected at several United Nations Educational, Scientific, and Cultural Organization (UNESCO) conferences. One of the most well-known conferences took place in Yomtien in 1990, when Freire stated that "every person shall be able to benefit from educational opportunities designed to meet their basic learning needs. These needs comprise both essential learning tools (as literacy, oral expression, numeracy, and problem solving)."

Studies have followed the many reports. In 1986, an important start was made with national research into quantitative literacy skills of adults as part of the National Assessment of Educational Progress (NAEP) project in the United States. In a first study, the Young Adult Literacy Skills (YALS), young adults were assessed on tasks related to three literacy scales, one being quantitative literacy. As reported by John Dossey in 1997, the scale measures the ability to apply the knowledge and skills to understand and use the information from texts similar to newspapers and popular magazines; to locate and use information contained in job applications, schedules, maps, tables, and indexes; and to apply arithmetic operations embedded in printed materials, such as recording checks in a check register, computing the amount of a tip, completing an order form, or determining the amount of a loan. According to Dossey, the results "were less than what the nation required in human talent for long-term international competitiveness." A follow-up of YALS was the National Adult Literacy Study (NALS), again with rather disappointing results. Performance on tasks used in the NALS suggests that many everyday or work-related

literacy tasks, involving either manipulation of numbers or comprehension of quantitative data, that are embedded in various types of text prove difficult for a large proportion of adults in the United States.

The Organization for Economic Cooperation and Development carried out an international study, the International Adults Literacy Skills Survey (IALS), in the period from 1990 to 1996. In 2000, the first phase of the OECD/PISA study was carried out; the second phase of the OECD/PISA study occurred in 2003, stressing mathematical literacy as its main component. In the same year, the follow-up survey of IALS, the Adult Literacy and Life Skills survey, was fielded. Other, more local studies on mathematical literacy include the National Completion Examinations in mathematics (NCEM) in Israel and the Victoria Common Assessment Tasks in Australia. Although the list of studies and reports mentioned here is far from exhaustive, it is clear that measuring mathematical literacy has taken full flight. The discussion about the consequences of the measurements and the true meaning of the data, however, just has started.

Literacy, Scientific

Peter J. Fensham

Monash University, Victoria, Australia

Glossary

need-to-know science The knowledge of science that citizens urgently require in order to cope with real-life situations in which they are involved.

public understanding of science A measure of the knowledge that members of the public have of science and its procedures of inquiry.

school science What is intended to be taught and learned about science in the years of formal schooling.

science for all A belief that meaningful learning of science can be extended to all students and citizens, not just those with interests in science-related careers.

scientific inquiry Processes and ways that scientists acquire knowledge in order to elucidate and explain the natural world.

scientific literacy Competencies and understandings about science that persons can acquire through formal and informal education.

the public The citizens of a society in general, in groups and individually.

The measurement of scientific literacy and of public understanding of science involves assessing what students and the public need to know about science and how scientific knowledge can be surveyed reliably and validly. Scientific literacy acquired in educational systems is now understood to be closely linked to public understanding of science; schools, as the major source of scientific teachings, are the source also of hope for a well-informed citizenry.

Introduction

The Public and Science

The interest of the general public in understanding science has a long history. Mechanics institutes, an early 19th-century innovation, flourished in many towns and

villages and served a central purpose of providing citizens with knowledge of science and technology. Early in the 19th century, magazines such as *Popular Science* and *Popular Mechanics* had substantial readerships; the contemporary equivalents, for English readers, are *Scientific American* and *New Scientist*, and similar magazines published in many languages are widely read throughout the world. In 1938, Lancelot Hogben published the first of many reprints and editions of *Science for the Citizen—A Self-Educator Based on the Social Background of Science Discoveries*. Numerous books by leading scientists for interested public readers were published in the 1940s. Since then, many well-known writers, such as Isaac Asimov, Stephen J. Gould, Stephen Hawking, Dava Sobel, and Margaret Wertheim, to name just a few, have been successful purveyors of the fascination of science and of background on how scientists develop scientific knowledge.

Paralleling the print media popularizations of science are the television programs about investigations by scientists in many fields, especially the natural world and the medical sciences. Science fiction, with its mix of reality and fantasy science, is a genre of literature that is read by large numbers of the public, and it is even more popular in the media of film and television. Interactive science museums and science centers are also now commonplace and are increasingly visited by members of the public as well as by school students. The Internet currently is an important means of access for the public to an ever-increasing amount scientific information. Finally, governments are the impetus for the public need for scientific knowledge, given that science-based regulations confront citizens everyday, from use-by dates in supermarkets to the compulsion to wear seat belts in cars. How much of this science does the public at large, or its subgroups of citizens, including students, understand, or need to understand?

School Science and Public Understanding of Science

It is only from the perspective of the 1960s onward that an association between school-taught science and public understanding of science makes any general sense. Prior to the 1960s, only a small minority of students in most countries undertook serious studies of science at school. A great period of science curriculum reform in the 1960s and 1970s initiated the rise of science as a more universal and serious component of academic curricula. This process also began to shift the locus of the public's understanding of science from adult sources to what was being taught and learned by future citizens in grade school through high school. This link between school science and public understanding was given further impetus in the 1980s, when a number of countries (Canada, the United States, and the United Kingdom) and the United Nations Educational, Scientific, and Cultural Organization (UNESCO) committed to the slogan of "Science for All" as a new goal for school science. The science education of all students, who are the general public of the future, was to be put on an equal footing with the original and traditional goal of school science, which was the selection and preparation of future scientists. Implementation of these new educational goals would require all students to study science for some years at school; the intent was to provide a base for the general public's understanding of science, regardless of what other community sources might contribute. By 1990, the original international slogan had evolved to become "Scientific Literacy," thus aligning the goal of school science with the educational imperatives of literacy in language and numbers. Furthermore, because measuring student learning is a standard aspect of schooling, it is not surprising that measuring student scientific literacy, as an indicator of what the future public's understanding of science would be, became, alongside measurement of learning, a national and international activity.

Public Understanding of Science

Nature of Public Interactions

In 1975, Benjamin Shen suggested that the interactions of the public with science involve three types of scientific literacy: practical, cultural, and civic. By practical, Shen meant scientific knowledge that has personal and practical usefulness. Cultural scientific literacy is associated with knowledge of, and interest in, science for personal appreciation, and civic scientific literacy is concerned with the knowledge that is required to follow the essence of the arguments that are presented, say, in the media about disputed socioscientific issues. Shen regarded the last

of these as "the cornerstone of informed public policy." These different types of knowing about science might also have led Shen and others to a recognition of different "publics," but such a differentiation of this target population has only more recently been a feature of the issue.

Need-to-Know Science

In the early 1990s, David Layton and his colleagues at the University of Leeds studied small groups of citizens who were in situations in which they had an urgent need to know some aspect of science. These case studies helped identify some specific abilities that are associated with Shen's practical and civic scientific literacies: the ability to access scientific information when required, to differentiate between the worth of different sources, to weigh the value of the information in relation to other social knowledge, and to differentiate between scientific questions and other questions about the pressing problem. These features of understanding science are not about a "conceptual cathedral" of science knowledge to be remembered, but rather about a "quarry to be raided" for information, to be put to use when needed. On the other hand, cultural scientific literacy involves a level of understanding that enables members of the public to share vicariously the investigations of scientists past and present—their questions, their quest for answers, and what they found.

Measuring Public Understanding

Beginnings

The notion that a public understanding of science should or could be measured is a recent idea, and, accordingly, there is still debate about the meaning of what is to be measured and how the measures can and should be obtained. An increase in media and tools for public access to science in the 20th century spurred the development of means to measure the public's interest in science. In 1957, the National Association of Science Writers surveyed American adults about their patterns of access to, and consumption of, writings about science. The issues about access to science have not been pursued in the more recent measurement studies, despite their increased importance in the age of the Internet.

In 1963, Michael Bassey published the results of a modest study under the title of *Science for Tomorrow's Citizens*, reminiscent of Hogben's title. He surveyed university-level humanities students who had studied some science at school, but not as their central interest or future intention. Bassey's view of the science to be understood consisted of some basic content knowledge that students should or could have been taught in science

in secondary schooling, and that they would be able to describe the standard scientific method in terms that included the role of hypothesis. The level of the content knowledge can be seen from some of Bassey's questions:

- Are there atoms in air, water, clay, and wood?
- Which of the following are properties of chlorine?
- Which of the following are basic aspects of the modern theory of evolution?

The residual memory among Bassey's respondents of the two fundamental aspects of science knowledge (basics and the scientific method) was not substantial, and the experience of school science that the university students remembered was that it seemed to be a long list of irrelevant facts. Bassey made a prescient link between his sense of citizens' understanding of science and the learning of science in schooling by starting with the question "What effect does learning science in school have on persons not engaged in science after they leave school?"

Political Interest

In the 1970s and 1980s, modern contradictions—how science and technology lead to rising standards of living in the developed countries and how the same combination of knowledge and application degrades the biophysical environment—began to be recognized nationally and internationally. The political awareness that yet more applications of science and technology would be necessary to resolve this dilemma has led to pressure for greater public understanding (and hence measures) of the role of science and technology in relation to decision making about the many socioscientific issues all societies now face. Shen's description of civic scientific literacy relates directly to this political pressure. The Royal Society in London released a report in 1985 entitled *The Public Understanding of Science*. It addressed the need for more education, of both the public and those in school, about science. It forcefully urged that there were a number of benefits, personal and national, to be gained from a public that was more informed about science. The Royal Society has been criticized for overemphasizing the public deficiency in factual knowledge of science, but the report also expressed concern about inadequate knowledge of the methods of science, its potential for achievement, and its limitations.

Scope of Understanding

The limited nature of the science understanding Bassey set out to measure (a few direct knowledge items and an open question about scientific inquiry) invited other aspects of understanding to be included in such measuring. In 1974, Peter Fensham made an attempt with several

accessible work groups of adults. They were interviewed about a range of questions:

- What type of scientist would be relevant to plagues of locusts, bridge failures, water quality, etc?
- Where would you look in an encyclopedia for information on colors in soap bubbles, on objects floating in satellites, on egg yolks blackening spoons, etc?
- How could observations such as warmer patches of water in a lake, skin rash in children in a neighborhood, etc. be investigated?

These questions were so hypothetical for the respondents that this direction of measuring a rather wider meaning of understanding science was not pursued.

Systematic Measuring

In 1972, the National Science Board in United States produced the first of a series of biennial reports on a set of science indicators. The initial focus was on the public's attitude to science in general and to some specific science issues, but subsequently this was widened in scope. In 1973 and 1977, the National Assessment of Educational Progress in the United States used a survey methodology to test large, but not generally representative, groups of adults to measure their factual science knowledge and their interest in science. In 1982 Arthur Lucas reported the use of the process of public opinion polling to survey the knowledge British adults had of some topics in biology, using questions that could have been on tests in the mid-years of secondary school biology. The use of the survey methods for polling public opinion thereafter became the main method of measuring public understanding of science. These have the strengths of representativeness and measure reliability that were lacking in the earlier studies of specific groups, but they have the validity limitation of what can be asked about science on such a wide scale, using the methods for data collection of this type of survey research (questionnaires or interviews asked face-to-face or by telephone).

J. D. Miller in the United States and J. Durant in the United Kingdom are two key figures in the measuring process at the public level. Miller, in 1983, suggested that public understanding of science can be thought of in three dimensions. The first dimension is like Shen's civic scientific literacy. It is about having a sufficiently confident knowledge of the vocabulary of science constructs that a media report involving conflicting aspects of science can be read and appreciated. The second dimension is an understanding of the processes of scientific inquiry, and the third is the understanding citizens have of the impact of science on society. The early attempts to measure the third of these dimensions

suggested that it varied widely across and within countries, and researchers have not persisted with this measure in the larger national and international comparative studies that have been undertaken since the 1980s. In the 1990s, when major surveys had also been undertaken in Europe, Bauer and Schoon argued that variation in the public's understanding of science (as, for example, in this dimension) should be seen as something interesting to investigate. To measure or record this variation, however, raises serious methodological problems.

In his first testing of the vocabulary dimension in 1983, Miller surveyed more than 1000 adults in the United States; Miller used a range of true/false factual statements such as "It is the father's gene that determines the sex of the child," "all radioactivity is man-made," and "the center of the earth is very hot." He concluded that the great majority on this dimension were scientifically illiterate, a conclusion that was supported when Miller and John Durant collaborated in the late 1980s to produce a set of knowledge items for use as a core set in surveys in Canada, China, Japan, Korea, New Zealand, and Spain, in addition to the United States and the United Kingdom. In 1992, a survey by telephone interview of 12,000 adults in the 12 member states of the European Union produced what was described as the Eurobarometer—measures on a broad set of knowledge and attitude items about science.

Scientific Inquiry

For Miller's second dimension, understanding scientific inquiry, a single open-ended item ("What does it mean to study something scientifically?") was found to produce useful results in both the United States and the United Kingdom. More concrete cases (for example, "Which approach [briefly described] of two scientists wishing to studying the effect of a certain drug on high blood pressure is better, and why?") have also been used with interesting outcomes.

Psychometric Aspects

Miller, in particular, has given attention to several of the psychometric issues associated with measuring public understanding of science. One issue is the durability of the measure: Can a measure be developed that has an enduring relevance to different publics and to these publics over time, so that changes in public understanding of science can be recognized? A second issue is the reliability of the measures: Can reliable scores be obtained from tests that contain a minimum number of common items? A third issue is the type of item to use in the measure? What type of item facilitates data collection and data richness? Finally, there has been the issue of level of understanding: What levels of understanding should be used when reporting cross-national comparisons?

Factor analysis of the results of testings in both the United States and Europe, using items designed to test Miller's first two dimensions, confirmed that two factors were present, one concerned with vocabulary and one concerned with the process of scientific inquiry. The scores on the two dimensions correlated highly, but were considered sufficiently different to be regarded as separate dimensions. Nine vocabulary items were common, although their loadings on the factor differed in the two studies. The use of a combination of factor analysis and the methods of item response theory on the data from their national studies enabled Miller and Durant to identify a core set of knowledge items that were then used in the eight-nation study referred to previously. When multiple groups are involved, as in this study, the methods of item response theory were used to compute item values and test scores that take into account the relative difficulty of items and the different composition of each national test. Reliable results were obtained with a minimum of 10 items. These items required respondents to provide, for example, definitions of DNA and a molecule and to answer true/false to statements such as "light is faster than sound," "all radioactivity is man-made," "earliest humans lived at same time as the dinosaurs," and "antibiotics kill viruses and bacteria." The type of item is very related to the mode of interaction between the researcher and the responding public. Both open-ended and closed items have been tried in studies in the United States and United Kingdom. In general, open-ended questions lead to measures that are likely to be more valid, but they are more difficult to interpret and hence to score compared to closed questions.

If a printed questionnaire is presented, multiple-choice items are feasible, although adults are more likely to be confused by this format than are students at school. When the interview is conducted by telephone, simple open-ended questions, such as asking for definitions, and the closed true/false items are much more appropriate. In either case, having more than one part to an item greatly helps to distinguish guessing from understanding. For example, when the true/false item "Earth rotates around the sun" was followed with a related question ("Does this rotation take a day, a month, or a year?"), a more realistic indication of the level of understanding was achieved. Of those who knew Earth goes around sun, 47% in the United States and 33% in Great Britain knew the period correctly.

The scoring of large-scale surveys that have quantitative comparative measures as their primary purpose requires a convergence of response to the various items—that is a "correct" response. Although this can be achieved when printed questionnaires and closed items are used, telephone interviewing, even with intentionally closed questions, leads to a wider range of responses. Respondents in the Eurobarometer study were asked the open

question, "What does it mean to study something scientifically?" Analysis of the responses by Bauer and Schoon found a richness in the respondents' understanding that would not have been possible with closed questions directed at a "correct" response. For reporting purposes, three levels have been established: literate or well informed ($\geq 67\%$ correct), partially literate (33–66%), and not literate ($< 33\%$). In the comparative study between the United States, in 1995, and Europe, in 1993, the findings for these levels were United States, 12, 25, and 62%; and Europe, 5, 22, and 73%.

Political Needs

Political Interest

Politicians seem fatally attracted to the survey measures, despite the overall dismal message of the outcomes. On the one hand, there always seems to be one or two items to which politicians can point successfully, emphasizing that their own ministry outscored some other rival ministry. On the other hand, the generally poor scores enable political arguments to be made for more funds for particular ministries. More fundamentally, survey measures may provide politicians with data that are only marginally related to the issues for which they need to produce policy.

Understanding and Support for Science

There is some evidence from repeated studies, and from the breakdown of responses by age, that young adults and those who have continued to study science do have a greater measure of scientific understanding. This trend has been acknowledged, but with the caveat that the presence of correct bits of science knowledge is not the same as being able to respond to science messages, a much more difficult thing to measure. In 1995, Evans and Durant looked at the relationship between the measures of understanding of science and the attitude to science, which has been of such interest to politicians. More understanding was weakly related to positive attitudes, but was more related to coherence in the attitude responses and to more discriminating attitudes about specific cases of the application of science. Miller's studies in the United States also found similarly real, but modest, linkages. When science applications were posed in general terms and in cases involving research that could be classified as useful and basic, understanding and support were directly related. For research that was controversial, such as embryo research or searching for new stars and planets, the most knowledgeable citizens were more strongly opposed. Martin Bauer analyzed the Eurobarometer data in terms of the degree of industrialization of the participating European countries. The most industrialized countries had higher

levels of understanding, but they recorded less interest in science. Age, gender, and level of education are also determinants of these attitudes, so the relationship is complex and by no means as clear-cut as some politicians have hoped or tended to assume.

Criticism

Methodological Limitations

The limitation that the opinion poll method of data collection places on the types of questions that can be asked and simply scored has already been mentioned. It is just one aspect of a basic concern about psychometric measures of complex things, such as having an understanding of science. Some aspects of this complexity may be amenable to large-scale measuring, whereas other important aspects of it are not. If measuring the accessible aspects goes ahead, and scores of the public's performance on these aspects are reported, the nonmeasurable aspects recede in importance or may be discounted entirely, even though originally they may have been seen to be of equal or greater importance. The previously mentioned caveat, concerning possessing bits of science as opposed to being able to construe science messages, relates to this problem, as does the absence of measures of the public's ability to access scientific information when it is needed. Cultural scientific literacy as an aspect of public understanding of science has been totally disregarded in the most widely publicized measures, even though the evidence of its importance, provided by best-selling books that popularize science and by the success of science programs on television, is readily available.

Multiple Publics/Multiple Sciences

The polling of random samples of adults about a common set of science knowledge items discounts entirely any sense of the local in citizens' need to know, or of their particular interests among the multitude of science topics. In this regard, in 1997, Edgar Jenkins, a colleague of Layton in the Leeds study, urged that the interest in measurement should recognize that there are a number of distinct, segmented "publics," differentiated by interest and situational need. Furthermore, there is a multiplicity of knowledge and understandings of science, and all of these entities are essentially functional and directed toward specific personal and social purposes. These ideas have generated a quite different approach to exploring the public understanding of science. It begins by identifying the needs for scientific knowledge that adults have, as they function in the variety of societal contexts that make up life in modern society. Rather than discounting the need-to-know aspect (from the Leeds case studies) as

idiosyncratic to particular situations, the approach suggests that there are aspects of science in the need-to-know category that large numbers of citizens may indeed share in common in their daily lives and work. The terms “citizen science” and “practical science-knowledge-in-action” have been proposed to replace the general term “scientific literacy.” In recent studies in three large cities in China, the perspective of citizens rather than science experts was deliberately sought. This has revealed some interesting examples of science knowledge that the different publics in these studies commonly needed to know.

Unjustified Importance

There has been serious criticism of the very idea of measuring public understanding of science. The argument is that, because scientific knowledge is a socially constructed form of knowledge, to measure its presence among the public at large gives it an unjustified and unhelpful status, relative to other types of socially constructed knowledge, such as the local knowledge of citizens.

Projections from School Measures

The Trends in International Mathematics and Science Study

The link between the science learning by all students in schooling and the public understanding of science in adult life means that a measure of the understanding achieved in schooling will provide some indication of what the public understanding may be in the years ahead. The Trends in International Mathematics and Science Study (TIMSS; formerly called the Third International Mathematics and Science Study) in 1994 was the first attempt to do this cross-nationally. As one of the tests of TIMSS, its creators, the National Center for Education Statistics and various partners in the United States, prepared an instrument referred to as Mathematics and Science Literacy. This test was taken by students in the final year of secondary schooling, whether or not they were still studying science. Despite a very considerable debate about the possible emphases this test's items might be given, it was finally developed as a rather traditional test with isolated items that required an understanding of the vocabulary of science constructs, some of which related to ongoing environmental contexts. Understanding of the nature of scientific inquiry was not included. The findings provided a useful cross-national baseline for future studies of the vocabulary knowledge of the young adult populations of the 21 countries that took part in TIMSS. There were, however, indications from studies associated with TIMSS that this type of knowledge was being forgotten even before the students had left school.

Organization for Economic Cooperation and Development/Program for International Student Assessment

Although both Shen's description of civic scientific literacy and Miller's elaboration of the first dimension of public understanding of science referred to the ability to read mass media science reports that include conflicting or competing science views, the abilities associated with such meaningful reading have not been directly measured at the public level. This is another example of the constraint that opinion poll testing places on the type of item used in the data collection. The captive populations that school contexts provide, however, makes it possible to include the test tasks of reading and critiquing actual media reports of science.

The Program for International Student Assessment (PISA) in Science, launched by the Organization for Economic Cooperation and Development (OECD) in 1998, based its first testing of 15-year-old students in 2000 on just such a set of tasks. It is thus more interesting than TIMSS as an example of projecting from school understanding. The purpose of this PISA survey was to provide measures of the extent to which the students' education in science had prepared them to “play a constructive role as citizens in society.” In this way, the PISA Science project took a large step away from the idea that the outcome of school science is, or ought to be, simply an accumulation of scientific knowledge and skills in the form in which they are presented in most science textbooks and classrooms. The project's view of scientific literacy is much more active. For the first limited measurement of science in 2000, the goal was defined as “being able to combine science knowledge with the ability to draw evidence-based conclusions in order to understand and help make decisions about the natural world and the changes made to it through human activity.” The measure the project was seeking would place students along a continuum of developing scientific understanding and procedural ability.

Five scientific procedures were selected for the design of the items of this initial measuring instrument:

1. Recognizing scientifically investigable questions.
2. Identifying evidence/data needed in a scientific investigation to test an explanation.
3. Drawing or evaluating conclusions.
4. Communicating valid conclusions.
5. Demonstrating understanding of scientific concepts.

The items were devised to involve these knowledge/process combinations as applied to media reports involving science, as examples of authentic, public socioscientific situations. The science constructs in the items were chosen based on criteria of everyday relevance, enduring relevance, and relevance to the media context. The

instruments that resulted contrast markedly with those used in TIMSS and in traditional school science tests, in which the question situations are so often contrived for the purpose, and hence fail to reflect the dynamic nature of either pure or applied science.

The immediate reactions to this proposed testing were that most 15-year-old respondents would not be able to deal with these types of tasks. It was suggested that the students were not mature enough to think in these ways about science issues or that, even if potentially mature enough, their education in science at school had not given them the opportunity or the incentive to develop these skills. The results of the first PISA testing in 32 countries in 2000 were encouraging beyond such expectations. Two-thirds of the students in the OECD countries achieved scores within one standard deviation of the average level, and the highest national averages meant achievement on about 75% of the items. This means that a majority of the students were able to use a number of the required scientific constructs to make predictions or provide explanations, to recognize questions that can be answered by scientific investigation, and/or to identify details of what is involved in a scientific investigation, and that they were able to select relevant information from competing data or chains of reasoning in drawing or evaluating conclusions. There were, of course, differences in the average scores of the students in the various countries, and attention has inevitably tended to focus on these differences and the rankings. This should not, however, obscure the promise that the results of the PISA project suggest for public understanding of science in the future.

Location Analysis

Charles S. ReVelle

Johns Hopkins University, Baltimore, Maryland, USA

Horst A. Eiselt

University of New Brunswick, Fredericton, New Brunswick, Canada

Glossary

competitive location problems Models in which each competitor takes the existing locations and the potential reactions of its competitors to its own actions into account.

dispersion problems Location problems in which the decision maker locates facilities so as to maximize the spatial separation between them.

flow capturing (intercepting) problems Location problems in which customers are assumed to travel on a path between home and work, and decision makers try to capture or intercept as much of the flow of customers as possible.

hierarchical location problems Location problems in which higher-level facilities offer specialized services in addition to the type of service that lower-level facilities offer. Problems of this type typically include some type of referral system.

location set covering problems (LSCPs) Location models in which the decision maker attempts to locate the least number of facilities that guarantee that each customer is no farther than a prespecified distance from a facility.

maximum covering location problems (MCLPs) Location models in which a decision maker sites facilities so that as many customers as possible are located within a certain radius.

p -center location A set of p facility locations that minimizes the longest distance between any customer and the facility closest to it.

p -median location A set of p facility locations on a network that minimizes the sum of weighted distances between the customers and the facility closest to them.

simple plant location problems (SPLPs) Location models that minimize the sum of transportation costs and fixed (establishment) costs of the facilities, so that the number of facilities is endogenous in the model.

undesirable facility location The location of facilities to maximize a function of distances between the facilities and their customers. Typically associated with (ob-)noxious facilities.

Weber problem A set of p facility locations in the plane that minimizes the sum of weighted distances between the customers and the facility closest to them.

Location models are designed to represent the process of siting facilities in some given space. Typical examples of such models deal with supermarkets, fast-food outlets, gas stations, landfills, and power-generating stations. Each application has its own idiosyncrasies, so that a large number of models is needed to model the many different scenarios in practice. With the exception of some fairly basic models, most realistic location problems tend to result in fairly complex nonlinear and/or integer optimization problems. The difficulties are exacerbated by the fact that most location problems require long-term planning, for which exact data are typically not available; have multiple objectives; and may require more than a single decision maker. This makes it even more important than in other optimization problems to treat the results of location models as suggestions rather than exact recommendations.

Introduction

The term location analysis refers to the modeling, formulation, and solution of a class of problems that can best be described as siting facilities in some given space.

The expressions “deployment,” “positioning,” and “siting” are frequently used as synonyms. We distinguish between location and layout problems. In location analysis, the facilities are small relative to the space in which they are sited and interaction between the facilities may or may not occur. In layout problems, in contrast, the facilities to be located are fairly large relative to the space in which they are positioned, and interaction between facilities is the norm rather than an exception. Four components characterize location problems: (1) customers, who are presumed to be already located; (2) facilities that will be located; (3) a space in which customers and facilities are located; and (4) a metric that indicates distances or times between customers and facilities. Applications of location problems abound, ranging from gas stations and fast food outlets to landfills and power plants.

In some nontraditional location problems such as product positioning, each facility represents a product, which is mapped into a feature space, each of whose dimensions represents a relevant feature of the product. Similarly, each customer (or, typically, group of customers) is mapped into the feature space, and the distance between customers and products will give an indication of which products the customers are going to purchase, thus allowing estimates concerning the sales of the products. In 1992, Eiselt provided a survey of many distinct applications of location models. As opposed to routing problems, location problems tend to be higher on the strategic, or tactical, operational continuum. As a result, location problems are likely to have multiple objectives; they tend to be fuzzy and ill-posed, making them doubly challenging—they must first be modeled before they can be solved.

The Space of Location Decisions

Location scientists often use the space in which facilities are located to distinguish between classes of location problems. We here distinguish between planar location problems and network location problems, each of which can be further subdivided into continuous or discrete location problems. The space in planar location problems is the two-dimensional real space of the plane. Distances in planar problems are most often either the rectilinear (or rectangular, or Manhattan, or ℓ_1) distance metric or the Euclidean (or straight line, or ℓ_2) metric, although other functions are possible and have been suggested. For the estimation of road distances between points based purely on the coordinates of the end points, Love and co-researchers have worked with a number of additional metrics, for example, in their 1988 study. The main reason for calculating distances between points whenever needed rather than storing them is the sharply decreased need for storage space; the coordinates of n given points

require $O(n)$ storage space, whereas all point-to-point distances require $O(n^2)$ memory.

In contrast, distances in network location problems are measured on the network itself—typically as the shortest route on the network of arcs connecting the two points. Using the shortest path usually requires a preprocessing phase to find all shortest paths between all relevant pairs of points.

Both planar problems and network problems can be further subdivided into continuous and discrete location problems. In continuous problems, the points to be sited can generally be placed anywhere on the plane or on the network. An example of a continuous location problem in the plane is the placement of a helicopter for trauma pickup; an example of a continuous problem on a network is the location of an ambulance or a tow truck along a stretch of highway. In discrete problems, the points to be positioned, in addition, can conceptually be placed only at a limited number of eligible points on the plane or network. Thus, discrete location models have gone through an additional preprocessing phase that has pre-selected candidate sites at which the facilities may be sited. An example of a discrete location problem in the plane is the positioning of transmitter stations that are to be placed at some permissible points within a region, such as mountaintops; an example of a discrete network location problem is the location of retail facilities that can only be sited on lots that are zoned for them.

As a result, continuous location problems, which are for the most part planar problems, typically tend to be nonlinear optimization problems, whereas discrete location problems, which are most often network problems, involve 0-1 variables that result in integer programming or combinatorial optimization problems. Clearly, there are countless hybrid models, many of which do not fall into these neat categories. Whereas some researchers concentrate on a space of their choice, many shuttle between classes of models.

Classes of Location Objectives

A variety of factors other than customers, facilities, space, and distance functions play important roles in location modeling. One such factor is the objective that is employed by the decision maker. Traditionally, the facilities that were to be located were assumed to be desirable in the sense that the closer they were to the customers, the better the value of the objective function. As Eiselt and Laporte pointed out in 1995, these are pull objectives. Clearly, there is a large variety of pull objectives, but two of the most prominent objectives within this class are the minisum objective, which minimizes the sum of transport costs or weighted distances, and minimax objectives, which minimize the largest customer-facility distance.

In planar continuous models, the minisum objectives are usually called Weber problems, after the German economist who worked on these problems at the beginning of the twentieth century and summarized his findings in his classical treatise, summarized by Wesolowsky in 1993. In network location models, facility sites that are chosen with a minisum objective are typically referred to as medians, or sometimes as points of production or of distribution. Solutions to problems with a minimax objective are usually referred to as centers.

As discussed by Erkut and Newman in 1989, since the late 1970s, researchers have also considered the location of noxious or obnoxious (or simply undesirable) facilities. In contrast to facilities for which nearness is desirable, customers wish, as one of their objectives, to push undesirable facilities as far from them as possible. By themselves and without any further restrictions, push objectives attempt to locate toward infinity. This is why they are often coupled with other, predominantly pull objectives. An example of a problem with these two conflicting objectives is the location of a (nuclear) power plant, an arguably undesirable facility. Whereas the customers and the population at large would like to push the power plant as far away as possible, the hydro commission, who has to pay for the connection of all customers to the power grid, would prefer to pull the power plant as close as possible. Combining the two objectives requires statements regarding the trade-off between the cost of connecting the customers and the proximity to a part of the population of the power plant. Finally, a third class of objectives is the achievement of equity. Models with such objectives attempt to locate the facilities so that the customer-to-facility distances may be as similar to one another as possible. This equalization gives rise to the term “balancing objectives.” Alternatively, the distances from clients to the nearest facility may be bounded by some generally recognized distance standard. This is done so as to provide relatively equal access to the facility or, equivalently in the case of undesirable facilities, to distribute the unpleasantness as equally as possible.

Other features of interest to the modeler include the number of facilities that are to be located. The simplest of the models attempt to locate a single facility, whereas more complex models might locate p facilities, where the parameter p may be fixed by the decision maker or imposed by a budget limitation. Alternatively, the number of facilities may be unknown at the outset and determined endogenously through the elements of the model's objective. The best known in this category of models with free entry is the plant location problem that minimizes the sum of plant-opening costs and distribution costs and that allows the number of facilities to be an output or consequence of the minimum cost solution. Another type of model in this category is the location set covering model, first introduced in 1971 by Toregas *et al.* The idea is to find

the least number of facilities so that all demand points are covered within a prespecified distance standard.

Other enhancements of location models include uncertainty or risk with respect to the ability to service demands within desirable distances. Sometimes barriers may exist that cannot be crossed in continuous location models. In addition, there is a category of facilities referred to as extensive facilities that cannot be modeled as points but that have length as well as position characteristics, thus providing a link between location models, layout models, and network models.

An early characterization of model forms and objectives that is still in use, provided in 1970 by ReVelle *et al.*, divides location problems into private-sector problems and public-sector problems. The private-sector problems seek the sites for plants and or warehouses; these sites are those that minimize the sum of the annual costs of distribution and amortized plant costs. Public-sector problems, in contrast, seek sites for facilities that optimize the population's access (measured in the various ways already discussed) to those facilities, the facilities being constrained either in number or by some investment level. Clearly, there are many shades of gray between the extremes of private and public. For instance, if a decision maker in the public sector accepts the measure of the average customer-facility distance as a proxy for accessibility, then the resulting model could be viewed as a special case of a transport-cost minimizing model that is typical for the private sector.

Continuous Location Problems

Minisum planar location problems dominated the location discussion until the mid-1960s. From the first three-customer, one-facility location problem posed by Torricelli in 1648, to Weber's seminal work in 1909 (discussed by Wesolowsky in 1993), to Kuhn and Kuenne's 1962 and Cooper's 1963 contributions, location problems were mostly discussed by geographers or regional scientists whose space of choice was the two-dimensional plane. The first algorithm for the minisum planar problem with one facility and Euclidean distance, however, was offered by Weiszfeld in 1937. His algorithm (written in French and published in a Japanese journal of mathematics) predated the similar algorithms of Cooper and Kuhn and Kuenne, but escaped attention until the 1970s when his early contribution was finally recognized, as described by Wesolowsky in 1993.

Setting up the two-variable objective function (the only variables are the two coordinates of the new facility) leads to $\text{Min } z = \sum_{i \in I} d_i w_i$, where d_i denotes the Euclidean distance between a customer at (a_i, b_i) and the facility at (x, y) to be sited; w_i is the known demand (or weight) of customer i ; and I is the set of customers. This nonlinear

function can be differentiated, resulting in two nonlinear equations that are set equal to zero but for which no closed form solution exists. A clever iterative technique tends to converge quickly. In contrast, when the objective of the minimum weighted squared distances is differentiated with respect to the x and y coordinates of the facility, the resulting equations are separable and a simple closed-form solution exists, providing the well-known center of gravity of the points. (For an excellent exposition of the history of continuous problems on the plane, see Wesolowsky's 1993 review.) Similarly, as shown by Vergin and Rogers in 1967, the single-facility location problem in the plane using the sum of rectilinear distances also has a separable objective function and can be solved easily.

As far as center problems (or minimax distance problems) are concerned, the model with Euclidean distances is typically solved by using either the 1972 approach of Elzinga and Hearn or, more efficiently, the methods from computational geometry involving farthest-point Voronoi diagrams. Elzinga and Hearn have also shown that the 1-center problem in the plane with rectilinear distances has a remarkable closed-form solution that results from the reduction of a large linear programming formulation to just four constraints that can be solved graphically.

The solution of planar location problems with multiple facilities requires not only the siting of facilities but also the allocation of customers to those facilities. Here, we typically distinguish between customer choice (or user-attracting) models and allocation models (or delivery systems). In customer choice models, the customers decide which facility to patronize—a system typically appropriate in the retail sector. On the other hand, allocation models are appropriate when the facility planner is also in charge of deciding which facility supplies a given customer. It is quite natural in allocation models for customers to be allocated to their closest facility (except in capacitated models). However, many customer choice models also allocate customers to their closest facility. Such an assumption makes sense only if (1) customers engage in separate trips to the facility and (2) customers are rational (i.e., utility maximizing) planners with utility functions that include only transportation costs that are assumed to be proportional to customer-facility distances. Presuming these assumptions are satisfied, we can define a set J of facility locations, where the point (x_j, y_j) is the location of the j th facility for all $j \in J$. Defining u_{ij} as the proportion of customer i 's demand that is served by the j th facility, the multifacility location problem can then be written as:

$$\begin{aligned} \text{Min } z &= \sum_{i \in I} \sum_{j \in J} w_i d_{ij} u_{ij} \\ \text{s.t. } \sum_{j \in J} u_{ij} &= 1 \quad \forall i \in I \end{aligned}$$

$$u_{ij} \in \mathbb{R} \quad \forall i \in I, j \in J$$

$$x_j, y_j \in \mathbb{R} \quad \forall j \in J$$

where the variables x_j and $y_j, j \in J$, appear only implicitly in the formulation in the guise of the distances d_{ij} .

Except for the case of rectilinear distances, in which the formulation can be solved by a linear programming problem, the problem is NP-hard for most distance functions. Hence, most exact algorithms can only solve problems of moderate size. One interesting approach that uses set partitioning and a form of column generation is due to Rosing. His method first enumerates all feasible partitions of the customers, solving within each of these subsets of customers a single-facility problem. The outputs of these subproblems supply the parameters of the larger problem that is solved as a set partitioning problem. Because the number of partitions is exponential in the number of customers, the approach is probably best used as a heuristic by simply considering only a subset of potentially promising or spatially reasonable partitions of customers. A well-known heuristic is Cooper's 1963 "alternate" method for location allocation. The algorithm switches back and forth between a siting phase and an allocation phase. Many other heuristics exist, including greedy methods and genetic algorithms. Multifacility minimax problems frequently use extensions of the Elzinga-Hearn procedure previously mentioned.

Network Location Problems

Although a few papers on network-based plant and warehouse location appeared in the operations research literature in the 1950s, serious attention to network-based problems was not paid until the middle 1960s. In 1964, Hakimi in a pair of seminal papers investigated the minimum weighted distance location of p facilities on a network of n demand nodes—a problem class he termed the p -median problem. Although he did not provide a solution method for the p -median problem, he proved the existence of at least one optimal solution in which all p facilities are located solely at the nodes of the network. His contribution is similar to that of Dantzig for linear programming in that it reduced the set of optimal solutions from a potentially infinite set to a finite (albeit astronomically finite) set. This result is commonly referred to as Hakimi's theorem or the node property.

Although Hakimi was actually dealing with a wiring problem in electrical engineering, his contribution may be viewed as the first in the line of research that we have referred to as public-sector location. In public-sector location, people's access to publicly owned facilities is optimized subject to a limit on the number of or investment in facilities. In contrast to the p -median problem, which

focuses on aggregate access, the p -center problem on the network seeks the set of facilities that minimizes the maximum distance that separates any demand node from its nearest facility. It is easy to demonstrate that solutions to the p -center problem typically do *not* have at least one solution in which the facilities are all at nodes of the network. That is, centers are usually located somewhere along an edge of the network. As a result, location scientists distinguish between node centers (in which the eligible facility locations may be restricted to vertices of the network) and absolute centers, in which the facility location could be anywhere on the network. It is apparent that the determination of a single node center would require the enumeration of each node as the eligible center. Determining a single absolute center is more involved. In particular, it is the minimum on the upper envelope of piecewise linear concave functions, so that the examination of a finite set of break points is sufficient to determine the optimal solution. The general case of p facility locations is considerably more difficult.

In 1971, Goldman showed that 1-median problems on trees have very simple properties somewhat reminiscent of single-Weber problems with ℓ_1 distances (a result that was independently derived by Hua Lo-Keng *et al.* in 1962). He also showed that 1-median problems on general graphs can be solved by a brute-force search in $O(n^3)$ time. However, no such results are available for the general p -median problem. In fact, Kariv and Hakimi demonstrated in 1979 that the general p -median problem is NP-hard. However, invoking Hakimi's theorem, we know that it is sufficient to search for the optimal solution on the set of nodes. Using this result, ReVelle and Swain were the first, in 1970, to formulate the p -median as a 0-1 programming problem. A variant of their original formulation is:

$$\begin{aligned} \text{Min } z &= \sum_{i \in I} \sum_{j \in J} w_i d_{ij} x_{ij} \\ \text{s.t. } &\sum_{j \in J} x_{ij} = 1 \quad \forall i \in I \\ &x_{ij} \leq y_j \quad \forall i \in I, j \in J \\ &\sum_{j \in J} y_j = p \\ &x_{ij} = 0 \vee 1 \quad \forall i \in I, j \in J \\ &y_i = 0 \vee 1 \quad \forall j \in J \end{aligned}$$

where the locational variables y_j are 1 if a facility is located at node j and 0 otherwise. Here, the allocation variables x_{ij} denote the proportion of the demand of the customer at node i that is assigned to a facility at node j , and p denotes the number of facilities that are to be located; the remaining parameters are as previously defined. To be sure that the optimal solution is truly found requires that the set of facility nodes include not only demand nodes but also empty nodes (i.e., nodes

without demand that are simply network intersection points). These network intersection points are not, however, included in the set of demand nodes I because they do not require assignment.

Among the exact algorithms is a 1993 procedure due to Galvão that employs Lagrangean relaxation and the 1970 linear programming relaxation of ReVelle and Swain. It is also possible to apply iteratively the dual descent techniques developed for the plant location problem in 1977 by Bilde and Krarup as well as Erlenkotter's 1978 dualoc procedure; Daskin, in 1995, provided an insightful description. Among traditional heuristic methods applied to the p -median problem is the 1964 location allocation heuristic of Maranzana, which is actually a contemporaneous nodal version of Cooper's alternate method. Another of the older, but widely known, heuristics is the more powerful vertex substitution technique of Teitz and Bart, reported in 1968. A speedier adaptation of the exchange heuristic was described by Densham and Rushton in 1992. In 1997, Rosing and ReVelle incorporated the exchange heuristic into a metaheuristic known as heuristic concentration, which has performed well, even against Rosing *et al.*'s 1999 tabu search. In 2000, Schilling *et al.* showed that the performance of both exact and heuristic algorithms on p -median problems depends on the extent to which the triangle inequality is satisfied in those problems. Genetic algorithms have also assumed their place in the context of solving p -median problems.

Standing in contrast to the p -median problem, in which the number of facilities is given in advance, is the simple plant location problem (SPLP). In this problem, an unknown number of plants is to be located so as to serve the demand and minimize the sum of transportation and facility costs. In 1965, Balinski provided a formulation that is very similar to the p -median formulation, except for addition cost terms in the objective that represent the costs of opening and potentially operating the facilities. The constraint that requires that p facilities are to be located is absent in the SPLP. Morris, in 1978, and ReVelle and Swain, in 1970, demonstrated through experiments that p -median problems and the SPLPs are integer-friendly, a term used by ReVelle in 1993; that is, their linear programming relaxations tend to have integer or near-integer solutions that require only a few branchings in a subsequent branch-and-bound procedure. Although many have worked on plant location solution methods, (see, for example, Galvão's 1993 report), the methodology that currently reports the best results in SPLPs is that described by Körkel in 1989.

The related capacitated plant location problem is identical to the SPLP, with the addition of capacity constraints on the facilities. Work in this area seems to offer ambiguous results. These additional capacity constraints destroy the property that all demand of a customer is satisfied

from a single facility, making the problem much more difficult to solve.

In 1996, ReVelle and Laporte exposed new and challenging problems in plant location. In 2000, Brimberg and ReVelle offered a solution to one of the many problems posed there, the maximum return on investment problem; however, to a large degree many practical plant location problems remain unsolved.

Although the p -median and the plant location problems, with their aggregate access and cost measures, have occupied a great deal of the discussion in the location community, especially for those interested in algorithms, another line of location thought has grown up, related to these two classic problems but aside from them. In some instances, particularly when emergency facilities are to be located, the concept of coverage may apply to siting decisions. A customer or demand node is said to be covered by a facility if the distance or time between a customer and its closest facility is no greater than a prespecified value of S , the distance or time standard. For example, it may be required that no tract of houses in a municipality be farther than 1.5 miles (or 5 min) from the nearest fire station or ambulance.

To illustrate the models, we again define 0-1 variables x_j , which equal 1 if a facility is located at node j and 0 otherwise. We denote d_{ji} as the distance between the j th facility site and the i th customer. We can then define coverage sets $N_i = \{j: d_{ji} \leq S\}$. The set N_i includes all potential facility locations that can dispatch to and reach customer i within the time standard S . The location set covering problem (LSCP) as introduced by Toregas *et al.* in 1971 and ReVelle *et al.* in 1976 can then be formulated as:

$$\begin{aligned} \text{Min } z &= \sum_{j \in J} x_j \\ \text{s.t. } \sum_{j \in N_i} x_j &\geq 1 \quad \forall i \in I \\ x_j &= 0 \vee 1 \quad \forall j \in J \end{aligned}$$

Although the problem is formally NP-hard, large instances of network-based LSCPs have been solved easily by linear programming and the occasional addition of solution-derived cutting plane constraints. The repetitive application of reduction rules that use the principles of row and column dominance and essential columns, discussed by Toregas and ReVelle in 1973, is usually capable of reducing the size of LSCPs dramatically and even of solving problems *ab initio*. A consequence of the ability of the location scientist to solve the LSCP easily is that the p -center or minimax distance problem on a network with a prespecified number of facilities can also be solved efficiently. In particular, Minieka suggested in 1970 a solution of the minimax distance problem for p given facilities by solving a series of LSCPs with successively decreasing distance or time standard S . As the distance

standards are tightened (i.e., decreased), the number of required facilities remain the same for a number of values and then suddenly increase. At the smallest distance value before the number of facilities increases from p to $p + 1$, the maximum distance from any demand node to its nearest facility is, by definition, a minimum—that is, the p facilities and their positions at this distance value minimize the maximum distance.

The LSCP requires that each customer must be covered, a requirement that is very restrictive. In a problem with many spatially dispersed population nodes, the requirement of complete coverage of all demands may produce solutions with an unrealistic number of facilities. Several possibilities for problem restatement emerge immediately. The first is known as the maximum covering location problem (MCLP), introduced by Church and ReVelle in 1974. Using weights w_i as the number of customers located at node i , the MCLP seeks to locate an economically feasible number of facilities, say p , in such a way that the number of customers covered within the time standard S by the facilities, is the maximum. The reduction rules for the LSCP no longer apply easily, making the MCLP potentially more challenging to solve. Nonetheless, linear programming supplemented by branch-and-bound, greedy, and exchange heuristics have all been applied with success. A thorough review of the application of covering problems from the location as well as other perspectives was offered by Schilling *et al.* in 1993.

Another possibility to get around the complete coverage requirement is to maximize the expected coverage of demand nodes, a problem that Daskin formulated in 1983 and solved. Still a third possibility is to solve the p -center problem given a number of facilities that reflects a realistic budget limitation. That is, in lieu of minimizing the number of facilities needed to cover all the demand nodes within the preset standard S , a realistic number of facilities is examined to determine the value of the smallest distance standard that can be achieved for all demands with p facilities. The problem can also be extended into the probabilistic realm with chance constraints on the reliability of coverage being available within a distance or time standard. Further, multiple types of interrelated facilities may be modeled. A review of location covering problems that apply principally to emergency services was provided in 1995 by Marianov and ReVelle.

Other Location Problems

In this section, we discuss some of the more interesting other location models, focusing on innovative structures, settings, and objectives that have been developed. The concept of undesirable facility locations has already been mentioned. An immediate observation is that, as opposed to minimax and minimax problems, a bounded set is

required, in which the location of the facility is to be chosen; otherwise, the optimal location moves to infinity.

The problems with balancing objectives have also been mentioned. There are very few actual (as opposed to potential) applications of location models with balancing objectives. The main reason for this appears to be the problem of measurement. It is not surprising that the definition of equity does, of course, lend itself to socioeconomic and even philosophical interpretations. Typical equity objectives use the variance, the Lorenz curve, or the Gini index as an expression that measures the equity or inequity of a set of sites.

A simple example demonstrates that equity objectives should be used in conjunction with an efficiency objective. Consider three customers, whose locations form a triangle, in which one angle approaches 180° . The point that optimizes the equality of distances is the center of the circle on whose circumference the three points are located. This point can be very distant. In moving the distant facility toward the three customers, each customer gains in that the customer-facility distance decreases. However, this gain is achieved at the expense of making the three distances more unequal. Equity objectives were discussed by Marsh and Schilling in 1994 and by Eiselt and Laporte in 1995.

Hierarchical location problems occur in many health-care contexts. There are different levels of health care: a doctor's office (or maybe just a nursing station) at the lowest level, a small clinic on the next level, and a full-service hospital at the highest level. Each facility on some level may be assumed to provide all the services of a facility on the next-lower level plus other services. The question is then how to cover as many people as well as possible within feasibility (e.g., cost) constraints. This topic was discussed in 1984 by Narula, and in 1993 and 1994 by Serra and ReVelle.

Hub location problems, an area of research introduced by O'Kelly in 1986, arise in contexts in which customers require transport between a large number of origin-destination pairs. Frequently, it is cheaper for the carrier, albeit more tedious for the passenger, to avoid direct routing between all pairs with traffic demand. Instead, hub networks are assembled that require customers to travel from their origin to a central hub, from there either to their destination or to another hub, and, if to a second hub, then to continue on to their final destination. Hub systems are very popular in the airline industry; a special 1996 issue of *Location Science* was devoted to such problems, and Bryan and O'Kelly provided a comprehensive review in 1999.

Competitive location problems may incorporate not only location decisions, but also pricing decisions as variables in the model. In its simplest form, a competitive location problem seeks the positions and prices that maximize market capture (as measured in

customers or profit) from previously positioned competitors. The field emerged with the Hotelling's 1929 contribution of duopolists competing in a linear market—Hotelling's famous "main street." The possibility of being undercut results in a large degree of instability, as shown by literature surveys by Eiselt *et al.* in 1993, Serra and ReVelle in 1995, and Plastria in 2001. The contributions in the economics literature typically deal with the existence of equilibria, as derived using the tools of game theory. Another approach described by Serra and ReVelle in 1993 and 1994 is the sequential competitive location, in which a leader in the (location or pricing) game is followed by a follower in the game. The earliest analytical location contribution in this area was in 1983 by Hakimi, who termed the locations of the follower medianoids. Medianoids result from conditional location problems, in the sense that the follower takes the locations of the leader as given. Hakimi referred to the leader's location as centroids; the leader of the game will take the optimized reaction of the follower into consideration and protect against it by using a minimax strategy. The first location science solution methodology applied to the siting of the follower was called the maximum capture problem and was offered in 1986 by ReVelle, who recognized capture as a form of covering and defined coverage/capture sets characterized by distance to nearest competitor.

Location-routing problems incorporate the issues of location and routing. For example, consider the simultaneous location of postal relay boxes and the routing of postal trucks for deliveries and pickups. Clearly, as just almost all known routing problems are NP-hard, the addition of a location component does not make them any easier to solve.

We also need to mention *p*-dispersion problems, which do not include any customers but which attempt to locate facilities so as to maximize the shortest distance between any facility and its nearest neighbor. Typical applications of this type of problem are found in the location of franchises, in which the head office attempts to locate its branches so that each can exist comfortably without interfering with the markets of the others.

As previously discussed, location-allocation models typically treat demand expressed at points and serve this demand through point-to-point travel. For many types of service, service stations, fast-food outlets, and automatic teller machines, customer demand does not occur at a point (e.g., the residence of the customer) but along a path (e.g., a customer's daily route to work). The idea now is to capture or intercept as much potential demand as possible. For that purpose, Hodgson introduced in 1990 the flow capturing location-allocation model (FCLM), which serves such demands by locating facilities to intercept them *en route*. He indicated that the model has the structure of the MCLP and stressed the need to avoid flow cannibalization, or double counting,

The model has been adapted by Hodgson and Berman in 1977 to the location of billboards, as well as to vehicle inspection stations. These models were reviewed by Berman *et al.* in 1995.

Outlook

As reviewed by ReVelle in 1997, the field of facility location is very active, with many interesting problems still being investigated, both from a problem statement/formulation standpoint and from an algorithm point of view. Although the field is active from a research perspective, when it comes to applications, there appears to be a significant deficit, at least as compared to other similar fields. One reason may be a preference of researchers for the solitary pursuit of ideas without regard to profit. Related to this preference is the fact that few location packages or turn-key software programs seem to exist. At the same time, it seems possible that the deficit of applications is a consequence of the fact that many of the practical location problems faced by executives and public-sector decision makers are strategic problems, having multiple objectives and structures that do not fall into the relatively easy categories outlined here. One possible way to overcome this barrier is to build more comprehensive, integrated models at the expense of an exponentially increasing complexity of the models and required algorithms. Other, possibly more promising, approaches would be to employ fairly simple subproblems with structures that fit our categories within the context of decision-support systems. Coupled with extensive sensitivity analyses, this approach appears to have potential. However, falling back onto a one-size-fits-all general mixed-integer programming problem may be required in the case of more complex scenarios.

Finally, the dearth of applications may be due to an inability of researchers to communicate results effectively. It is not that location scientists cannot explain what they do but that spatial decisions may demand spatial display. Geographic information systems software, coupled with location models and algorithms and bundled in user-friendly packages, may, in fact, provide the keys to unlock the city's gates.

Locational Decision Making

Daniel A. Griffith

University of Miami, Coral Gables, Florida, USA

Anthony C. Lea

Environics Analytics Group, Toronto, Ontario, Canada

Glossary

agglomeration economy Centripetal forces that encourage the geographic clustering of economic activities; a type of external economy of scale comprising localization economies (e.g., the clustering of special suppliers or customers) and urbanization economies (e.g., the existence in an urban area of inexpensive services such as high-quality water or special garbage disposal), and the minimization of assembly and distribution transport costs for intermediate goods and services.

decision making The act of making a judgment that results in a choice, often based on the use of selection principles and rules coupled with imperfect/incomplete information, and frequently involving computational tools.

economies of scale The quantity of production output increasing more than proportional to the quantity of inputs, resulting in a decrease in the per unit cost of production, especially because fixed costs are spread across more output units of production.

geographic accessibility A measure of aggregate nearness of a given point to a set of points that are important or desirable to be near in a region, taking into account the locational configuration of these points and their interlinkages.

geographic cluster A disproportionate concentration at a single location, or in a relatively small area, of individual objects exhibiting a commonality in terms of one or more attributes.

geographic information system (GIS) Computer software and associated georeferenced data in which the spatial features and their associated attributes are housed in a structured database management system, and in which the software allows users to manage, integrate, edit, manipulate, analyze, display, and map these data to plan, design, and solve problems.

geographic scale The absolute size of a region, often indexed by the ratio between the size of this region on a map and the size of its corresponding segment of Earth's surface, and frequently accompanied by increasing detail with decreasing size.

least-cost location The location where the sum of assembly and distribution transportation costs plus production costs are at a minimum; usually considered to be the optimal location because assumptions are made that effectively hold revenues constant over different locations.

locational advantage A combination of attributes of a location that differentiates it from other locations and gives it a comparative advantage over other locations when a choice is made among them; important attributes include geographic accessibility, resource endowments, and the nature and degree of existing nearby agglomeration economies.

location-allocation model An optimization model, designed to identify the "best" (e.g., minimum aggregate travel distance) single or multiple centralized locations within a region, while at the same time optimally allocating geographically distributed demand (which is to be efficiently serviced) to these selected centralized locations; more sophisticated versions of these models take into account the fixed costs of establishing facilities at the centralized locations, resulting in the optimum number of facilities becoming an additional solution variable.

location rent The economic rent due to a given location's relative positional advantage, with respect to the locations of buyers/suppliers, over the location of the marginal consumer/supplier.

optimal location A location that is better than all other considered or relevant locations, each having a given value for some criterion defining "best" attached to it, in the sense that the criterion function is either minimized or maximized at that location.

spatial dependence The correlation of attributes for nearby locations that arises because of proximity; attributable sometimes to interactions among these locations, and sometimes to geographic influences or factors they share in common.

spatial externality An external economy—or a (joint and nonexclusive) effect unpriced in the market—in an explicitly geographic context, for which a person, firm, or organization is made better off without paying (the full price) or worse off without being compensated (the full expense); common examples are congestion, pollution, and housing price, each of which tends to have a geographically articulated, distance-decaying influence zone.

transportation costs The total of costs incurred when an item is shipped between locations, or a person (e.g., a customer) travels between locations, including a rate per item per unit of distance separating the origin and destination, and associated overhead costs, such as insurance, consular fees, forwarders' charges, and loading/unloading fixed costs.

Locational decision making is the process of evaluating a set of alternative geographic locations, given a certain quantity and quality of information, in order to answer a “where” question concerning the location of homes, stores, businesses, or any type of facility used by individuals or society.

Introduction

Individually and collectively, people frequently must select geographic locations for purposes such as owning a residence, operating a store, and/or visiting a recreational facility, regularly engaging in economic, and sometimes other types of, locational decision making. Their judgments for selecting among alternative locations involve hard copy, digital, and/or mental maps housing geographic information with various degrees of completeness and uncertainty. Locational decision making has been guided through the ages by selection rules based on locational advantage. Prior to urbanization, locational advantage apparently was defined in terms of safety and defense. The rise of cities added commerce and resource (such as water) accessibility to the criterion list. The development of advanced economies in the 18th century extended this list to more abstract economic considerations.

Locational advantage has a different flavor in different contexts. Most commonly, but not exclusively, this advantage is conceptualized in economic terms. A gas station on the corner of two high-traffic streets has a locational advantage as far as access to traffic is concerned. An oil refinery located beside a large oil well has a locational

advantage. A drug store inside of a hospital has a different type of locational advantage. Common to establishing these various forms of locational advantage are specific principles that guide judgments differentiating among geographic locations. These principles exploit prominent geographic patterns and variability, conferring privilege on or disenfranchising particular locations.

The Principle of Optimizing Distance

Geographic distance—the measure of separation between two locations on Earth's surface—may be measured in various ways, including as a great circle distance (i.e., a straight line in relatively small regions), as a minimum path through a network of connections, as the cost (e.g., time, money) incurred to move from one place to another, and as the similarity of attributes. Using this metric, locations can be differentiated with a distance-minimizing, a distance-maximizing, or a min–max criterion.

Distance minimization is often employed when locational decision making involves the selection of new locations from among a set of existing locations, even if these new locations are a subset of the existing ones. Alfred Weber, the German economist/sociologist and younger brother of Max Weber, exploited this principle in 1909 to describe normative (i.e., what works the best, according to some criteria) patterns of manufacturing on a continuous surface. His fundamental idea, extended to general facility location under the heading of the “*P*-median” problem, gave rise to the location–allocation literature, either on a continuous surface or a network. The principal objective function (i.e., a function, associated with patterns, that rigorously defines what is the best) minimizes distance weighted by the quantity of material shipped. Additional selections may require placing constraints on this objective function in order to satisfy criteria such as minimizing the maximum distance of any location from a facility, or minimizing the number of facilities required to serve efficiently some constituency. Maximizing rather than minimizing distance, Walter Christaller (in 1933) and August Lösch (in 1938) exploited this principle to describe the normative number, size, and geographic distribution of urban places. The foundations of their work optimize profits by quantifying sales with a hexagonally truncated concave demand cone in order to determine the spacing of locations.

The seminal work of Johann Heinrich von Thünen in 1826 exploited the distance-optimizing principle to describe normative land use patterns, and as such bridges these minimization and maximization classes of location decision making. The key idea of von Thünen was location rent (LR), or the locational advantage a relatively better positioned producer has over the location of the marginal producer of a commodity. The additional location decision-making input here is the commodity to produce.

von Thünen described the geographic pattern of agricultural production around a market town on an undifferentiated plane. This conceptualization also can be applied to spatially separated markets, yielding the transportation problem, the solution of which renders two types of LR: one is established by the marginal producer and quantifies locational advantage in production; the other is established by the marginal consumer and quantifies locational advantage in terms of the marginal market. Much of what became known as the new urban economics is founded on von Thünen's work, which was extended in the 20th century by the seminal contributions to this literature by William Alonso.

Measures of geographic accessibility—the aggregate nearness of some location to selected other locations—differ from the distance minimizing specifications by using distance as a discounting factor. One simple version of this quantity, called the potential model, derives from the notion of social gravitation and is calculated for each location as a weighted sum of distance-discounted “masses” for all locations. Some versions of this measure then standardize the quantities by dividing by the total of all accessibility measures. This latter specification relates to entropy-maximizing trip distribution models as well as to market-potential models.

Spatial Competition, Agglomeration Economies, and Externalities

The role of spatial competition in locational decision making was first examined analytically by Hotelling in 1929. Hotelling cast the delivered price of a commodity as a function of distance. The increase in price due to transportation costs imposes geographic limits on suppliers, establishing market areas in which one supplier has a clear advantage. A simultaneous mutual attraction between supplier and demander coincides with a mutual dispersal of suppliers, another situation—in which one type of distance is minimized while simultaneously another type is maximized—that links directly to the work of Christaller and Lösch. One outcome is the emergence of spatial monopolies within market areas. Locational decision making involves the selection of strategic locations and results in spatial dependencies, because each locational choice is vitally affected by the positions of competitors.

Agglomeration economies are an important component of locational decision making. Economies of scale (decreasing per unit production cost with increasing quantity of output) are critical to an efficient space-economy. These scale economies can be either internal or external to an organization, with external ones motivating geographic clustering of activities (i.e., agglomeration). Such concentrations bring intermediate

producers together as a way of deliberately minimizing transportation costs. These concentrations also set in motion centripetal forces that attract complementary activities, allowing specialization to emerge. The selection of a location when agglomeration economies prevail may well deviate from that suggested by a purely distance-minimizing criterion. External diseconomies of scale have the opposite impact, setting in motion centrifugal forces that repel activities.

Spatial externalities (unintentional and incidental impacts on the production of one activity by normal actions of another) are also a function of proximity. A given activity generates an externality field, where the maximum effect takes place only at its location, with this effect decreasing as distance from its location increases. Locational decision making here results in the selection of places that allow some activities to transfer costs to other activities without compensation. Positive spatial externalities promote clustering; negative spatial externalities promote scattering.

The Role of Geographic Scale, Hierarchy, and Spatial Dependence

Geographic scale is determined by the ratio of the distance between two locations on a map and the corresponding distance on Earth's surface. Geographic scale refers to the order of magnitude of the size of a regional landscape, and may be illustrated by considering the continuum ranging from the microscale of an individual household location to the macroscale of a continent. Moving across this continuum often involves the geographic (dis)aggregation of locations. The extent of aggregation determines geographic resolution, with relatively little aggregation referring to a fine resolution and considerable aggregation referring to a coarse resolution. Uncertainty in locational decision making increases as coarseness of resolution increases, because less is known about the geography within aggregations. Locational decision making is compromised by increasing scale with decreasing resolution, because the combinatorial nature of alternative location comparisons increases exponentially. Often a compromise is struck between scale and resolution in order to ensure feasibility with reasonable accuracy. The massive amounts of data that emerge with increasing scale also lead to sequential rather than simultaneous selection assessments.

In many instances, spatial organization comprises articulated layers of maps. According to some graded ranking, each location is assigned to a layer, with layers nesting to form a hierarchy. The most publicized geographical hierarchy is that associated with urban places. Two classes of spatial dependencies (nearby things tend to be more similar and more prone to interact) are depicted by this

resilient conceptualization of geographic space, one functioning within a layer, or hierarchical level, and the other functioning between hierarchical levels. Geographic diffusion characterizes these dependencies in terms of contagious and hierarchical components. Trans-hierarchy-level dependencies result in locational decision making needing to take into account geographic scale, with interscale distance possibly being measured as the number of intervening hierarchical levels.

Conceptual Background

Basic conceptual features of locational decision making essential to understanding it are introduced in the following sections. Definitions of notation used throughout appear in Table I.

Descriptive, Predictive, and Normative Considerations

Theories may be classified as being descriptive, predictive, or normative. Descriptive theory seeks to describe a state of affairs, or how something is done or happens. It is the most basic form of theory and the first task of science. Descriptive theories of location focus on a description of a part of reality in which location is celebrated; they describe how people, firms, agencies, and

other organizations select/choose locations. Predictive theory seeks to predict what will happen either in the future or under certain specified conditions. Predictive theories of location are of two broad types: those that predict which locations will be selected and those that predict the impacts on people, firms, institutions, or the environment of a particular location being selected. Normative or prescriptive theory is often viewed as the highest form of theory; it seeks to state what should happen or what would be optimal. Normative location theory seeks to prescribe what the best or optimal location, or set of locations, would be under certain assumptions or conditions.

All three forms of theory (descriptive, predictive, and normative) are valid and have different roles to play. In general, good predictive theory requires or builds on good descriptive theory. Although normative theory can be based on descriptive and predictive theories, it does not require them. Rather, it may simply be a statement postulating that if certain processes are followed and/or conditions are met, then the resulting locations are best or optimal. However, truly useful or applicable normative theory should be based on some principles, norms, or values on which there can be wide agreement. For example, in locating emergency medical facilities, most people would agree that facility locations should be positioned so as to minimize distances or travel times. In recent years, most scholarly interest and research

Table I Symbols Used in Locational Decision Making

<i>Symbol/acronym</i>	<i>Description</i>
α	Store attractiveness parameter in the Huff model
A_j	Measure of the attractiveness of store j in the Huff model
β	Market-specific distance decoy parameter in the Huff model
D	Distance
D_{ij}	The distance separating households area i from store location j in the Huff model
GIS	Geographic information system
LA	Location-allocation
LCL	Least-cost location
M	Market
n	Number of existing locations
P	Number of facilities
P -median	The P th central facility
P_{ij}	Huff model probability of a household from area i patronizing a store at location j
r	The exponent for the Weberian model distance calculation
RM	Raw material
(u_i, v_i)	Cartesian coordinates for demand point i
(U, V)	Cartesian coordinates of the optimal location point
w_i	Weight associated with existing location i
Z	Objective function value being minimized
\sum	Summation notation
$\binom{m}{n}$	The combinatorial number of m objects, taken n at a time, which equals $m! / [(n!)(m - n)!]$ using factorial notation

efforts have been in the predictive and normative forms of location theory. Earlier in the 20th century, more effort was devoted to descriptive theories of location. In the case of normative location theory, much of the work that has been done, especially in terms of determining solutions, falls under the disciplinary heading of operations research, wherein considerable emphasis has been given to algorithms that find or compute optimal locations.

The Entities Being Located

Any physical entities can be the subject of location theory and locational decision making. Indeed, the field of locational analysis and decision making is very wide ranging. Location plays a more fundamental role and is of greater intrinsic interest for certain entities that have been of particular interest to geographers, regional scientists, economists, and planners, who are the ones most likely to study locational issues. Although many location principles relate to all or most types of entities, certain types of entities require slightly different versions or theories. One very distinctive entity is the city or town, and a body of principles and theories has been designed for urban areas. There are some important differences between public entities and private entities (in the literature specific to this field, the words “facilities” or “activities” are typically used instead of “entities”; for simplicity, the word “facility” is used here to refer to what is being located). Public facilities or activities are owned and/or operated by some level of the state. Their locations reflect public decision making that incorporates politics, social welfare, equity, fairness, justice, and other similar considerations. Normative theories of public location are interesting because the focus is on locating facilities in the public interest, which can be defined in many ways.

The largest body of literature and theory relating to location relates to the private sector in Western-style economies. One of the most important features here relates to economic sectors: resource extraction, resource conversion, primary manufacturing, secondary manufacturing, utilities, wholesaling, shopping centers, retail stores, professional services and medical offices, business services, and so on. Most empirical research and theory construction focuses on one or a few of these sectors because the issues involved are often quite different.

Trade-offs between Transportation and Other Costs

In locational analysis and decision making, the costs associated with overcoming space or separation are always important (if they were not, locational issues would be unimportant). The costs associated with overcoming distance go by different names. When goods or materials are

physically moved, the costs are variously called transportation, shipping, delivery, or forwarding costs. Sometimes the organizing firm or agency (the “shipper”) pays these costs, and sometimes the recipient pays them. Who actually pays is an important factor in constructing principles, theory, and decision rules. If shippers pay, and these costs are not incorporated into prices, then buyers or recipients care less about shippers’ locations; but shippers care because poorly selected locations with respect to buyers come with a significant cost penalty. For some types of facilities customers, clients or citizens effectively pay for overcoming space by paying for delivery charges directly—as would be the case for furniture—and indirectly—as would be the case for pizza (incorporated into the price) and for garbage collection (incorporated into property taxes). A very common way end-users effectively pay is via travel costs and time. Most retailing functions in this manner.

Because transportation/travel costs are key costs in location studies, they are often pitted against all other costs. For example, the main costs associated with manufacturing are raw materials, including possible transportation costs, labor, energy, water/sewage utilities, communications, shipping output, and the annualized costs of capital (land, plant, and equipment). Minimum transportation costs suggest that there should be many supply or service locations—in the limit, one for each customer or buyer. But this would be an extreme and inefficient solution. Why? Because building many separate small facilities is often very expensive per unit of “output” compared to a single large facility, which could service everyone. It is not only the facility construction or capital costs that support solutions with fewer facilities, but also production costs. Most production processes and many service processes have economies of scale, or increasing returns to scale. This means that both average and marginal costs become smaller as the scale of the facility or plant becomes larger. Larger scales of facilities mean fewer facilities and larger transport-related costs or travel costs. The trade-off discussed here is in terms of the total costs of a service or production facility, including the travel/transport costs. Sometimes different constituencies pay different transportation costs for their output. Manufacturing plants always pay the production costs and sometimes pay the transport costs. If they pay delivery costs directly, then they are concerned about being close to their customers. If buyers pay these transport costs (directly or embedded in the price), then manufacturers do not trade these off against production costs. Rather, these costs are still important to producers because (1) buyers will buy less because the effective price they pay is higher, and (2) competitors could take advantage of space by locating in such a way as to serve these customers less expensively. All organizations that have, or could have, multiple facilities face these trade-offs.

Seeking Optimal Locations

Organizations and firms that have facility systems do tend to seek optimal locations for one facility or for all facilities that are part of the system. Facilities are built infrequently, and hence the selection of locations at which to build them usually is considered a long-run decision. One exception is traveling units, such as bookmobiles and street vendors (e.g., mobile hotdog carts). Another exception is when the activity in the facilities can relocate to other nonspecialized facilities easily and inexpensively (e.g., automatic teller machines). Relocation is always a possibility but often comes at a very large cost, whether this is in terms of renovating or building custom facilities, lost production time, or lost customer business in retailing. To the extent that facilities last a long time or are specialized, that relocating is expensive, or that location is part of the package being sold (as in designer women's wear), location decisions should be well informed and should take all relevant present and future costs and benefits into account.

In almost all systems of facilities, the optimal location for any individual facility is clearly dependent on the locations of the other facilities. For example, the optimal location of a school, a retail chain store, or a national beer company brewing plant is profoundly affected by the location of other facilities. Interdependence is driven by one or both of these issues. If the customer pays the costs of travel to the facility, as is common, then the facility of choice will tend to be the most accessible or cheapest. If locations are added to the network, then facility usage pattern will be altered and some facilities could be underused and others overused. On the other hand, a facility system that delivers generally finds supplying each customer from one facility to be efficient. The supplying facility is the one that is the cheapest overall supplier for that customer, which usually means it is the one with the lowest transport costs. The addition of facilities changes the best pattern of who gets supplied by which facilities, and this can affect the overall costs of the network. Of note is that, for these problems, the "other facilities" that are part of the system effectively are treated as competitors. In most senses they really are! A customer served from one facility tends to be a customer that is not served from another facility in the same system. Because of facility locational interdependence, the optimum location of facilities in a system is a difficult analytical problem; this has been called the "location-allocation problem."

Optimal locations may be defined in various ways: the consideration may be to minimize costs; to maximize revenues or benefits; or to maximize profits, net benefit, or social welfare. Another important consideration is whose costs and benefits or profits are to be optimized. In the private sector, it is clear that this is the firm. In the public

sector, it should be society, an objective that can be defined and operationalized in many ways. Sometimes the system owner or controller is not aware that locations are being selected to optimize something. But that is just a case of incomplete conceptualization or information. In general, if locations are not optimized in a competitive environment, firms may go out of business in the long run, and certainly forgo profits in the short and long runs.

The true "optimum" must always relate to profit, net benefit, or social welfare because both costs and benefits must be considered simultaneously. Following a long tradition in location theory, a location or system of locations that minimizes costs or maximizes revenues is often considered to be an "optimal location"—even if it is not formally optimal. A location that minimizes costs could be clearly nonoptimal. For example, a location of a brewery at the North Pole would likely have no demand, and hence no production, and no costs. A location or system that minimizes costs must have some constraint on it (usually relating to revenues or benefits) if it is to be considered a proxy for optimal. Examples of constraints are "supply the demand locations with an average price lower than X ," "be within 10 miles of all customers," "revenue from sales must be at least N ," or simply "using a fixed number of facilities." Similarly, constraints are also necessary for maximizing revenue to be considered a reasonable proxy for "optimal." Maximizing revenue can always be done with very high costs—as would be the case in which each customer had her/his own supplier facility located next door. Typical constraints here would be that costs of the system must be lower than X , or the number of facilities must be less than or equal to Y .

Choosing a Single Location

Most of the literature, case studies, and theory relating to location decisions pertain to single locations. For example, the location of a single plant, warehouse, retailer, office, or dwelling is at issue. We seek to understand its location if it exists and seek to predict or optimize its location if it does not yet exist. The extension of this is to multiple locations being considered simultaneously or sequentially; this more complex case is treated in the next section.

Key Variables in the Decision-Making Process

The question being addressed here concerns the identity of the important variables that influence, affect, or help determine locations. A variable can be important descriptively, predictively, or prescriptively. If being near a waterfall on a river is important for a town (as was the case in 18th-century New England), or if being

close to consumer households is important for a grocery store, then this is an important descriptor, a good predictor of location and a good prescriptive variable. The type of entity for which location is being discussed is critical for assessing the importance of variables. Certain variables are more or less important to selecting a location because they influence one or more of the following parameters: direct costs, direct revenues or benefits, indirect costs or via negative externalities, and indirect benefits or via positive externalities. Of note is that some cost- and benefit-type variables do not vary by location. If a variable does not vary over space, it cannot affect locational decisions in that space. For example, because the cost of basic telephone service is constant within most cities, the selection of a location for a house is not affected by this cost.

One of the entities that has had a very long tradition of location theory—the manufacturing plant—can serve as a helpful illustration here. A summary of locational factors considered when selecting a plant location appears in Table II. Many of the variables reported in Table II also are important when locational decisions are made for cities, exhibitions, warehouses, shopping centers, stores, service facilities, offices, public facilities, dwellings, and so on. The variables that are the most important in any particular case are those that either contribute significantly to the costs of running an enterprise or contribute to the benefits of its output, or are those costs/benefits that vary most appreciably over space. For example, steel plants

require a steady supply of iron ore and coal/coke (which are very expensive to ship), a cheap source of power, ready access to lots of water for cooling, and a trained labor source. Being close to buyers is also important because steel is heavy and expensive to ship. The importance of these key variables is strongly affected by production technology. In contrast, the key variables for warehousing seldom are the actual costs of running the facility or skilled labor; rather, they are a combination of shipping costs of goods from manufacturing plants and to stores or final consumers. These principles can be extended to nonmanufacturing locational decisions.

Geographical Scale and the Nesting of Locational Decisions

The selection of “locations” for activities can span geographic scales, ranging from continents, through countries, regions, and cities or markets, to neighborhoods and street addresses or points. The entity and the context of the location decision determine the appropriate scale or scales that must be addressed. International firms or organizations usually start searches for best new locations (or closures) within continents, countries, and regions. They then progress to smaller scales, and eventually particular sites. Sometimes all scales are addressed simultaneously, as when a real estate director has pro forma information on many sites in different countries. For firms that operate

Table II Key Variables Relating to the Location of Manufacturing Plants

<i>Variable class</i>	<i>Variable</i>
Direct costs	Access to/price of raw materials to process, or primary suppliers Cost of shipping to buyers/customers Labor costs Power costs Water/sewage costs General local/regional transport and communication costs Taxes (beyond labor and power costs) Availability of/cost of supporting services (e.g., doctors, lawyers, accountants, insurers) Marketing/advertising costs
Indirect costs	Pollution Congestion Crime
Direct revenues or benefits	Locating close to buyers whose principal considerations are low delivered prices, short delivery times, good service, or a combination of these factors When customers are citizens and the facility is public, the benefit is easy/fast/convenient access to the facility in order to “consume” the good or service being offered there
Indirect revenues or benefits ^a	Urbanization economies—The reduced costs of a wide range of more general services characterizing cities because of their clustering together near the location (a good example is universities) Localization economies—The reduced costs of interacting with a set of specialized suppliers or buyers because they already have clustered together near the location (a good example is offices clustering in order to facilitate face-to-face communication)

^a Indirect benefits are often realizations of low costs for one or more important inputs or services.

in particular countries, regions, or cities, the normal process would be to select locations in only these familiar territories. The decision to expand outside these areas is taken with considerable trepidation. An entrepreneur in a city or region has a very strong incentive to add facilities in local territory because the costs, benefits, and risks are more likely to be known, better understood, and better controlled, and she/he has successful logistics experience there.

The variables that are important in locational decisions vary with the scale being considered. At the international scale, political stability, national government policy, currency value, exchange rates, culture, and language are critical. At intermediate scales, access to markets and the costs of raw materials, transportation, labor, power, taxes, and so on (see Table II) are most important. At local scales, local variables come to the fore. Density of demand, accessibility considerations (e.g., the availability of parking, nearness to public transit stops, and availability of local shopping and restaurants), the security environment, and land costs or rental rates become important. At very small scales (sometimes not considered location problems), other interesting variables become important. The location of a soda cooler inside a store must take into account location of the cash register, the candy displays, the electrical outlets, and available space, for example.

Sometimes the distinctive requirements of a location mean that specific site attributes are more important than country or regional variables are. For very upscale fashion retailers, being located in areas next to other similar retailers is critical. Even if the population and income of a new region appear able to sustain such a retailer—if there is not an agglomeration yet—selecting a location in this situation will be very risky. The location of large new sports stadia in North American cities has been dominated by issues of available unencumbered land, first, and by access or convenience, second. The location of manufacturing is strongly influenced by the availability of highly skilled labor for its industry coupled with a large number of underemployed workers. The selection of large-scale areas commonly affects the types of variables that are important at smaller geographical scales. Selecting rural locations means that access to labor and to adequate supplies of water will be critical. Selecting New York City means that proximity to the subway system and land costs or rent will be critical. In general, the location decision at one scale is strongly affected by the location decision at other spatial scales.

Least-Cost Models and Decision Support Tools

The optimal-location theory literature celebrates the selection of single best locations. As noted previously, there

are effectively three approaches to this locational decision making: (1) cost minimization, (2) revenue or benefit maximization, and, (3) profit or net benefit maximization. For either the first or second to be a good proxy for “optimal,” assumptions have to be made. For example, meaningful cost minimization requires assuming that revenues or benefits are constant.

The premier seminal theory for the cost minimization criterion was proposed by Alfred Weber in 1909. Weber dealt with the problem of selecting the location of a plant with respect to three points—a market and two raw material suppliers. He described the conditions under which the best location would be at one of these three points, and those situations in which the location would be at an interior location. The generalization of the Weber problem from 3 to n points—either material locations or markets—has been a well-known problem in location theory since the early 1960s (and the $n \geq 3$ reference points are no longer restricted to manufacturing-oriented locations). The point location that minimizes the sum of transportation costs in supplying a fixed amount of materials to each of the reference points is known to be the bivariate median location. Its coordinates in continuous space are not easily found; rather, they must be solved for using nonlinear programming. This n -point Weber problem is a key component of the location-allocation problem in which the goal is to locate a set of facilities so that total transportation or travel costs associated with required flows to/from other points are minimized. The continuous space location-allocation problem has been further generalized to discrete space as the problem of selecting the cost-minimizing location, or locations, from a set of predetermined feasible, or available, point locations in a transportation network setting.

Maximum Revenue and the Hotelling Problem

For retail locational analysis and similar applications, a cost minimization framework is not as suitable as a revenue maximization framework. Customers incur the cost of travel; retailers want to locate stores such that sales are maximized. Two common assumptions underlie this perspective: (1) customers patronize the closest store or (2) customers patronize a number of nearby stores, taking into account the attractiveness of a store and its intervening distance, relative to other competing stores that offer the same goods. In the former case, a retailer seeks to maximize the number of people who are closer to his/her store than to other stores; this would be the reference point with a large Thiessen polygon around it. This approach is also consistent with people buying at the lowest price and reducing the amount consumed as the price increases. The classic reference to

demand maximizing location and locational competition is the 1929 work of the famous economist Harold Hotelling, who used the example of two mobile ice cream vendors on a beach with a uniform distribution of bathers. When consumers are pure cost minimizers, each vendor has an incentive to locate immediately beside the other one but on the longer stretch of the beach. Because customers would go to the closest vendor, this locational decision would maximize revenue. But the vendor adjacent to the short stretch of beach has an incentive to relocate on the opposite side of the other vendor in order to secure the longer stretch of beach. Leap frogging would continue until both vendors are located at the center of the beach. And, there they would stay. This is a good example of a situation in which competition would lead to a socially suboptimal result. Customers (society) would be better off if the two sellers locate at the quartiles of the beach length—the average distance traveled would be minimized.

The second, more realistic, assumption also recognizes such factors as people's realistic multiple trip-making behavior (for a wide range of purposes), people's uncertainty about the availability of goods at specific destinations, and uncertainty about traffic. David Huff, writing in 1964, was able to apply the Luce choice axiom (i.e., a rule for calculating the probability that a possible alternative will be chosen) to store and shopping center patronage in a spatial context, using principles of distance and store attractiveness trade-offs—extending the 1929 work of William J. Reilly known as the “law of retail gravitation.” The Huff model generates probabilities of a person or household at location i selecting a retail choice at location j from a set of alternative stores. The alternatives include stores in a particular chain, and all competitors. Attractiveness variables associated with destination store j include measures of store size, visibility, parking, modernity of the store interior, price, and service. Based on this model, a retail trade area is not a Thiessen polygon, nor indeed a polygon at all; rather, it is a surface depicted as a set of concentric rings surrounding a store that represent increasingly lower probabilities of patronage. This spatial interaction type of model can be extended to underpin a good estimate of the expected revenue at a store. An estimate of the total demand available in each customer source area (i) is multiplied by these probabilities and then summed over i to estimate the expected sales of a store at j . To find the optimal location for a new store in a system, a retail location analyst would compute the expected revenue using this approach for all available feasible locations. The one with the highest expected revenue would be the recommended site.

Other types of retail site evaluation models have been perfected as decision support tools. The objective of this type of model is to estimate the sales at an existing store in a network or at a hypothetical new store location. These

models also can be used to estimate the sales effects of dropping either an existing store or a competitor. Similar models can be developed for certain services, offices, and recreational facilities or areas, too. A common and popular tool here is the multiple regression model, the dependent variable of which may be store sales in the preceding year. Independent variables include demand-related surrogates, represented by trade area socioeconomic and demographics; situation variables such as local traffic volumes and number of nearby stores; site variables such as size, age, and visibility of store, signage quality measures, hours of service, and parking places; and, measures of in-store features such as management quality, number of cashiers, and stock depth. Retail companies either build these types of site evaluation models or contract with service firms/consultants who specialize in constructing them. Collecting, cleaning, and structuring the necessary data usually take longer than the time required to calibrate these models. Some retailers also build optimization models that search for best single sites—with a site evaluation model as the engine. Both types of model recently have been embedded into user-friendly software with mapping (geographic information system) interfaces. Users can query what the sales would be at a proposed new location by clicking on a point on a map, then keying the attributes of this site/store into a pop-up window, and finally automatically running the model.

Choosing Multiple Locations

The exercise of choosing multiple locations can take two forms. The first is selecting single locations many times (for example, in sequence; if mutually independent selections of different locations are made, then no new discussion needs to be added to the Conceptual Background section). The second form is selecting, typically at one time, multiple locations where the resulting network functions as a system of interdependent locations.

Key Variables in the Decision-Making Process

With a few important exceptions, the key variables in the locational decision-making process for multiple-location problems are the same as those that are important in single-location decision contexts. If closeness to raw material sources or markets of particular types is important to a single plant, then these factors still will be important when multiple plants are being located. If parking availability or nearness to upscale shopping is important to one store, then these factors still will be important to multiple stores in a chain.

The new variables that become important in multiple-location problems are the ones that capture the interdependencies of locations. These variables are typically not like the variables concerning availability of cheap power, skilled labor, parking, or hours of service. Rather, they are variables such as distance between facilities, and relative closeness to customers or markets. A second type of variable also becomes more important—one that relates to the optimal number of facilities in a system. The key variable underpinning the optimal number of facilities is the trade-off between the fixed costs of production (driving economies of scale) and transportation costs, as is previously discussed. Typically the fixed costs of production (dominated by the costs of land, physical plant, and equipment) are relatively simple matters to account for in single-location problems. If the economic activity to be undertaken is justified, the costs of setting up at least one facility must be incurred. But the overall size and spatial variation in these costs take on an additional importance when designing a multiple-locational system. If fixed costs are relatively low (as, for example, in dry-cleaning storefronts without processing equipment, or ATM banking), then the number of facilities in the system will be relatively large if finished good transport costs or travel costs are important. With more facilities to locate, more possible locations need to be considered, and hence the data collection process becomes more onerous. If fixed costs are high, then economies of scale become a key issue in a trade-off with the number of (small) facilities, and the optimal solution is fewer larger facilities.

Costs related to relative distances and accessibilities are more difficult to conceptualize. Imagine a problem in which there are already three facilities in a city—plants, warehouses, stores, or offices. Why should a search for additional locations avoid the areas close to these three facilities? Additional facilities that ship products to demand points virtually always reduce the aggregate costs of transportation. But if the new facility is close to one of the existing ones, then only small reductions in costs of shipping to customers would be realized. Thus the best locations for new facilities are in areas where they can service customers at a lower cost, compared to the existing facilities. This trade-off is complicated when the location of a new facility can help secure additional customers because the effective delivered price to them is lower than the price charged by competitors. Serving additional customers requires additional capacity, which in turn could lower per unit production costs at existing facilities if economies of scale exist. Possibly the only way of securing the additional customers is by adding additional facilities.

If people travel to the facilities to buy or be serviced there, the reason for spacing out the facilities is intuitive and compelling. Putting facilities side by side fails to capture many new customers (from competitors or a present

state of nonconsumption). A cost-effective strategy is to place additional facilities at locations in which they will capture as many new customers as possible while not cannibalizing existing customers from existing facilities of the store chain. Cannibalization, a critical consideration in multiple-location systems, is not present when locating a single facility—this is the case even if a single new facility is being added to an existing system. In addition, new facilities would greatly benefit by avoiding locations close to strong competitors who would detract from a likely incremental draw. Moreover, in multiple-location systems, distances to other facilities in the system can be as important as distances to suppliers and customers, and to competitors. In systems involving specialized facilities that have to ship to or receive from other facilities, or involving certain service or technical employees who must travel between the facilities, the importance of interfacility distance increases, resulting in a tendency for facilities to be located closer to one another.

Geographical Scale and the Nesting of Locational Decisions

In multiple-location systems, selection of the geographical scale of the system is a very concrete and strategic decision. Because the system is interdependent, its boundaries must be especially clear. If Canada is the appropriate scope for an auto muffler franchise chain, then the whole country must be treated as one system at this scale. If, because of legal or cultural issues, the province of Quebec has to be treated differently, then there should be two systems treated separately. This change in objectives, which is geographically articulated, gives rise to a significant impact on the number of locations and on the specific locations selected. The optimal configuration of facilities in a system clearly depends on the scope of geography being served by the system. Sometimes there are legal, economic, political, or even cultural constraints on the size of the region to be served.

What is the optimum configuration of fire stations to serve a political jurisdiction—for example, a city? If the city in question is one political unit, the locational problem for fire stations is a system-wide problem. If the city contains n political jurisdictions (examples being Minneapolis-St. Paul or the Dallas-Forth Worth areas), then the problem becomes n different unrelated systems problems. In a multiple-jurisdiction situation, many neighborhoods ultimately are served by fire stations that are not the closest facilities to them—because the closest fire station may be in another jurisdiction. The average distance between serving facilities and demand points can be shown mathematically to be larger when there is any division of the overall space into different jurisdictions. The general moral of this story is that anytime a system is divided into smaller autonomous subsystems, the optimal solution

for this system becomes suboptimal in global terms, no matter how the optimum is measured. Moreover, an optimal solution to a larger problem cannot be obtained by optimally locating facilities in smaller subareas first. If the constraints that create subregional systems can be removed, then a good case can be made for doing so. However, there may be sound reasons for having smaller regions. In a political context, smaller jurisdictions tend to be more sensitive to the preferences of common subgroups. In an economic context, smaller markets have more in common, and can be better served with similar packages of merchandise, store concepts, and policies. If smaller regions make sense—taking all matters into account—then locational systems designed for these smaller regions should not be referred to as suboptimal. In general, the optimal number of facilities to serve a region or a market depends on the level of service that is desired and for which customers or people (via governments) are willing to pay.

Models and Decision Support Tools

Multiple-location problems have been well studied, classified, and modeled, and have generated a large body of literature about solutions, formulations, and algorithms. Almost all of these problems/models now are called “location–allocation” (LA) problems/models. A common feature of all of these problems is that the locations of multiple facilities—in a system—are being selected. They have to deal with both the locations of facilities and the allocation of demand points to these located facilities. Describing all of these problems, models, and solution approaches is an impossible task; the literature comprises at least 2500 scientific papers. This literature is remarkably diverse in its disciplinary heritage and scope, and can be found in the journals of operations research, management science, industrial engineering, geography, regional science, transportation science, logistics, applied economics, agricultural economics, applied mathematics, combinatorics, integer and nonlinear programming, and computer science.

Before dissecting these problems, their application contexts merit some comments. These models can be applied to any set of facilities that functions as a system, including manufacturing and processing plants of all kinds, refineries, warehouses, storage and distribution facilities of all kinds, transshipment points that are not warehouses, shopping centers, stores, offices, health care facilities, and kiosks. Furthermore, these models can be applied to any set of public facilities that functions as a system, including schools, hospitals, day care facilities, police stations, fire stations, ambulance dispatch centers, airports, parks, playgrounds, recreational facilities (e.g., tennis courts and swimming pools), and solid waste and other dump sites. The following taxonomic

principles are helpful in formulating discussions of these problems:

1. Types of geographic space in which facilities can be located.
2. The number of facilities as an additional solution variable.
3. Capacity constraints for facilities.
4. Distinctive types of objective functions.
5. Interactions among the facilities being located (e.g., hierarchies of facilities).
6. Static versus dynamic settings.
7. Deterministic versus probabilistic variables (especially demand).
8. Closest facility assignments or multiple facility allocations.
9. Elasticity of demand.
10. Solution procedures.

Types of Geographic Space in which Facilities are Located

Three types of geographic space are discussed in the literature. The first is continuous space, meaning that facilities can locate anywhere on a plane. The location of a single facility to serve a set of n demand points distributed in continuous space is the generalized Weber problem previously mentioned. Each demand point is to be served by the closest facility, and all of the demand points need to be optimally partitioned into n compact subsets, each with its own optimally located central facility. This is the classic and first formally articulated LA problem initially discussed in the literature in the early 1960s by Leon Cooper. The continuous space feature of this LA problem generally is accompanied by the assumption that travel can take place in every direction at the same cost, which is computed as Euclidian distance. Other metrics also have been used, including the Manhattan metric, or city block distance. Advantages of this conceptualization of space include simplicity, classical geometric underpinnings, and solutions based on commonplace mathematics. Disadvantages include that one or more facilities can be placed at infeasible geographic locations. Although extensions to this problem allow solutions to avoid infeasible subareas (e.g., lakes), this complication can be circumvented by employing another type of space.

The second type of space is a network or graph theoretic structure. Demand is located on an explicit transportation network, usually at the nodes, and the service facilities must be located on this network. In 1965, S. Louis Hakimi proved that an optimal solution to the N -facility location problem (known today as the P -median problem) is such that the facilities are located at nodes of the network. Accordingly, the problem becomes one of selecting a subset of n nodes of a network, or vertices of a graph, so

that the total cost of transportation or travel between the demand points and the service facilities is minimized. Demand points in the simple version of this problem are always served by the closest supply points, and transportation or travel distances are computed as shortest paths through the network.

The third type of space is discrete or punctiform in nature. Demand is located at a set of points in a continuous space. The supply points are to be located only at a subset of preidentified points in this space, usually a subset restricted to the demand points. These feasible points may be actually or conceptually the nodes of a network, or points that have been shown to be feasible (e.g., have available real estate) locations. In these conceptualizations (often found in the geography and regional science literatures), distances are typically computed as Euclidian distances (or sometimes Manhattan distances). If network distances are computed, this space is identical to a network space.

The Number of Facilities: An Additional Solution Variable

Whereas the literatures of geography, regional science, applied economics, and mathematics largely deal with the simpler LA problem, the more complex problem in which the number of facilities is also a solution variable is dominantly treated as an operations research, management science, or transportation science problem. The more complex problem has at least a fixed cost associated with establishing a facility; this fixed cost could be uniform or variable across locations. The existence of nonzero fixed costs is sufficient for the number of locations to become a solution variable in the LA problem, primarily because fixed costs are associated with economies of scale. Other forms of cost often are associated with more realistic LA problem formulations, including concave total cost curves characterizing continuous economies of scale. This form of the problem in which the number of facilities is a solution variable is called the “plant or warehouse location problem,” a mixed-integer programming problem with zero/one variables associated with the existence of a facility at a location, and continuous variables associated with amounts shipped between the plants and the demand points. In general, the solution to this problem involves solving a series of subproblems, called “transportation problems of linear programming,” in which the goal is to ship supplies from known supply points to known demand points at minimal cost. One such computationally onerous transportation problem has to be solved for each of a set of combinatorial alternatives featuring a different number of supply points at different locations. In general, the cheapest facility is the facility to serve a demand point. However, if the facilities are capacitated (see the Choosing a Single Location section), then facilities other than the cheapest often must be selected. The key to

solving practical-sized problems of this type, consisting of hundreds of possible supply points, is to be able to “implicitly enumerate” (i.e., not actually do the work to solve or totally enumerate) many solution configurations, and then rule them out because they can be proven to be either infeasible or more expensive than a known solution.

Capacity Constraints for Facilities

Initially, simple LA problems were defined and solved with facilities lacking capacity constraints, the assumption being that these facilities could serve whatever demands were made on them. Indeed, in some contexts the capacity of a facility was planned on the basis of the demands made on it in an LA solution. The existence of modern mixed-integer programming code means that capacitated plant location problems can be solved quite easily by exploiting the framework of the “transportation problem,” which has capacities built into it. A natural extension to this formulation is to select among several differently sized facilities with different fixed costs and different capacities—the “multilevel fixed-charge LA problem.” Although almost all capacitated problems in the literature today are plant location-type problems, an early problem defined in continuous space was an LA problem with capacity constraints on the amount of demand that could be met by each facility. Today, this problem formulation is used for political redistricting or sales territory planning, whereby the goal is to create a set of compact districts with equal populations or demands. The focus in this problem is on the compactness and rationality of territories (assigned to each facility), rather than on the location of central facilities per se (which are merely incidental entities necessary to achieve compactness).

Distinctive Types of Objective Functions

The type of objective function being optimized has a profound impact on a solution. The most common objective by some margin is minimization of all relevant costs. Although appearing to be different conceptually, this is mathematically identical to maximizing revenue or profit objectives. Minimization of all travel or transportation costs alone frequently is referred to as a distance or transportation cost minimization problems. In fact, objective functions can be defined in many possible ways.

Another type of objective emerges in public facility location problems, one that often is nonstandard or requires the use of a proxy for something that is not easily measured. Consider, for example, locating fire stations, hospitals with emergency departments, or ambulance dispatch centers. A reasonable objective for this problem might be to minimize the maximum distance that has to be overcome in the geographic distribution of demand points—known as the minimax LA problem. In other words, the multiple locational pattern should be such

that the distance between the least accessible (“the worst off”) neighborhood and its closest facility is to be as small as possible. The objective is designed to maximize equity or fairness in a geographic context. (Indeed, in the past 20 years, the literature on justice and fairness has tended to use minimax concepts.) This minimax location problem also has been called the M-center problem in a continuous space. The optimal solution can be shown to contain a number of neighborhoods that are tied for being the worse off.

The number of facilities also can be treated as a solution variable. The “location set covering problem” requires finding the minimum number of facilities and their locations such that all demand points can be “covered” within a maximum of D distance units from the closest facility to each. To solve this problem, decision makers first must select a distance D beyond which travel distance is considered to be unacceptable. The number of facilities required clearly increases as this coverage distance D becomes smaller. These problems can be solved with relatively simple linear programming formulations, and typically have a number of different facility location configurations as solutions. Differentiating among these configurations has motivated consideration of supplementary objectives, such as to find the solution that covers as much demand as possible at least twice.

When the goal is to minimize “inefficiency” as the sum of distances traveled or shipped subject to an equity maximum distance constraint, the formulation becomes the P -median problem with maximum distance constraints. If P is given (e.g., as a generalized budget constraint) and D , the maximum distance allowed, is very large and nonbinding, then this extended problem reduces to the simple P -median problem. As D becomes smaller and the constraint becomes binding—to the point where further reductions make the problem infeasible—then this formulation approaches the M-center, or minimax location problem. For intermediate binding constraint levels of D , the problem is truly a mixed-breed problem; but it is still tractable.

Changing the objective to one of locating P facilities in such a way that the maximum amount of demand is included in the coverage distance D renders the multiple facility “maximal covering problem.” As before, D denotes the maximal service distance that is “acceptable.” This formulation differs from the location set-covering problem, in which the objective is to minimize the number of facilities required to achieve a certain coverage. The location set-covering problem frequently is defined in continuous space, whereas discussions of maximal covering problems typically have been defined in discrete or network spaces. The “maximal covering problem” also has been extended to one in which there are additional maximal distance constraints imposed on demand points not covered within the coverage distance D —as a concession to equity. In

this version of the problem, a fixed number of facilities may not permit a feasible solution as D decreases.

Finally, the problem could be to locate some set of facilities that most people consider locally noxious, such as toxic waste dumps and sewage treatment plants, or even hostels for the homeless, halfway houses for former inmates, or psychiatric hospitals. One suitable objective here is to select a fixed number of locations such that the minimum distance is maximized—a maximin solution.

Interactions among the Facilities being Located

The type of facility system that is the optimum for delivering certain kinds of services can be quite complex. Some systems require the optimal locations to support interfacility shipping, travel, and/or communication. Such requirements arise because of specialization of facilities and/or employee positions. Entering interfacility distances or travel costs into most simpler LA problems makes them more complex but not intractable, partly because solution procedures already deal with space efficiently and tend to be interactive so that the locations of facilities in the last iteration can be treated as if they were demand points in the current iteration.

An interesting and practical extension to this problem formulation is one in which the facilities to be located are multilevel. A typical example is a system of both plants and warehouses; these need to be located in a way that will minimize total costs in meeting fixed demands at known locations. Plants must be located by taking real estate costs into account and dealing with distances to both raw materials and warehouse locations. Warehouses must be located by taking real estate costs into account and with respect to both plant locations (for their source of shipments) and the location of the demand points or markets. The literature contains examples of solutions to practical multilevel fixed-cost problems like these. A simple formulation involves using “transshipment problem of linear programming” shipment subproblems instead of transportation problem subproblems in the overall LA problem formulation.

The more intellectually and computationally challenging extension is the “hierarchical location-allocation problem,” which contains several levels of facilities, such as plants, warehouses, stores, and kiosks. Each level of facility might interact only with facilities at adjacent levels in the hierarchy. Thus, for example, warehouses would get all their supplies from plants, and would ship their stock just to stores. The “central place problem” of locating a system of cities, towns, and villages optimally to service a consuming public is a similar problem. Here the consumers travel to all levels of “facilities” rather than to just one (or two). Thus, people will go to the smaller local facility, say, twice a week for milk and

bread; to a larger nearby town, say, once a week for meat and vegetables; and, to the closest but more distant city, say, once a month for clothes and specialty items. These last two complex problems can be formulated as mixed-integer programming problems, and then solved with sufficient computer resources. The multilevel and constrained flows problem is easily accommodated within this problem formulation. The key tractability issue in this case is the number of zero/one variables involved.

Static versus Dynamic Settings

In all of the versions of the location–allocation problem discussed in the preceding sections, the problem is conceptualized as a one-shot static solution—albeit to a long-run problem. Because building a facility system all at once that will be optimal in the long run is extremely expensive, an additional feature of the problem becomes the optimal sequencing of investment over time. If the time horizon is truly long run, a facility system that is optimal for the long run should be determined, followed by solving the optimal sequencing as an independent problem. Sequencing can focus on short-term (i.e., myopic) or long-term (i.e., hyperopic) impacts. In a stagnant situation, the first facility locations optimize the objective function for the current time, having the largest effects across the time horizon. Facilities added in later time periods have smaller effects on the objective function value. This dynamic location–allocation formulation becomes even more compelling if, for instance, demand is projected to grow over time. Although the ultimate configuration of locations is best for the long run, short-run decisions may appear suboptimal when the long-run objective function is being optimized. In contrast, optimization of short-run objective function values could be suboptimal across the time horizon. Although dynamic LA problems were formulated in the early 1970s, only small problems could be solved because they require zero/one variables for each potential facility location for each time period, resulting in a combinatorial explosion in the number of variables as the number of feasible locations or time periods increases. More powerful computers coupled with more efficient mixed-integer programming code allow relatively quick solutions to be obtained today for problems with several hundred feasible locations and up to about 20 time periods.

Deterministic versus Probabilistic Variables

The LA problems described in preceding sections contain no probabilistic components. In reality, many components of these problems should be formulated in probabilistic terms. But probabilistic components are not very interesting if they do not really change a solution. For example, the projections of demand that are (or will be) present at demand points in a system really are expected values based on a selected probability distribution.

Accordingly, if mean values are inserted as the effective demands when optimizing an objective function, solutions are not affected. However, if demand projections inserted are random drawings from the probability distribution, the different sequences can be deemed optimal. Repeating these random drawings many times allows confidence bounds to be attached to optimal facility numbers, facility locations, and overall costs. Other components of the problem have been treated as probabilistic, including transportation or travel costs, fixed costs, and production costs.

Closest Facility Assignments or Multiple Facility Allocations

One of the strongest assumptions in conventional LA problem formulations is that all interactions take place only between demand points and their closest or cheapest supply points. Though typically reasonable for systems in which a single undifferentiated product is being shipped by a facility system owner to demand points, this assumption is not reasonable in many situations in which customers travel to facilities that they have selected. Patronizing retail stores is a case in point. The personal decision of selecting facilities to patronize is a multidimensional behavioral problem that is truly complex. Customers are observed to patronize multiple facilities over a period of time, even for the same category or product. One reason for this behavior is that customers have multiple origins, not just home; for example, they go to stores from work, from grocery shopping, or from dental appointments. Further, traffic can change, for which convenience may suggest different choices at different times of the day. In addition, customers may be simply uncertain about the availability of stores or products at particular locations.

The “allocation problem” can be recast as a non-closest-store behavior patronage problem. For example, a Huff-type model can be used to capture realistic store patronage behavior. In the Huff model, the probability of a customer at a demand point patronizing a store is a function of the distance to this store (relative to other stores) and the attractiveness attributes (e.g., size or hours of operation) of the store. Demand areas are assigned probabilities of patronizing each member of a set of reasonably close stores. In these problems, competitor stores along with their attractiveness attributes are entered into the model as possible choices for consumers even if the model does not attempt to locate or relocate these competitors optimally. The problem becomes especially difficult to solve optimally because it is even more nonlinear in structure than a traditional location–allocation model is. Supply–demand interactions are no longer just zero/one variables. These problems are solvable using heuristic approaches that find very good, although not necessarily optimal, solutions. Retail location analysts have begun

using these types of models to solve what are called “optimal store” or “bank branch” network problems. This formulation typically is used in the context of the P -median problem in which the analyst decides the value of P , as opposed to the fixed-cost “plant location” type of model, which nevertheless offers a reasonable formulation and tractability.

Elastic Demand

In the preceding discussions, even for the Huff-type extended problem, demands points are assumed to be known and constant. Besides the issue of defining these as random variables, two types of situations require that demand levels should be considered variable—in this case, “elastic.” The first situation is one in which the existence of a facility in a neighborhood would cause more money to be spent on the goods sold there than would be the case if people had to travel some distance to buy them. Examples of this include an ice cream specialty store and a donut or coffee shop. Selecting good locations for such stores can cause the total amount spent in a market on specialty ice cream or coffee or donuts to increase. Rigorously specifying the level of total elasticity of demand requires a study to be conducted in one or more markets with significantly varying densities of stores.

The second situation is one in which a system is only partially modeled. For example, the number and locations of existing grocery stores clearly affect revenue expectations when adding new stores to a network. Rather than putting all of the grocery stores in the model as explicit competitors, it is possible to deal with their effects indirectly by building an elastic demand function. In this approach, the amount of demand in a small area that is available for new stores is an inverse function of the accessibility of fixed grocery stores to that demand area. This latter accessibility can be measured using “mathematical potentials” (see the Choosing a Single Location and The Principle of Optimizing sections).

This second type of problem, in which demand is a function of accessibility to fixed facilities, is structurally identical to one with simple fixed demands. It is therefore solvable using conventional LA solution approaches. The first formulation, in which the demand in a small area is a function of distances to the facilities being located, is especially difficult to solve optimally because of the substantial increase in nonlinearities. Nevertheless, fairly robust heuristic solutions (e.g., the vertex substitution approach; see the Least Cost Models and Decision Support Tools section) have been shown to work well in solving these problems.

Solution Procedures

Most location–allocation problems are very difficult to solve optimally—they are combinatorially explosive problems. For example, the number of possible ways

of locating 20 facilities in a subset of 100 feasible locations is

$$\binom{100}{20},$$

or approximately 5.3×10^{20} . Furthermore, many of the problem formulations involve nonlinearities in the objective function, the constraints, or, worse, both. In general, the size and difficulty of a problem are most strongly influenced by the number of feasible locations for the facilities being located. Second in importance is the number of facilities to be located. The number of demand points to be served is typically the least important variable affecting problem size and solvability. Finally, problems in which transportation or travel costs are computed as shortest paths through a network are more onerous.

Geographic Cluster Generators

Sometimes locations are selected on the basis of clustering in geographic space, rather than strictly on the basis of some distance optimization process. Geographic clusters usually emerge from nonlinear relationships, agglomeration effects, or dependencies arising from tangible and/or intangible spatial interactions.

Trade-offs between Economies of Scale and Transportation Costs

A multilocal enterprise seeks to minimize distance to both its input sources and output demand points, while maintaining at least a minimum distance between its individual facility site locations in an effort to prevent self-duplication or overlapping of geographic coverage. But the cost of maintaining multiple sites often disproportionately increases as the number of sites increases. A certain overhead is incurred with each site, intersite communication multiplies disproportionately with more sites, and the enterprise tends to acquire more unutilized capacity as it expands its number of sites. Consequently, a trade-off materializes between benefits attributable to fewer larger, more centrally located sites and those attributable to a more intensive network of smaller sites covering a geographic landscape—a site at every location incurs too much overhead, whereas a single site often has inadequate accessibility. For economic activities, this trade-off has three salient components: assembly costs, production costs, and distribution costs. Reducing fixed costs, such as overhead, per unit of production means economies of scale are being tapped. The number, size, and spacing of site locations to be selected are those for which an increase in sizes no longer reduces fixed costs by more

than accompanying increased assembly and distribution costs, and a decrease in sizes no longer reduces assembly and distribution costs by more than accompanying increased fixed costs. Final sizes determine spacing, and hence the relative number of facilities, through the supply–demand relationship. Mass production requires clustering in geographic space, and as such becomes a standard for selecting among geographic locations.

Agglomeration Economies and Spatial Externalities

Assembly and distribution costs frequently are impacted by a clustering of enterprises. The maxim “the whole is greater than the sum of its parts” describes this situation. When individual entities congregate in geographic space, many of their common requirements can be more effectively and efficiently furnished. For example, a transportation terminal can be operated to service both passenger travel and regional importing and exporting of industrial goods for all of an area’s manufacturers. Agglomerating such transportation needs into a single location results in the terminal being more fully used and prevents the need to duplicate repeatedly a smaller version of the same facility throughout a region. Cost reduction benefits from this type of agglomeration also accrue when specialized infrastructure and ancillary services are needed, encouraging the construction of industrial parks, shopping centers and malls, and housing developments. Increased costs due to increased congestion and an overloading of infrastructure and ancillary services also can exist. The locational decision is whether to gravitate to geographic clusters in a deliberate effort to reduce various types of transport costs that are not offset by other costs.

Activities that are gathered together in space also reap benefits or incur costs from spatial externalities, or spillovers from one site to another that are unable to be internalized by the occupiers of each site. This is a scale economy arising from the size of a geographic cluster, rather than from the size of an individual activity within the cluster—an external economy of scale. One commonly cited example of a positive form of this effect is called “urbanization economies.” These include the spatial concentration of labor forces, educational institutions, research establishments, and cultural facilities, coupled with the dampening impact of large numbers of actors on cyclical fluctuations in local supply and demand. A commonly cited example of a negative form is pollution. These spatial externalities also materialize as localization economies, promoting a clustering of, for example, hospitals, in order to share medical specialists and better utilize expensive equipment; shoe stores, in

order to disproportionately increase patronage through provision of a wider range of selections and a comparison shopping environment; similar housing stock, in order to preserve house prices; and, office activities, in order to facilitate face-to-face contact. In other words, the decision to locate becomes one involving “urban considerations.”

Spatial Dependencies

Spatial externalities are a special case of spatial dependencies, or spatial autocorrelation. Nearby geographic locations tend to have similar attributes associated with them. For example, soil types, geological structures, altitudes, moisture contents, and temperatures for two juxtaposed locations will be similar. Continuity of the geographic distributions of many physical phenomena means common factors generate geographic clustering. Agricultural regions emerge from the clustering of particular farming activities. Spatial interaction is facilitated by nearness, promoting contagious diffusion of everything from ideas to communicable diseases. The existence of a differentiated geographic landscape, in which various chemical elements vary in concentration rather than being ubiquitous and homogeneous, results in hot spots of environmental contamination. And, preferences of households to reside in localities inhabited by other households similar to them create segregated, ethnic neighborhoods. The geographic clustering of similar attributes sometimes furnishes a selection criterion for locational decision making—if a cluster of activities is thriving, then joining the cluster becomes appealing.

The Geographic Information System: A Tool for Locational Decision-Making Support

Locational decision making addresses the problem of finding one or more suitable sites for some activity. Inputs for solving this problem include skilled analysts, georeferenced attribute data, models for evaluating relevant data, and an ability to construct maps displaying the data and enabling identification of potential sites. Many of these tasks can be efficiently and effectively executed with the help of a geographic information system (GIS). This computer software tool supports locational decision making by furnishing an attribute data viewer table, data manipulation facilities, and graphics capabilities for displaying results as layers on a map. A GIS helps guide a decision-making progress—albeit operational, tactical,

or strategic—by furnishing timely access to attribute data, speedy data manipulations, and rapid map updates. The focus is on decision support, not replacement of a decision maker. GIS, in its spatial analysis mode, is applicable to this spatial decision-making context.

Log File Analysis

Casper D. Hulshof

University of Twente, Enschede, The Netherlands

Glossary

frequency analysis A method for log file analysis that focuses on the frequency with which operations are performed.

interaction As used in this article, the interplay between human behavior and feedback generated by a computer program.

log file A sequence of behavioral data, stored on a permanent medium.

protocol analysis A method for obtaining information on cognitive processing of persons who are carrying out a specific task, by having them think aloud.

sequence analysis A method of log file analysis that focuses on the sequence in which operations are performed.

transition analysis A method for analyzing cognitive processing; can be used to classify persons by focusing on transitions in reasoning.

Log file analysis encompasses those strategies that can be applied in order to analyze behavioral patterns. One of the basic assumptions in contemporary psychology is that (invisible) cognitive processes can, in principle, be inferred from studying and comparing types of overt behavior. Log file analysis can be used when the purpose is to infer the cognitive processes of persons who interact with a computer program. Log files can be obtained by a number of methods, such as by having the computer register a person's operations or by having a person think aloud. Subsequent analysis can then be performed in a number of ways—for example, by examining the frequency with which different operations are carried out or by focusing on the sequence in which operations occur. In social measurement, the best results may be obtained by using an experimental design in which a combination of different methods of analysis is applied.

General Description of Log File Analysis

Log file analysis is the systematic approach to examining and interpreting the content of behavioral data. Its goal is to assist in finding patterns in the behavior of people as they interact with a computer. The behavior that people demonstrate while working with a computer program is influenced both by the program (its interface, or how it responds to user behavior) and by cognitive factors (e.g., the expectations and beliefs the user has in mind at any moment). Log file analysis can be applied to gain insight in the way these factors influence behavior. Keeping track of user behavior is of interest in two contexts, practical and scientific.

In a practical context, knowing the interaction style that people pursue while working with a computer program can be of great value. Because the number of people who use the computer on a daily basis continues to increase, human–computer interaction plays a role in an increasing number of areas. The implication is that there are more and more cases in which there is a need for studying the way users interact with a computer application. As the complexity and scope of software packages increase all the time (e.g., updated versions of Microsoft Word always add new, more complex features), not only people's judgment about the usefulness of a computer program and its interface should be studied, but also the way they use computer programs. This leads to insight about features that are preferred and about sequences of operations that are more typical than others. Based on this, a program's interface can be modified to suit the users' expectations and preferences. For a business, it is of the utmost importance that its product, rather than that of competitors, is experienced by users as better and easier to use.

In a scientific context, the way people interact with a computer program is of great interest to social science.

For example, in education, many studies have examined the (sometimes lack of) effectiveness of learning with computers. Although a computer can add value to the learning experience, many students experience trouble in making sense of the computer programs that are used. As has been pointed out by John Sweller and his colleagues, the interface that is used and the way in which information is presented to a learner influence cognitive load, which in turn influences learning effectivity. A large body of research has been devoted to studying the way these factors affect learning. Research on discovery learning with computer simulations has found sustaining evidence about types of support (assignments, model progression, interactive feedback) that learners need. In these studies, both computer-registered operations and analysis of think-aloud data have been used to examine behavior.

Before a system of keeping track of human–computer interaction is implemented, the purpose of measuring user behavior should be determined. Three purposes can be distinguished: supervising, monitoring, and examining interaction. The purpose of supervising interaction is either to keep a constant check on whether a user does nothing that is deemed “illegal” or to guide users through a program, with rigid restrictions on behavior that is out of bounds. Monitoring interaction means being able to interfere with a user’s actions at certain moments, to avoid or minimize the effects of any mistakes. Constant monitoring provides users with a certain level of freedom, but this is limited in order to avoid actions that are considered to be mistakes. Finally, examining interaction means keeping track of the actions without any interference at all. Users experience complete freedom of action while interacting with a computer program. The decision to supervise, monitor, or examine behavior has implications for the method of obtaining log files and storing data on a permanent medium (e.g., the compact disk read-only memory).

Obtaining Log Files

One of the underlying assumptions in research on cognitive processes has always been that these processes are ordered in time, that is, they proceed in a serial fashion (e.g., the modal model of memory). This assumption, which is based on the computer metaphor of thought, links behavioral processes (that overtly proceed in time) with cognitive processes. An implication of this assumption is that cognition can be studied through the behavior that a person exhibits. Behavior that is expressed explicitly—through actions that are performed or through verbal statements that are made during a task—can be measured and subjected to analysis. Interaction can be analyzed either while a person works with the computer

(real-time analysis), or afterward (*post-hoc* analysis). In real-time analysis, what is known to the system is someone’s behavior up to the point in time that the analysis is carried out. An example is the field of intelligent tutoring systems, a goal of which is the creation of suitable learner models. An intelligent tutoring system (ITS) can develop a model of a learner’s knowledge state while he or she works with a computer program. This model consists of all information that can be gathered, and can be put to use to provide appropriate and intelligent feedback.

In a practical sense, it can sometimes be useful to track behavior in real time, without storing it on a permanent medium. This is the case when personal data cannot be stored due to privacy issues, but also when a user’s behavior during just one session with a computer program is needed. As an example, consider the “dynamic menu system,” a software feature that tracks the computer program options that people prefer to use. This feature can be seen in recent versions of Microsoft Office. Available options of the software that are used infrequently will eventually disappear from sight on the menus. The idea is that menus are kept uncluttered by limiting the number of visible options. What should be visible is induced from frequency of use. In this example, it is necessary to track only one thing: the options that are chosen by a user from the available menus. Other operations, such as the text that is typed or the sequence in which different menu options are selected, are not of interest, and should therefore not be registered. Real-time analysis differs from *post-hoc* analysis in that it tries to capture as much relevant information as possible about the human–computer interaction.

A number of methods can be used to obtain log files. Three methods that are most widely used are eye movement registration, protocol analysis, and computer-registered operations. Although different methods can be combined, usually only one type of measurement is chosen.

Eye Movement Registration

Eye movement registration is discussed in detail in the book by Duchowski, *Eye Tracking Methodology: Theory and Practice*. The method entails recording eye fixations while a person is performing a task. Afterward, fixation points can be combined with the things that happened on a video screen. It is assumed that the direction and duration of eye gazes indicate what part of the visual field people are paying attention to, and hence the type of information they are processing. Eye movement registration results in very detailed log files. When a task has a large visual component, eye movements may provide researchers with more information than other methods of obtaining log files would provide. However, interpreting fixations can be difficult, which may deem the method

less suitable for tasks in which high-level cognitive processes are studied. Also, only one subject at a time can be tested using eye movement registration. One implication is that in many practical applications of social measurement (e.g., collaborative problem solving or studying group processes in a classroom), it makes no sense to just measure eye movements.

Protocol Analysis

Protocol analysis (also referred to as the “think-aloud method”) is a popular method for obtaining a detailed report of real-time cognitive processing. The method was made into a coherent system by Allen Newell and Herbert Simon in their seminal work on problem solving; a subsequent overview of the method by K. A. Ericsson and Simon was published in 1993. Obtaining a log file of think-aloud data involves three steps: transcribing, segmenting, and encoding. Transcribing refers to the process of typing in the verbal data. Segmenting a protocol means breaking it down into separate meaningful chunks (or “segments”). Encoding means categorizing each segment and developing a descriptive behavioral model based on the sequence of categories. Interpretation and encoding of a protocol influence each other, which means that the whole process occurs in cycles. However, Ericsson and Simon have noted that segments should be encoded in isolation, that is, disregarding the particular sequence in which they occur. Obtaining think-aloud data is a suitable method when there is interest in higher order cognitive processing, although the segmenting and encoding process involves some subjective judgment.

Computer-Registered Operations

Computer-registered operations is a method that involves keeping track of all interaction, where interaction is defined as all user-initiated behavior that leads to a change, visible or invisible, in the computer program for which the interaction pattern is studied. In practice, this means registering all mouse-button presses and keyboard operations that a user undertakes during a task. The resulting log files usually are extensive, but do not explain people’s reasoning behind the actions they have performed, which makes interpretation a complex affair. An important advantage of the method is that it can be applied to a group of people simultaneously, which can be very practical. This makes the method most useful when the purpose is to get a global overview of the operations that people perform when they interact with a computer program, or when groups of subjects are expected to vary in the activities they display when they work with different configurations of a computer program. When human reasoning is the focus of research,

registered operations may be too ambiguous or shallow to merit a reliable interpretation.

Practical Issues in Registering Interaction

A log file represents a recorded version of the behavior that a person has displayed while working with a computer program. The goal in creating a log file is to store a person’s behavioral pattern in such a way that it can be faithfully “played back” afterward. In other words, it should be possible to reconstruct the sequence of relevant operations from the log file data. Whichever method of obtaining log file data is applied, the result is a sequence of actions that can be subjected to analysis. The following discussion explores the type of information that a log file can contain, and the way this information can be systematically stored. To illustrate how guidelines for storing registered interaction in a log file work in practice, an example case is described.

A number of guidelines can be given for storing interaction behavior in a log file. In addition to user-initiated behavior that changes the computer program, a log file should include information on the type of operations, the time operations take to complete, and the object(s) on which an operation is performed. In logging interaction, a distinction can be made between different types of operations. Some operations change only the “mode” of a program. For example, a word processor could allow the active font to be changed by pressing a button on the screen. This action, which in itself does not have a visible effect, will have a visible effect on subsequent operations. Thus, the type of operation that is performed can be included in a log file. Furthermore, a distinction can be made between operations that take place instantly (the mode operation in the previous example) and operations that take some time to be completed. For example, a drawing program may allow objects to be dragged on the screen. The operation of selecting an object and dragging it to a new destination takes a certain amount of time. Thus, the time that operations take to complete should also be included in a log file. Finally, some operations that are carried out in a computer program are performed on one or more objects. Again, an example is dragging an object to a specific spot. A log file should include not only the operation “drag,” but also the type of object that the operation affects. The application of these guidelines can be illustrated by an example from research by Casper Hulshof on the computer simulation “Optics.” An excerpt from a structured log file is displayed in [Fig. 1](#). Reference source not found,” is displayed. It represents a raw log file, i.e., one that is not yet edited or filtered for specific operations. The excerpt shows a short

Figure 1 Excerpt from a log file (see text for discussion). Adapted from Hulshof (2001).

time sequence in which a number of different operations are carried out with the Optics computer simulation. The program helps students discover properties of geometrical optics. In experiments that were carried out with Optics, students worked individually with the simulation. The method for obtaining log files was computer-registered operations (Fig. 1). As can be seen from close examination of Fig. 1, structure was put into Optics log files by separating different operations. Each operation has a clearly defined beginning and ending; in this case, an easily recognized “@” symbol is at the start of each operation and a dot is at the end. Starting time and (in case of operations that took more than a second to perform) ending time were included with each operation. The mode operation on the second line indicates that a student intended to add a lamp to the simulation, an operation that occurs immediately afterward (at time 492.0). After this operation, the “rotate lightbeam” mode is entered and the direction of the lightbeam is altered. The object on which this rotation operation is performed is included in the log file (the lamp is identified in the log file as ‘lamp3’). In the example, some information about dragging of objects with the mouse was also registered (the “drag” operations). This example shows that a mechanism for registering user operations results in an elaborate and informative log file that conforms to all guidelines. What remains is the actual analysis.

Methods for Analyzing Log Files

To analyze the string of operations that a log file consists of, usually some sort of conversion of the log file to a format that can be processed by tools such as Microsoft Excel or

SPSS is needed. This can be done by applying clever sorting mechanisms in either of these programs, or through a conversion script. For example, the log files that resulted from the studies with Optics (as shown in the example in Fig. 1) were converted to SPSS-readable format through the use of a program script written in Practical Extraction and Reporting Language (Perl, for short). Not only are there no generally available algorithms for converting log files to files that can be processed, nor are there as yet general guidelines for analyzing log files once they are processed. Studies in which log files were obtained have usually applied their own type of log file analysis method. When a log file is examined, at first operations may appear to follow each other in seemingly random fashion. Analysis means probing for regularities or patterns in the string of operations. Different strategies can be used to discover regularities, which differ in complexity and in the way results are interpreted. Some methods can be applied to a single log file; for others, a number of log files should be available for analysis. In the following overview, four general methods are discussed: transition analysis, frequency analysis, learning indicators, and sequence analysis. An outline for a fifth method, which combines frequency and sequence analysis, is briefly discussed.

Transition Analysis

A simple yet powerful way to draw conclusions from people’s behavior is to examine whether some typical transition in behavior is displayed. This mechanism can be applied to classify persons based on only one distinguishing action. An example is a study on the process of discovery. In the study, the distinction between two strategies in rule discovery (experiment or hypothesis based) was grounded in the way subjects came up with the correct rule: either by using an experiment that pointed in the right direction or by just coming up with the idea to change the frame of reference. The defining transition in this case is the frame shift that occurs: either doing an experiment in a new “space of experiments” and reaching the right conclusion (the experimenter approach) or reaching the right conclusion without having done any experiments in the “right” space of experiments (the theorist approach). The discovery study was designed in such a way to allow for a careful distinction in the way a transition occurred. The dimensions of the experimental domain were relatively small, which means that all operations within the domain could be fully described as occurring at a specific location in the experimental space. Other studies make use of domains in which there are many variables with complex relations; it is impossible to describe fully the experimental domain or to describe formally one defining transition that differentiates between subjects. Domains in which it is possible to observe

the kind of transition as in the discovery process study appear to make up the most appropriate setting for this type of analysis. Other domains need a more complex type of analysis.

Frequency Analysis

Frequency analysis is a generic method of analysis that is used not only in studies that apply to social measurement but also in studies in many other scientific fields. Because it has always been so widely used, the method is usually not acknowledged when it is used, in contrast to other methods of log file analysis. The reason for its popularity is that it provides a simple way to measure quantitative aspects of behavior. Groups of subjects can easily be compared using a variety of standardized statistical tests. However, frequency analysis can also be used to examine the interaction pattern of a single person. In such a case, the relative frequency with which different operations are performed supplies most information.

Performing a frequency analysis means tallying the frequency with which each operation occurs. In the case of protocol analysis, segmented codes are counted. Different statistics, e.g., averages and standard deviations, can be computed for each operation. These averages can be compared (for example, to examine which operation has the lowest occurrence and which one the highest). Depending on the questions that a researcher has in mind, statistical tests can be performed to compare the frequencies of specific operations.

Although frequency analysis is relatively easy to perform, it has its drawbacks when used as the sole method of log file analysis. This is most evident when a comparison between two or more subject groups is made. When no difference is found in the frequency with which different operations are carried out, it can easily be concluded that the groups generally interacted similarly with a computer program, and experienced working with the program in a similar way. But do they? Frequency analysis tends to “even things out,” which means that the interesting variation in the level of activity that people show is filtered out of the equation. Also, although the overall level of activity may be similar, the reasons people have for acting the way they do may be completely different for different groups. Intentional problem-solving behavior in one group may look similar to random guessing in another group, when only frequencies of operations are compared. When a theoretical research question predicts differences in the behavioral pattern of different groups of subjects, it may be sensible to perform more than just frequency analysis.

Learning Indicators

The learning indicator approach can be seen as an offshoot of frequency analysis, and has similar advantages

and disadvantages. The method consists of constructing clusters of operations that roughly occur roughly with the same frequency. An example of this approach to studying behavior is the Smithtown study by Shute and Glaser in 1990. Smithtown is a computerized learning environment. Shute and Glaser were able to derive global learner differences on the basis of learner interaction measures. The analysis that was pursued focused on the large-scale extraction of clusters of interaction patterns. The method was to take operations together (these operations were called “learning indicators”) to distinguish between global processes that take place during learning. The learning indicators were derived from both log files and protocols, by clustering similar operations. Based on this analysis, three types of broad “rational categories” were distinguished: a general activity level (e.g., total number of experiments), data management skills (e.g., total number of notebook entries), and thinking and planning behaviors (e.g., number of variables changed per experiment). The approach by Shute and Glaser can be summarized as involving (1) counting frequencies of actions, (2) categorizing them into meaningful units, and (3) making comparisons across groups. This approach can be helpful to compare groups of subjects at a global level. However, as in the case of frequency analysis, it can also be a misleading approach, because differences between learners can even everyone out. When students of high and low competence are compared, other factors (e.g., prior knowledge about the domain) may influence interaction with a computer program.

A main disadvantage of both frequency analysis and the learning indicator approach is that they both ignore the way behavior changes or progresses over time. A broad overview of the activity level of subjects does not provide answers with respect to the reason for any differences. For this, analysis of the sequence in which operations occur may be a more appropriate method.

Sequence Analysis

Frequency analysis looks at user-initiated operations as isolated events. When interaction with a computer program is studied, it is not very realistic to assume that each operation that people perform is not connected in any way to the operations that come before it and after it. As Bakeman and Gottman have argued, interaction “reveals itself unfolded in time.” This implies that the information that is contained in the sequence of operations may be just as meaningful as the information contained in the overall number of specific operations. (The mathematical and statistical details of sequence analysis cannot be discussed in detail here, but an introduction to the topic of sequence analysis can be found in the work by Bakeman and Gottman.) The purpose of sequence analysis is to examine the connection between operations as they occur over

time. Such an analysis is performed by computing, for each possible operation, the probability of that operation following or preceding each of the other operations. An advantage of sequence analysis over other types of analysis is that it takes account of interaction as it occurs over time. Sequences of operations that occur together are recognized as such. This creates the possibility of inferring from a log file, to some extent, a user's intention in performing certain behavior. When looking at different phases of working with a computer program, sequence analysis may also reveal the type of operations a user focuses on in the beginning (when not everything about the computer program is known) and at the end (when knowledge about the program has been acquired). In spite of these advantages, sequence analysis is used only infrequently in social measurement. This has both a practical and a theoretical reason. From a practical point of view, sequence analysis is difficult to perform. Standard statistical software packages usually have only limited functionality for computing sequence probabilities. Also, the level of expertise needed to understand and interpret p -values of sequences may pose a barrier for researchers with basic statistical training. From a theoretical point of view, there is a risk in performing a sequence analysis, because it may lead to a misinterpretation of operations that appear to occur after one another. Because sequence analysis looks at the probabilities of each operation occurring before and after the other operations, there is a high chance that "noise" will lead to a significant probability. Separating relevant from irrelevant patterns of behavior can be a complex affair, for which no standard method exists yet.

A Different Approach: Finding Patterns in Variable Manipulation

Each of the four methods of analyzing log files that have been discussed has its own advantages and disadvantages. In this section, a method of analysis that combines frequency analysis with sequential analysis is outlined. The idea is that by taking advantage of the strong points of these two methods, another type method for analyzing log files can be constructed. The underlying idea is that the relevant operations within a computer program can be seen as consisting of the manipulation of variables. A variable is here defined as anything in a computer program that changes, by manipulation by a user or by manipulation by the computer program. Manipulating variables means that users apply a change to one or more parameters in a computer program, and then observe the effect of these changes. When defined this way, three types of variable manipulation can be distinguished: single, alternating, and sequential. Single manipulation means that a variable A is changed a number of times. Alternating variable manipulation means

Table I Variable Manipulation and Possible Intended Behavior

<i>Manipulation type</i>	<i>Possible goal</i>
Single	Effect of variable A
Alternating	Relation between A and B
Sequential	Exploring available options

that, first, variable A is modified, then variable B is modified, then A again, and so on. Sequential manipulation means that available variables are all changed, one after another. In Table I, the three types are shown together with the possible goal that can be inferred from that type of manipulation.

When variable manipulation is used as a starting point for analyzing a log file, frequency analysis can be combined with sequence analysis. The idea is to combine the variable manipulations that a computer program allows into meaningful sequences that conform themselves to one of the three types of variable manipulation, as shown in Table I. It is important to note that this construction of meaningful sequences can be done at a stage of research when no log file is yet available. Also, the sequences that are defined are different for each computer program with which interaction is studied, because they depend on the way variable manipulation is implemented in a particular computer program. Once sequences are defined, the frequency with which they occur can be computed by analyzing log files. The frequency of different sequences of variable manipulation gives information on the different goals that people pursue while they work with a computer program. This method of computing frequencies of sequences does not require sophisticated techniques, so that it can be performed within standard statistical software packages. The outlined method combines some of the strengths of the other methods, but it is unlikely that it could completely replace them.

Conclusions

Log file analysis is a powerful tool for gaining insight into the cognitive processes that underlie behavior—specifically, interaction with a computer program. Obtaining a detailed record of interaction can be achieved relatively unobtrusively through a number of different methods, and resulting log files can be structured in such a way that different methods of analysis can be applied. Each method has its own advantages and disadvantages. An analysis method that uses types of variable manipulation as a stepping stone to combining frequency analysis with sequence analysis has been outlined. There is room for the development of new analysis methods or improved schemes for the classification of interaction behavior. It

is clear that in log file analysis the problem is not so much one of collecting interesting information on the type of operations that are performed, as it is one of inferring people's intentions in carrying out these operations in the first place. At least protocol analysis allows users to state clearly their intentions while interacting with a computer program. In conclusion, the strongest experimental design may be created when the behavior of a limited number of subjects is measured using protocol analysis, in combination with a large-scale measurement of computer-registered operations. In such a research design, the power and elegance of statistical analysis of registered eye movements or computer-registered operations can be used in conjunction with the depth and thoroughness of protocol analysis.

Log-Linear Models

Peter K. Dunn

*University of Southern Queensland, Toowoomba,
Queensland, Australia*

Glossary

contingency table A table in which individuals are cross-classified as belonging to particular levels of various factors.

factor A variable for which the individuals are classified into one of many categories.

level One of the categories of a factor into which an individual can be categorized.

Poisson distribution A statistical distribution used to model counts.

treatment coding A method for converting the levels of a factor into a numerical variable for inclusion in a mathematical model.

A large amount of data collected in the social sciences are counts cross-classified into categories. These counts are nonnegative integers and require special methods of analysis to model appropriately; log-linear models are one sophisticated method. The counts are modeled by the Poisson distribution, and related to the classifying variables through a logarithm. Models can then be built, critically analyzed, evaluated, and compared to develop a suitable statistical model for modeling the count data. Log-linear models are powerful enough to cope with many classifying variables, and permit many model-building ideas similar to those in standard statistical regression.

Introduction and Background

Log-linear models (also written as log linear models or loglinear models) are analysis tools for modeling counts cross-classified into categories. Initially, count data itself is discussed.

Classifying Count Data

Count data can be cross-classified by a number of variables; for example, Gender (with values “male” or “female”) and Employment Status (with values “employed,” “unemployed,” or “not in workforce”). Both of these variables are categorical variables, also called *factors*: the values of the variable refer to the different classifications (in contrast to numerical measurements). Gender has two levels or categories; Employment Status has three. Categories must be both mutually exclusive (no observation can appear in more than one level of each factor) and exhaustive (any individual must belong to one of the given levels for each factor).

Noncategorical variables, such as Age, may be coerced to factors. For example, ages may be classified into the categories “Under 20,” “20 to under 35,” “35 to under 50,” and “50 or over.” (Note the categories are mutually exclusive and exhaustive.) Some noncategorical variables have so few possible values they are often considered categorical; for example, the number of political party memberships currently held is a numerical variable. However, this (numerical) variable could be treated as categorical with levels “0,” “1,” and “2 or more.”

Types of Factors

Factors can be identified as either ordinal (or ordered) or nominal. The levels of a nominal factor can be ordered in any convenient way. University faculties can be listed alphabetically, by size, or by some other criteria; there is no natural ordering. An ordinal factor implies the categories have some natural order. Examples include smoking habits (“do not smoke,” “light smoker,” “heavy smoker”) or opinions rated on a Likert scale (“strongly disagree,” “disagree,” “neutral,” “agree,” “strongly agree”). Specific

models for ordered factors are available but are beyond the scope of this article. In general, ordinal factors can be adequately treated as nominal factors.

Displaying Data

Conveniently, counts can be displayed in a contingency table; see [Table I](#) for example. There are four factors: Age (say A) is an ordered factor on three levels, Depression Level (D) is an ordered factor on two levels, Label (L) and Gender (G) are both nominal factors on two levels. The data form a $3 \times 2 \times 2 \times 2$ table, with $3 \times 2 \times 2 \times 2 = 24$ cells.

None of the totals in this table has been fixed beforehand: selected subjects are just classified according to their age, label, gender, and depression level. Tables may, however, have some totals fixed (for example, a fixed number of males and females are interviewed, or a fixed total number of people are interviewed). Fixed totals are not variables, which has implications for the model fitting but is beyond the scope of this article. Briefly, those parameters referring to fixed totals must be included in the model.

Purpose

It is difficult to grasp the connections between levels of each factor, especially for large numbers of factors, when the data are presented in a contingency table. Log-linear models are used to examine associations among levels of categorical variables. As in any modeling exercise, the analyst is searching for the simplest model not contradicted by the data. In some special cases it may be possible to summarize the data by collapsing the table over one of the factors.

Table I The Number of Seriously Emotionally Disturbed (SED) and Learning Disabled (LD) Adolescents Classified by Age (A), Gender (G), and Depression Level (D)

Age (A)	Label (L)	Depression (D)			
		Males		Females	
		High	Low	High	Low
12–14	LD	79	18	34	14
	SED	14	5	5	8
15–16	LD	63	10	26	11
	SED	32	3	15	7
17–18	LD	36	13	16	1
	SED	36	5	12	2

Note: The data are from Maag, J. W., and Behrens, J. T. (1989). Epidemiologic data on seriously emotionally disturbed and learning disabled adolescents: reporting extreme depressive symptomatology. *Behav. Disorders* 15, 21–27.

The Model

The counts in a contingency table are assumed to be possibly related to the factors by which they are cross-classified; the interest is in quantifying this relationship. (A contingency table with one of the factors on two levels may also be modeled using a logistic regression model.) The two most important aspects of the log-linear model considered herein are the underlying assumption of a Poisson distribution for the counts, and the logarithm which relates the factors to the counts.

The Poisson Distribution

In the log-linear model considered here, the response variable is the number of observations, say y_i , in each cell i of a contingency table. The data are non-negative integers; an appropriate distribution for modeling counts is the *Poisson distribution*. For a given cell i with mean μ_i , the Poisson probability function is

$$f_Y(y_i; \mu_i) = \Pr(Y = y_i) = \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!} \quad (1)$$

for $y_i = 0, 1, 2, \dots$ and $\mu_i > 0$. For the Poisson distribution, the mean equals the variance; that is, $\mu_i = E(Y_i) = \text{var}(Y_i)$.

Coding of Factors

Before fitting a log-linear model, the classifying factors need to be coded numerically; additions and multiplications cannot be performed on a factor level “male.” A factor with k levels is coded into $k - 1$ binary variables (variables that take only two values, often 0 and 1), called *dummy variables*.

Many coding systems exist (and are sometimes called *contrasts* under special conditions). One of the simplest is treatment coding, described next.

The factor Gender has two levels and requires one dummy variable. This dummy variable could code 0 for females and 1 for males (or 0 for males and 1 for females). These numbers are merely identifiers. Similarly, coding “female” as 1 and “male” as 2 does not imply males are in some way twice the value of females; the numbers merely identify the levels of the factor.

For the [Table I](#) data, the factor Age has three levels; two dummy variables are needed. Define variable A_1 as 1 for subjects 15–16 years of age, and zero otherwise; define variable A_2 as 1 for subjects 17–18 years of age and zero otherwise. The age group “12–14” is called the *reference*, or *baseline* category. Age group “12–14” is assigned the codes $A_1 = A_2 = 0$; age group “15–16” is assigned the codes $A_1 = 1$ and $A_2 = 0$; age group “17–18” is assigned the codes $A_1 = 0$ and $A_2 = 1$. Thus Age

(A) has been unambiguously coded numerically using dummy variables A_1 and A_2 for incorporation into the mathematical model. Similarly, code L_1 as 1 for the SED label, and zero otherwise; G_1 as 1 for males, and zero otherwise; D_1 as 1 for low depression, and zero otherwise.

The Logarithm Link

In log-linear models, the counts in each cell are assumed to follow the Poisson distribution. In addition, the mean of the distribution in each cell is perhaps related to the classifying factors. After appropriate coding, the factors in Table I are then related to the Poisson mean in each cell through

$$\log \mu_i = \beta_0 + \beta_1 A_1 + \beta_2 A_2 + \beta_3 L_1 + \beta_4 G_1 + \beta_5 D_1, \quad (1)$$

where the parameters $\beta_0, \beta_1, \beta_2, \dots$ are values to be estimated, and A_1, A_2, L_1, \dots are the (dummy) variables. (The log function is the natural log with base $e \approx 2.71828 \dots$) This equation gives rise to the name “log-linear models,” as the model is linear on the logarithmic scale. Technically, the logarithm is called the *link function* in the nomenclature of generalized linear models. Equivalently, but more concisely, the right-hand side of the model can be written as $1 + A + L + G + D$.

Equation (1) can be rewritten as $\mu_i = \exp(\beta_0 + \beta_1 A_1 + \beta_2 A_2 + \dots)$; thus the logarithm ensures the Poisson means μ_i always remain positive. Using the log implicitly assumes the factors have a multiplicative effect on the response, not an additive effect. (Equivalently, the effect of the factors is additive on the log-scale.)

Fitting the Model

Log-linear models have a firm theoretical foundation and established fitting algorithms as they are a subset of generalized linear models. Iterative algorithms such as iteratively reweighted least squares (IRLS) are used to fit the models; the algorithms are quite robust. Most statistical software has the facility to fit log-linear models.

Interactions

The model that considers only the effect of each factor on the counts is called the *main effects model*; this models the numbers of observations in the totals for each factor level. For example, the model only incorporating the factor Gender would model differences in the number of observations for each level of Gender. This is of limited interest; of more interest are the interactions between the factors.

Commonly, the levels of the factors interact with each other. For example, interaction between Age and Gender in Table I would indicate how the proportions of males and females differ across the age groups. This interaction is written using as $A:G$. Since Age has two dummy variables and Gender has one, the interaction is specified by $2 \times 1 = 2$ dummy variables.

Zero Counts

The presence of zeros, or of many small counts, in a contingency table can adversely affect parameter estimation. Two types of zeros exist. Structural zeros refer to necessarily zero counts, such as the number of males receiving a hysterectomy. These cells should be discarded from the analysis.

Sampling zeros are counts that are not necessarily zero; a larger sample may produce counts for those cells. Because these cells contain legitimate counts, they should not be discarded. Some authors recommend adding $1/2$ to each count in a table with zeros and/or small counts. Alternatively, some factor levels may be combined if possible and sensible (for example, combine “strongly agree” and “agree” into one category “agree”).

Model Criticism and Comparison

The process of building a suitable log-linear model for given data is an art as much as a science. In a typical contingency table with more than two factors, numerous models are possible. Each must be evaluated and compared to find a best model. Some evaluation criteria are discussed below.

Residual Analysis

The differences between the observed counts y_i , and the expected (modeled) counts μ_i are an indicator of the adequacy of the fitted model. Using the Poisson distribution implies the mean equals the variance, implying large difference are more likely when μ_i is large compared to when μ_i is small. (That is, a predicted count of 3 is unlikely to be in error by as much as 10, but is reasonable for a predicted count of 2000.) Thus, the residuals must be scaled appropriately. The Pearson residuals are therefore defined for the Poisson distribution as

$$r_{P,i} = \frac{y_i - \mu_i}{\sqrt{\mu_i}}.$$

Alternatively, deviance residuals can be used, defined for the Poisson distribution as

$$r_{D,i} = \text{sign}(y_i - \mu_i) \sqrt{2[y_i \log(y_i/\mu_i) - (y_i - \mu_i)]}.$$

(The function $\text{sign}(x)$ is 1 if $x > 0$, is -1 if $x < 0$, and is 0 if $x = 0$.) Both types of residuals should have approximately a normal distribution.

Overall Measures of Discrepancy

Residuals indicate how well the model fits for each observed count. It is useful to also have an overall measure of discrepancy for the model. The X^2 statistic for a table of n cells is defined as

$$X^2 = \sum_{i=1}^n r_{P,i}^2 = \sum_{i=1}^n \frac{(y_i - \mu_i)^2}{\mu_i}.$$

Similarly, the deviance can be defined as

$$D = \sum_{i=1}^n r_{D,i}^2 = 2 \sum_{i=1}^n y_i \log(y_i / \mu_i) + (y_i - \mu_i).$$

This form of the deviance but without the term $(y_i - \mu_i)$ is also known as the G^2 statistic.

The deviance is actually related to the log-likelihood for the Poisson distribution, and is often defined as

$$D = -2 \sum_{i=1}^n \log f_Y(y_i; \mu_i),$$

where $f_Y(y_i; \mu_i)$ is the probability function for the Poisson distribution defined in Equation (1). For any given data, the two forms of the deviance differ only by a constant. Hereafter, the second form will be used.

Approximately, the change in deviance between nested models has a χ^2 distribution; often this approximation is poor. (Model 1 is nested in Model 2 if Model 2 has all the parameters fitted in Model 1, plus additional parameters.) Hence, significant changes in the deviance are identified by comparing the change in deviance to the appropriate χ^2 distribution.

For both X^2 and D , smaller values indicate a better model. However, a model having both X^2 and D equal to zero, indicating a “perfect” model (see the Example), can be created simply by adding more classifying factors and interactions. Typically, this model, called the *saturated* or the *full* model, is unnecessarily complicated; a simpler model may be just as useful. The Akaike Information Criterion (AIC) addresses this difficulty. It is defined as $AIC = D + 2p$, where p is the number of estimated parameters in the model. The AIC penalizes the deviance by $2p$ to discourage the inclusion of unnecessary parameters. (Other similar criteria also exist with different penalties.) The best model has the smallest AIC.

Model Building

Sometimes, prior information (either theoretical or otherwise) may be used to propose the preferred log-linear

model, or at least a set of possible models. However, it is also possible to have no prior expectations of the model. In either case, many possible models may exist for modeling a contingency table with many factors. As stated earlier, models may be compared using the deviance.

Consider Model A with p_A estimated parameters and deviance D_A , and Model B with p_B estimated parameters and deviance D_B . If Model B is nested within Model A, $p_B < p_A$ and $D_B \geq D_A$. Then $(D_B - D_A)/(p_A - p_B)$ has approximately a χ^2 distribution on $p_A - p_B$ degrees of freedom (df).

Important factors (and interactions) may be identified in two ways using the above ideas: by adding terms to a main effects model sequentially, or by removing terms from a saturated model sequentially. The two methods may produce a different set of important factors.

Over- (and Under-) Dispersion

Using the Poisson distribution for the counts implies the mean of the counts equals the variance. Commonly, the (estimated) variance is larger than the (estimated) mean; this is called *over-dispersion*. *Under-dispersion* is less common in practice.

The degree of over- or under-dispersion can be estimated using the Pearson estimator $\hat{\phi} = X^2/(n - p)$ or the mean-deviance estimator $\hat{\phi} = D/(n - p)$. An estimate greater than 1 indicates over-dispersion, and an estimate less than 1 indicates under-dispersion. Serious over-dispersion results in inflated standard errors, and inferior inference.

In the case of over-dispersion, a negative binomial distribution may be of use. Discussion of this model is beyond the scope of this article.

Model Interpretation

It is often difficult to find an interpretation for a log-linear model, though some useful interpretations exist for two- and three-factor models. A table may be collapsed to aid understanding and interpretation; rather than use, for example, a $3 \times 4 \times 2$ table, there may be no information loss to consider the equivalent 3×2 table. This must be done with great care: in a three-factor case, a collapsed table cannot be formed unless at least the three-factor interaction and one two-factor interaction is unnecessary in the model.

This implies that a contingency table with more than two factors should not be analysed by considering each two-factor table separately.

Example: Fitting a Model

Consider the data in Table I with coding as defined above; numerous models are possible. Initially, however, it is

Table II Predicted Values, Deviance (D), Number of Estimated Parameters (p), and the AIC for Five Log-Linear Models Fitted to the Data in Table I

Count	Predictions from the models				
	M1	M2	M3	M4	M5
79	77.5	81.1	76.2	77.1	79
18	20.4	16.8	18.8	19.1	18
34	37.3	33.7	31.9	31.2	34
14	9.8	13.4	18.0	17.6	14
14	17.1	17.9	16.8	15.9	14
5	4.5	3.7	4.2	3.9	5
⋮	⋮	⋮	⋮	⋮	⋮
12	14.1	12.8	12.7	13.7	12
2	3.7	5.1	1.4	1.5	2
D	60.24	25.57	10.35	9.66	0.00
p	6	9	15	16	24
AIC	176.91	148.24	145.02	146.33	152.67

Note: Model 1 has only main effects; Model 2 has insufficient terms; Model 3 is a good model; Model 4 includes one unnecessary interaction term; Model 5 includes all interactions. For full details, see the text.

common to include all the main effects in the model. For this example, the main effects model (denoted $1 + A + L + G + D$) gives a deviance of $D = 60.24$ on 18 df.

There are six second-order interactions ($A.L$, $A.G$, $A.D$, $L.G$, $L.D$, and $G.D$), four third-order interactions ($A.L.G$, $A.L.D$, $A.G.D$, and $L.G.D$), and one fourth-order interaction ($A.L.G.D$), plus all the additive combinations of these. Commonly, but not universally, higher order interactions may be included only when lower order interactions are already in the model; these models are called *hierarchical* models. For example, the interaction $A.D.G$ is only permitted provided A , D , G , $A.D$, $A.G$, and $D.G$ are in the model. This reduces the number of possible models, but the number is still large.

One simple model is

$$1 + A + L + G + D + A.L + D.G + A.G + A.D + A.D.G;$$

adding more terms does not produce a significant reduction in deviance.

As a demonstration, five models have been fitted here: Model 1 has only main effects; Model 2 adds the interaction $A.L$ and $D.G$ only; Model 3 is the model above; Model 4 adds the interaction $L.G$ unnecessarily to Model 3; and Model 5 is the saturated model. A comparison of the models is given in Table II. Note the deviance decreases as more terms are added, but the AIC begins to increase as unnecessary terms are added to the model.

In this example, Model 3 gives $\hat{\phi} = 25.57/(24 - 9) = 1.71$, indicating slight over-dispersion.

Longitudinal Cohort Designs

John Bynner

Institute of Education, London, United Kingdom

Glossary

age, cohort, and period effects The different extrinsic components of variation in a cohort study data point, as opposed to the intrinsic variation reflecting developmental processes unique to the individual.

attrition Loss of sample members due to death, movement, noncontact, or dropout from the study.

cohort Any subgroup of a population defined by a demographic attribute, such as age or gender, for which the members of the group are followed up individually across time.

event histories The individual record of statuses, such as jobs, partnerships, and housing, and their duration in the intervals between follow-ups.

fading relevance The tendency for theoretical frameworks that informed the early stages of the study and the variables used to operationalize them to lose scientific salience for later users of the data.

net and gross effects Changes in a population over time compared with changes in a population and among the population members over time.

period The historical era or time when data are collected.

prospective and retrospective enquiry The distinction between collecting event data contemporaneously with each sweep or retrospectively through recall.

quasi-experiment Follow-up of a treatment and a control group, when there has been no random allocation of individuals to the two conditions.

sequential and quasi-sequential cohort designs The distinction between designs that follow up different cohorts of the same age and those that follow up cohorts of different ages.

sweeps and waves The follow-up surveys to collect data at each time point as the cohort study progresses.

This article discusses the main features of cohort studies, examining their scientific aims and the main forms that

they take within the context of longitudinal research designs and draw on a number of exemplar studies to illustrate their main features. The distinctions between the intrinsic and extrinsic (age, cohort, and period) components of the variation that they embrace are discussed. Methodological challenges are considered, focusing particularly on sample attrition, missing data, reliability, and validity, including the problem of “fading relevance.” Ways of enhancing the data through administrative records are then discussed, bringing in the ethical questions that arise in relation to certain types of data linked at the individual level. Finally, it is concluded that despite their weaknesses, cohort studies are one of the most powerful instruments available to social scientists for understanding how the human life-course is shaped under changing conditions. They therefore fully merit the high levels of investment that go into them.

The Cohort Study

Growing interest in long-term life-course processes has led to a burgeoning of longitudinal cohort enquiries in social science—the equivalent of the large-scale facilities such as “atom smashers” in the physical sciences and the Human Genome Project in medicine. The 1994 inventory published by the European Science Foundation (ESF) (1985-1991) Network on Longitudinal Studies concerned with Individual Development lists over 500 studies that met the ESF criteria of follow-up with more than 30 subjects over more than three time points and a minimum of 3 years’ duration. Another major inventory of U.S. longitudinal studies published by the Henry Murray Research Center in the Radcliff Institute at Harvard University, lists in 2003, 270 high-quality, fully

documented studies available in their archive for secondary analysis.

What is meant by cohort study and what information can it provide that other types of research cannot? Cohorts were subdivisions of Roman legions, originally 10% (600–800) soldiers, but soon becoming any specified subdivision. The idea of a group “marching forward” from a home base to some designated destination carries over, in modern usage, to that of any subdivision of a population followed up through time. Age cohorts are identified with groups of a particular age; birth cohorts are defined as people born at a particular time. There are also sex cohorts and social class cohorts, cohorts defined by social situation, cohorts defined by health condition, and so on. Cohort studies are concerned with charting the development of such groups from a particular time point either prospectively, by following them up subsequently, or retrospectively, by asking them to recall past events in their lives.

In other words, cohort studies are about the life histories, recorded over a designated period, of sections of a population and the individuals who constitute them. They can throw light on the circumstances in early life that are associated with the population’s characteristics in later life—what encourages development in particular directions and what appears to impede it? Development can be studied across any stage of life in any life domain: education, employment, housing, family formation, citizenship, and health.

There are, therefore, two immediate payoffs from cohort studies. They help in forecasting the effects of particular early experiences and circumstances on outcomes in later life. Working retrospectively from particular outcomes, they also provide the opportunity to model the life-courses of the people who exhibit the given outcomes. When the same model is applied to different cohorts, there is an opportunity to determine how social (or secular) change is affecting the parameters of the model and consequently the life-course processes involved. Thus, Glen Elder, one of the leading proponents of life-course studies, compared the lives of cohort members in the Oakland Growth study, starting with births in 1920–1921, with those of cohort members in the Berkeley Guidance study starting with births in 1928–1929. He used the comparison to demonstrate the dominance of the Great Depression in the United States as a lasting influence across the whole of the latter cohort’s lives.

Cohort studies are therefore a special case of the broader set of longitudinal or panel enquiries defined by any set of measurements or observations taken on the same set of units across time. They contrast with other types of panel study that take whole cross sections of a population and follow them up over time, e.g., household panel studies, audience research panels, and product testing panels.

Interpreting Cohort Data

Cross-sectional data collected on repeated occasions are longitudinal at the macrolevel in the sense that they enable one to monitor the effects of societal (or secular) change on a population’s characteristics—“net effects.” Cohort data are essential for investigating changes in individuals within the population as well—“gross effects.” These incorporate information about changes in the individual members of the cohort as well as the cohort as a whole and are essential for gaining any purchase on possible causal processes. Researchers need to know about sequences of life experiences and events, and which individuals appear to be affected by changes in their external environment, while others remain impervious to them. Thus, poor educational performance can be attributed in part to low parental aspirations, if changes in the former follow changes in the latter. A cross-sectional survey could establish only a correlation between parents’ aspirations and children’s educational attainment, with no basis on which to infer cause and effect.

Cohort studies come into the category of what are called “quasi-experimental designs.” One cannot allocate individuals randomly to different conditions in the way that the “true experiment” demands. Hence, one can never be certain that a variable identified with an hypothesized cause is not confounded with another variable that has not been measured. Is it aspiration or social class that one is really measuring? On the other hand, one can unravel how particular life histories develop, and draw strong quantitative or qualitative inferences through the experience that some individuals rather than others have had, as to what has shaped them. Who moves up through the social structure, who moves downward, and who stays immobile?

Types of Research Design

Figure 1 shows the way that the cohort study relates to other kinds of research design. Each of the large blocks represents a population or (subpopulation) of a country. The vertical axis of each block shows chronological age and the horizontal axis shows the time (or “period”) of data collection in chronological years. Each vertical section represents a population survey at a particular time point. Each horizontal section represents repeated surveys of a single age group across time—3 year olds, 10 year olds, and so on. Such “time series” of observations on one or more age groups or the whole population provide a means of monitoring changes in the population, indicating response to policy shifts or where policy development is needed. The Connecticut crackdown on drunk driving, which was accompanied by a fall in deaths from

Figure 1 Longitudinal research designs.

driving, was used by Donald Campbell as an example of a quasi-experiment in his classic paper, *Reforms as Experiments*.

Cohort Designs

The cohort study is represented by the diagonal line, which shows the age the cohort has reached at each year in historical time. Thus, a baby born in the year 2002 will be age 8 in the year 2010 and age 43 in the year 2045. The cohort is generally identified here with a particular age group of a population usually described as a birth cohort because all the members must share a common age. These can encompass all births over the given year, as in the British Millennium Cohort Study (see Fig. 2), or all births in a single week, as in the earlier 1946, 1958 and 1970 cohort studies. The U.S. National Children's Study focusing on the effects of environmental factors (biological, chemical, physical, and social) on children's health, and scheduled to begin in 2005, will be based on 100,000 births with follow-up over the next 20 years. Many cohort studies follow a wider range of groups including the birth year conceived either as a single cohort or as a set of birth cohorts. The variable intervals between follow-ups are also shown in Fig. 2, indicating the scope for cross-cohort comparison. Cohort

studies in Scandinavian countries, such as Sweden, start at much later ages than birth, e.g., 10 or 13 years of age, relying on the comprehensive administrative data held on state registers to supply information about earlier ages.

The cohort study can extend to multiple populations representing one or more countries, such as the Paths of the Generation Longitudinal Study established by Mik Titma following up high school graduates. In its second version, this extended from Estonia, where it began, to 15 countries and regions of the old Soviet Union—a sample size approaching 50,000 individuals. The study can also be based on the populations of different towns or regions within countries, such as the Dunedin Multi-Disciplinary Study and the Christchurch Child Development Study in New Zealand or the Malmö Longitudinal Study and the Gothenburg Evaluation through Follow-up Studies in Sweden, starting in 1938 and 1961 respectively. Alternatively, the study can involve follow-up of different groups (subpopulations), including those that have been subjected to some form of treatment or policy intervention, while others have not. Under “true” experimental conditions, there would be an allocation of individuals to such groups on a random basis, who then become the cohorts for investigation. In the absence of such allocation, i.e., the cohorts are naturally occurring, one has another form of quasi-experiment. The validity of such

a design for experimental purposes depends on the extent to which the groups are matched with respect to all attributes related to the outcome.

The temporal sequencing of the longitudinal data that cohort studies produce offers a powerful means of control in comparison with a cross-sectional survey. One can monitor the circumstances and experiences through which cohort members’ life histories unfold to assess how these interact with personal characteristics to produce particular social, economic, psychological, or health outcomes. Contemporary data accumulated over the life cycle—establishing the sequencing of events, circumstances, and characteristics—provide a particularly valuable tool in the search for causal explanations of differential development and its outcomes. Dated event histories can be used to describe and model dynamic processes, rather than the static states observed in cross-sectional “snapshots.” Such possibilities have been greatly enhanced by advances in statistical methodology for the analysis of longitudinal data and the development of high-powered computer technology to apply them.

Sequential and Quasi-sequential Cohort Designs

Figure 1 also introduces another distinction in cohort study design: “sequential” or “quasi-sequential” cohorts. Sequential cohorts have a starting point on one of the horizontal lines. A series of birth cohorts is established with births separated by, for example, 2-, 5-, or 10-year intervals. This is the basis of the “youth cohort studies” set up in many countries to monitor the transition from compulsory schooling to the labor market. In contrast, the quasi-sequential design starts on one of the vertical

axes in Fig. 1 and follows the cohorts defined by the different ages on it. For example, one might select age groups separated by 4-year intervals—7 year olds, 11 year olds, 15 year olds, 19 year olds—and follow them up over time. Such age groups are of course also a series of birth cohorts. The difference with the sequential cohorts design is that the latter has full information back to the starting age, whereas for the quasi-sequential design, age-based (developmental) data are missing in increasing amounts the older the cohort’s starting age.

The advantage of the quasi-sequential cohort design is that the information is obtained much earlier from the study for older age groups than would be the case if they were all followed up from the same starting age. It will not be until the third decade of the new century, for example, that the “Millennium” birth cohorts started in a number of countries will yield data on adult life. A good example of the quasi-sequential cohort design is the U.S. National Longitudinal Study of Youth (NLSY). In the first and continuing NLSY, a set of age cohorts of 10,000 young people ages 14–21 have been followed up annually since 1979. The new NSLY starting in 1997 comprises a cohort of over 9000 young people ages 12–16 who have been followed up annually since 1997. In contrast, the Canadian National Longitudinal Study of Children that began in 1994–1995 embraces a younger set of cohorts extending from age 11 back to birth, comprising 25,000 children.

Case Control Studies

Another variant in design favored in medical enquiry particularly is the “case control study.” This might be based on people with identified characteristics in adult life such as the long-term unemployed, those with criminal

Figure 2 British Birth Cohort Studies Programme. Note: 1. Initial survey carried out at ca. 8 weeks. 2. Initial survey carried out at ca. 9 months.

records, or those having a particular medical condition, who are subsequently followed up with a matched control group not showing the specified criterion characteristic. In studies still at the stage of collecting data from children, high-risk and control groups can also be identified and followed up to determine whether hypothesized outcomes later in life are observed.

Intergenerational Studies

A final, though fairly rare, variant of the cohort study design extends data collection to the next generation—that of cohort members' children. This creates unique three-generation data sets involving cohort members, their parents, and their children, with the opportunity to identify intergenerational continuities and discontinuities in development, and the factors associated with these. The data can throw light on such central societal concerns as “cycles of deprivation,” i.e., deprivation in families transmitted from one generation to the next. The first U.S. National Longitudinal Study of Youth, for example, collected data from and about female cohort members' children at 2-year intervals from 1986. The British National Child Development Study also collected such data in a substudy of one-third of cohort members and their children, when the cohort members had reached age 33. In such a design, however, the population is still defined by the cohort members because of the built-in logical dependency of the age of the child on the age of the mother. The children therefore must be seen as attributes of their parents and not as a cohort in their own right.

Age, Cohort, and Period Effects

In the 1960s, Schaie, followed by Baltes, pioneered the work on different components of variation in the data yielded by a cohort design. They drew attention to the distinctions between individual variation in the cohort at any particular time that is a function of the experience and biological make up of the cohort members—“intrinsic effects”—as opposed to that which is externally determined—“extrinsic effects.” Cohort data confound three extrinsic sources of the individual variation, which need ideally to be accommodated in the research design: age, period, and cohort effects. Data collected at a particular time point in a cohort study may be a product of the age of the individual concerned (age effect), the time when the individual was born (cohort effect), and the period when data were collected (period or secular effect). These effects are logically related through the formula: $\text{Period} = \text{Age} + \text{Cohort}$ and are therefore confounded with one another.

In the interest of unambiguous interpretation of cohort data, it is necessary to determine the significance of

these effects and to exercise a degree of control over them through the research design. To assess the cohort effect, controlling for age and/or period (both cannot be controlled simultaneously), one needs to collect data from individuals of the same age but born at different times (cohorts). To assess the age effect, one needs to collect data from individuals of different ages controlling for cohort and/or period. To assess the period effect, one needs to collect data from individuals at different periods controlling for age and/or cohort. Such designs—though an improvement on the single cohort—can never overcome the confounding entirely because of the logical dependencies that remain. To isolate the effect of age, cohort, or period effects, independently of the others, one therefore must assume constancy of one of the effects that are not controlled. Thus, comparing 30 year olds born at 12-year intervals, as in the British birth cohort studies, controls the age effect, leaving cohort and period confounded. If the strong assumption can be made that there is no period effect, which might be reasonable for differences between cohorts in the prevalence of a health condition, for example, then it is justified to attribute variability between cohorts entirely to a cohort effect, i.e., differential exposure of the two cohorts to changing societal circumstances is producing the difference in the health outcome.

The subsidiary requirements of cohort data follow more precisely from the conceptualization of the phenomenon under investigation.

First, to understand long-term processes such as value formation or social exclusion, the developmental data must be collected over a substantial period of people's lives.

Second, to analyze variation within a society between individuals and between socially defined groups, it is necessary to have cohorts comprising large representative samples of the total population. Alternatively, the cohorts can comprise samples of groups with special characteristics with relatively low population prevalence, such as disability, with the facility of a baseline longitudinal study or matched control group for comparison. The most comprehensive cohort study designs combine both features, differentially stratifying the sample to ensure that groups of special scientific interest are adequately represented within a probability sample. Representation of the population as a whole can then be achieved through reweighting.

Third, to embrace societal change itself in the design, one needs ideally more than one birth cohort studied across time (sequential cohorts) or follow-up of broad cross sections embracing multiple age groups (quasi-sequential cohorts).

Fourth, to embrace the historical and cultural context of such change, one needs studies that involve more than one region or more than one country. This third “spatial” feature of cohort study defines with age period and

cohort what Alwin, in 1994, referred to as the “space–time coordinates” of longitudinal study.

Finally, the cohort study design needs to incorporate the relevant variables for investigation of the phenomenon of interest. Much cohort study with a medical orientation restricts the data collected to a limited number of variables hypothesized to be implicated in the pathology of a particular medical condition. For studies of developmental processes such as educational achievement, it is necessary to ensure that the data not only embrace experience of the education system, but also the wide range of family circumstances, family and peer relations, and individual functioning and personal attributes that precede or accompany it.

From the above, it can be concluded that large-scale and long-term developmental studies, within what can be described as a broad life-course, or holistic, interdisciplinary perspective, are going to yield the best returns for behavioral and social science. Such developmental studies embrace circumstances and experience across the different domains of life, with a view to revealing connections between them across time.

Methodological Challenges

Attrition and Missing Data

The value of longitudinal study must be judged against the problems of collecting longitudinal data and the implications these have for data quality. Magnusson and Bergman, in 1990, set these out in the third of 10 books resulting from the work of the European Science Foundation’s network on longitudinal research referred to earlier. The most serious of these data quality problems is “attrition”—the loss of sample members over time. Subjects may disappear from the study because they have died, moved house, changed their names (through marriage), or are simply no longer interested in taking part; others move in and out of the study depending on their availability at the time a particular survey is to be carried out.

Such changes in the cohort’s composition can seriously weaken the research potential of the data. Sample loss reduces the numbers available for data analysis—a particular problem in longitudinal analysis that strictly requires complete records across the time span of the research. Attrition can also bias the data if those who leave the study are not typical of those who started it. On the other hand, unlike the cross-sectional survey, with any longitudinal data set there is full information about the characteristics of the sample when the study began. Accordingly, if reduction in the size of the cohort through attrition occurs differentially across groups, e.g., groups defined by socioeconomic status of parents, then

the sample can be reweighted to restore the distributions of such key variables to the form they were earlier. This is only a partial solution, however, as the variables of central interest, on which the missing cohort members differ from those still participating, may not have been measured at the start of the study. The most effective cohort studies, therefore, place a large amount of investment in minimizing attrition by maintaining contact with the cohort in between surveys and tracing the present whereabouts of sample members through administrative records, and even national and local media publicity campaigns, when leading up to a new one.

Missing data are not restricted to loss of cohort members from the study. Nonresponse at the variable level due to respondent failure or refusal to answer a particular question, or accept a particular measurement, can occur across the data set. Much of this nonresponse is unlikely to be occurring at random and thus constitutes another source of potential bias in the data. Again, the problem multiplies across follow-ups, both reducing the numbers available for longitudinal analysis and increasing the bias. The solution must be an analytic one. There have been major developments in the statistical methodology for “imputing” missing data, which are increasingly applied in the analysis of cohort study. But again prevention is better than cure. Comprehensive development work involving much piloting and prepiloting of all survey procedures is an essential prerequisite for any new follow-up. They need to be minimally burdensome and maximally sensitive to the cohort member’s situation.

Measurement Quality

Other data quality issues that are common to all social scientific enquiry arise but their effects are likely to be exacerbated in a cohort study. All measurement contains error, which reduces its reliability and can lead to incorrect inferences. This effect will again multiply for repeated measures across time. Questions of validity and usability also arise. Bias due to memory loss may be a serious problem, especially for studies in which events such as unemployment spells are recalled across intervals of several years. As theory shifts about the origins of behavior, i.e., the balance changes between biological, individual, situational, and environmental perspectives, so the variables entered into the design of the longitudinal study will change as well. Often theories in which cohort data are employed specify variables for which data have not been collected and those that have been are no longer of interest: the relevance of the data “fades” with time. The significance of the social and historical context of development, as exemplified in life span developmental psychology, ecological psychology, and life-course study, was not recognized in the more psychogenically oriented approaches to developmental processes

that were prominent up to 20 years ago. Moreover, in designing a new follow-up in a cohort study, measurements taken earlier in the study may no longer be considered operationally adequate by those using the data later on, but to change them would rule out repeated measurement on which causal inference strictly depends.

The most effective multipurpose longitudinal studies overcome these measurement difficulties, by using well-developed and trusted measurement procedures, including standardized tests and structured interviews conducted by well-trained interviewers. Analysis can again also play a part through the specification and estimation of more generic and stable latent variables corrected for attenuation, which structural modeling methods such as LISREL offer. The team will also consult as widely as possible in their research communities about the critical variables to include in the attempt to optimize prospective usability before finalizing the data specification. Much effort is invested in documenting the data in considerable detail, and keeping the raw data alongside the computerized data set, so future researchers are able to recode answers in terms of more appropriate variables and new classifications. For example, the classification of occupations usually changes from one census to the next. The International Classification of Diseases is similarly subject to regular review and updating. Only by storing the raw data can researchers be sure that the most up-to-date classification is consistently applied across all data points.

The need to optimize measurement value also demands retention of full information about data sources, so that with cohort members' permission, if necessary, the original sources can be returned to for more information. Medical records have often been used in this way, especially in Scandinavian countries. Of course, it will not always be possible to do such tracking back through the cohort members' lives to enhance the data; often the data sources themselves, e.g., schools, teachers, doctors, and their records, will no longer exist. In such cases, either the past data must be reconstructed from present information, or from what can be recalled by subjects, or treated as "missing".

Retrospective Alternative

These formidable data quality issues in utilizing data collected in a prospective cohort study need to be set against the main alternative: the collection of cohort data entirely retrospectively. All cohort studies contain elements of retrospection to complete the record of events in between follow-ups. Nevertheless, all prospective studies are committed to collection of as much data as possible contemporaneously.

The completely retrospective approach has been effectively used in a program of research under the

direction of Karl Ulrich Mayer of the Max Planck Institute for Human Development. Individuals were selected from the German Micro Census in three birth cohorts spanning a period of 50 years to find out to what extent cohort effects had brought about changes in employment and other aspects of life patterns. The Norwegian Life History Project is another example that covers the same period and has been used in comparative research with Germany. The advantage of the method is that the problem of attrition is solved, because there are complete samples of the contemporary population. Also, data collection can be targeted precisely on the variables of interest. The disadvantage of the approach is that problems of long-term memory decay make recall for many life events, such as job change and spells of unemployment, over anything more than a few years, of dubious accuracy. Methodological research involving overlapping recall periods for event histories in the same and different cohort studies (e.g., recall from age 30 to age 16 compared with recall from age 23 to age 16) point to 3 to 4 years as the maximum length of time over which such events as unemployment spells can be recalled accurately.

Even more seriously, although objective information, such as work, family formation, and housing histories, can in principle be collected retrospectively, certain kinds of data involving moods, feelings, states, attitudes, values, knowledge, and skills, can be assessed only at the time that individuals are experiencing them. Such variables are crucial mediators of social relations in transition processes. In studies of the life-course, one might therefore conclude that the best kinds of longitudinal data are those collected prospectively.

Finally, another important feature of cohort studies needs to be mentioned. Large-scale cohort studies can be expensive to carry out and, if they last a long time, require considerable commitment from a dedicated team to keep the study going. Maintaining a continuing flow of funds may be a major challenge, because of the peaks and troughs in activity corresponding to data collection follow-ups and the periods between them. The complexity of the cohort data and the post-fieldwork editing and coding that needs to be carried out before use means that there are also often extended delays before results are reported. More poignantly, those who start the study off are unlikely to be the ones to finish it, and as retirement or other interests beckon, there is always a danger that the study will die. This is why, rather in the nature of a small business, effective cohort studies need a well-funded infrastructure to ensure their continuation. It is where this has happened that the greatest potential for research on a given topic is likely to lie. Despite the huge expansion of longitudinal enquiry, there are still only a limited number of cohort studies that fully meet this requirement.

Data Enhancements and Ethics

The standard prospective cohort enquiry is likely to be relatively self-contained, relying on the research team to collect the required data from cohort members or their parents. There are potential benefits, however, from extending the scope of data collected to other administrative data sources. It is common to link aggregate data, such as local area unemployment and poverty rates, to large-scale cohort study data. More difficult issues arise in relation to linking individual level data.

Individual record linkage is widely employed in Scandinavia and in the United States, where data protection legislation has not inhibited its use as much as it has in some other countries. In its simplest form, record linkage may involve no more than linking administrative data, such as employment or housing records, to a cross-sectional survey of school children via the individual identifiers, when the sample has reached adulthood. In Scandinavian countries, such linkage extends to relying exclusively on state registers to supply the data in the early years of the study. More typically, the method is used in conjunction with longitudinal data collection from the cohort members throughout the study. Thus, Sweden's Project Metropolitan started with a sample of over 15,000 13 year olds in Stockholm in 1964. Childhood data were collected exclusively from education and other records. Further government administrative data were linked to the directly collected data from age 13 onward, including criminal convictions.

However, apart from data protection legislation and other government restrictions on the use of personal data obtained from administrative records for research, there are other problems with record linkage that need to be taken seriously. Administrative records often are inaccurate through clerical error or are incomplete; for example, large numbers of criminal acts go undetected. Thus, within a cohort study to which criminal convictions have been linked, there are likely to be large numbers of "false-negatives," i.e., people who have committed crimes but are not recorded as having committed them.

Another problem arises in relation to research ethics, but may also have practical consequences. Longitudinal data are collected from individuals on the basis of trust within an implicit or, in some cases, explicit contract between them and the researcher. They, or before them their parents, are assured of confidentiality and told that the data will be used only for specified purposes. Other people, such as doctors and teachers, supply data about them on this understanding. During adulthood, permission to use other sources, such as medical records, can be sought directly from the cohort member at the time of a survey. For records of a highly confidential nature,

such as those having to do with tax, crime, drug problems, and abortion, the researcher is unlikely to seek permission, and if permission was sought, it is unlikely that it would be given. Using such data sources secretly not only raises the ethical problem of researcher probity, but may also damage the survey directly. If the news that such records have been used gets back to the cohort members, it is likely that many will withdraw from the study. In the case of the Stockholm-based Project Metropolitan, such feedback reached respondents through press reports and the study subsequently collapsed.

The best compromise is the pragmatic one of judging each question of data linkage on its merits. If the data from administrative sources are linked within a framework of what survey practitioners call "informed consent," i.e., it is very unlikely that the respondent, knowing the subject of the study, would object to their use, then it seems legitimate to use them. If there is any doubt about this, their use is best avoided.

Conclusion

This article has revealed the power of cohort studies as an aid to social scientific understanding, while also pointing to some of the problems in undertaking them. They can involve long-term commitment and large-scale funding. There is a risk that the data collected will prove irrelevant to later social scientific purposes. There may be heightened concern about data protection issues ruling out the use of data that may be central to the study's success. There may be growing unwillingness among members of the public and their children to commit themselves to collaboration with a research team involving the supply of information about themselves throughout their lives.

It is perhaps for these reasons that relatively few countries have engaged in large-scale cohort studies based on representative samples. For those that have—such as the United States, Great Britain, Sweden, New Zealand and Canada—there are rich social scientific rewards. A record of the changing lives of a country's citizens in response to social change has been described as a "treasure trove" for learning how the human life-course is shaped under different social conditions. Extending the scope of cohort studies comparatively through cross-national designs, and intergenerationally is the next stage in their development. In a rapidly changing world, there can be few better social scientific investments.

Longitudinal Studies, Panel

Scott Menard

University of Colorado, Boulder, Colorado, USA

Glossary

intraindividual change A transition in the attitudes, behaviors, or other characteristics of a specific individual, as opposed to an aggregate of individuals.

measurement interval The time between which measurements are taken; measurements may be taken continuously, but more often are taken at predefined intervals of minutes, hours, days, years, or longer periods, such as the 10-year measurement interval for the U.S. Census.

panel attrition The loss of research participants in the second and subsequent waves of data collection.

panel conditioning Changes in the responses of research participants as a result of their experience as participants in previous waves of the panel.

wave A measurement period, which may be a single moment in time or may span one or more years; the period for which the data are collected; panel studies involve two or more waves of data collection.

Longitudinal panel data have two defining characteristics. First, components (people, cities, nations) of the panel are measured for two or more points or intervals in time (the measurement periods, or waves). The act of measurement may occur only once, at the end of the last wave, or for all of the waves, in a retrospective panel design, or it may occur at the end of each period for which the data are being measured, in a prospective panel design. It is the number of periods for which, not at which, the data are measured that defines the longitudinal panel design. Second, at least one variable is measured for two or more waves. This is the longitudinal aspect of the data, which allows the measurement of qualitative or quantitative change within individuals or cases from one wave to the next. Strictly speaking, a longitudinal panel design is a time series design, insofar as the same participants

are measured at two or more waves, but the term “time series” is usually reserved to refer to the repeated measurement of a single case or at most a few cases over many waves. Time series designs allow the measurement of change, but typically not for a panel of respondents representing a total population or a representative sample of that population.

Types of Longitudinal Panel Designs

Longitudinal panel designs in their purest form measure exactly the same participants at every wave, but this ideal is rarely met. In any longitudinal panel design, particularly involving individuals as study participants (although cities and nations change and even cease to exist as well), the study may not be able to follow every individual; some may die, some may relocate, and some may refuse to continue to participate in the research. In some panel designs, participants are added to the study. For example, in the 1992 Panel Study of Income Dynamics, data were collected about families and about all individuals in those families. The panel of individuals may thus not only be reduced by death, failure to locate, or refusal, but may also be increased by birth or marriage. New families have also been added as children have reached adulthood and moved out of the originally sampled household, or as a result of divorce between members of the original households. Allowing for both additions to and losses from a panel, a design that attempts to measure all of the individuals in a population at two or more waves may also be considered one variant of the longitudinal panel design, specifically a total-population design. In another variant of the longitudinal panel design, the revolving panel design, individuals are included

in the panel for some number of measurement periods, then are replaced by other individuals. This was the design of the 1989 National Crime Victimization Survey.

The term “longitudinal panel design” is most often used, however, to refer to a design in which the same individuals are measured for every wave, with no additions to the panel and (in principle, but often not in practice) no losses from the panel. The research participants may all be drawn from a single birth cohort (people born in the same year), which results in a single-cohort longitudinal panel design, but more often the participants span several cohorts, which results in a multiple-cohort panel design. Because there are no additions and, ideally, few or no losses, the age structure of the panel changes over time; the oldest age at the last period is older than the oldest age at the first period, and the youngest age at the first period is younger than the youngest age at the last period. The 1989 National Youth Survey is an example of a multiple-cohort panel design; the data were first collected in 1976, when the research participants were 11–17 years old, and the same individuals were followed into adulthood, with the tenth and eleventh waves of data being collected in 2002 and 2003, when the original participants reached their late thirties and early forties. Figure 1 illustrates the structure of the designs for total population, a revolving panel, and a multiple-cohort panel.

Purposes of Longitudinal Panel Studies

Longitudinal research serves two primary purposes: to describe and explain patterns of change and to establish the sign (positive or negative), direction (from X to Y or from Y to X), and magnitude of causal relationships (a relationship of magnitude zero indicates the absence of a causal relationship). Change is typically measured with respect to one of two continua: chronological time or age. Both chronological time and age may be measured in the same units (seconds, minutes, days, or years), but chronological time is measured externally to the research participants, whereas age is an internal measure, in the sense that age is a characteristic of the individual but chronological time is not. Changes associated with age often represent developmental changes, i.e., physiological, psychological, or social contextual changes (for example, puberty, increasing absolute intelligence, and graduation from high school) that occur in conjunction with aging from childhood to adolescence to adulthood to old age. Changes associated with time often represent historical changes; these changes occur as a result of events external to the individual, but may have some common effect on individuals at different ages. It is also possible that historical changes interact with age, with

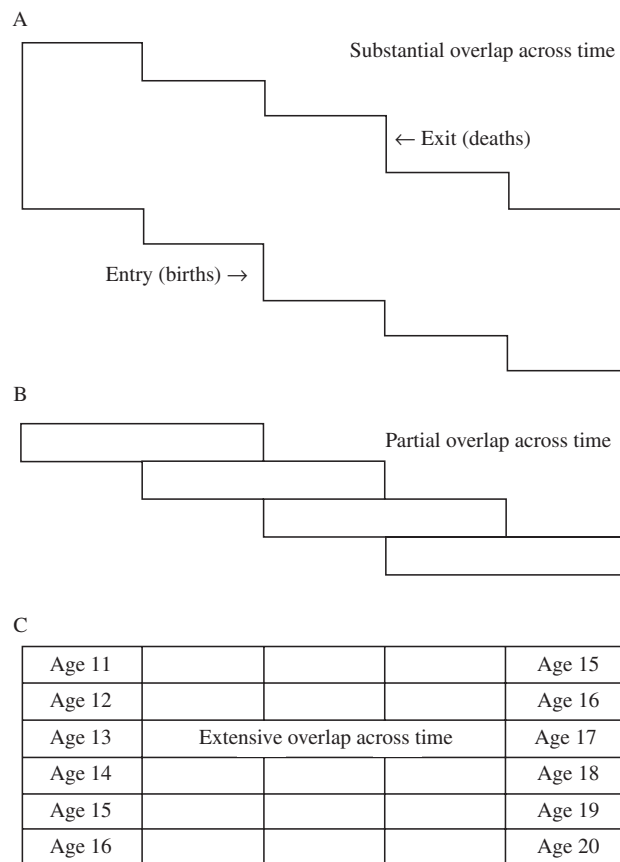

Figure 1 Longitudinal designs for data collection. (A) Total-population design; (B) revolving panel design; (C) multiple-cohort panel design.

the result that different age groups or cohorts experience different consequences from the same change.

Qualitative and Quantitative Changes

Changes may be qualitative or quantitative. In qualitative change, a particular change either did or did not occur; for example, the individual either got married or remained single. Qualitative changes may vary in specificity; in such cases, an individual did or did not, say, change political parties, or more specifically, changed from Democrat to Republican or from Republican to Democrat, the latter two transitions representing two different and more specific subsets of the more general change in political party. Qualitative change is thus typically measured as a yes-or-no dichotomy. Quantitative change, in contrast, is measured numerically, as the difference between an individual’s “scores” or “ranks” on a characteristic at two waves. For ratio variables, but not interval variables, it may also make sense to calculate proportional change (the later score divided by the earlier score) or percentage change (the proportional change multiplied by 100), as

long as division by zero is not involved. Changes may also occur in measures of relationships, such as correlation and regression coefficients, and these (because they are measured on a ratio scale) may be represented as differences or percentage changes. These and other measures of change have been described in the literature, but in all cases, the measurement of change at the individual level, whether the focus of the study is a person, a city, or a nation, requires panel data.

Longitudinal Panel Designs and the Study of Change

Longitudinal panel studies may be used to examine changes in individual characteristics within a single individual over time and age (for a single individual, the two cannot be separated), and also to examine changes in relationships among variables. Examples of change in individual characteristics include changes in physical characteristics such as weight, mental characteristics such as cognitive ability, and behavioral characteristics such as frequency of involvement in illegal behavior. Changes in relationships among variables as an individual ages could include the changing influence of diet on weight (a diet that once resulted in weight maintenance now results in weight gain), the changing influence of sleep on cognitive ability (more or less sleep is needed for peak mental performance), and the changing influence of family attachment on involvement in illegal behavior (the influence of the family may first decline from early to late adolescence, then increase in early adulthood). Changes in characteristics and relationships can be historical as well as developmental. For example, at the national level, fertility and mortality rates may decline over time, and the relationship between mortality and fertility rates may be higher or lower in one period than in another.

Single- or multiple-cohort panel designs, in contrast to total-population and revolving panel designs, cannot provide comparable age-specific cross-sectional data from one wave to another (because the age spans are different in different waves), except possibly for a subset of the original sample. For example, in the multiple-cohort panel design diagrammed in Fig. 1, it is possible to compare respondents at ages 15 and 16 at the first and last waves of the panel. The multiple-cohort panel design is, however, well suited to the analysis of developmental changes. The revolving panel design, particularly when it involves a relatively short time span (3 years for the National Crime Victimization Survey), is not as well suited to the measurement of developmental change, because it may cover too small a segment of the life course for the developmental changes of interest to manifest fully. The revolving panel design can, however, provide

a reasonably comparable cross-section of individuals at each wave, so it is better than the multiple-cohort panel design for tracing historical changes that occur in aggregates of individuals over time. The total-population design has in principle both the advantage of comparable cross-sections over time plus the ability to follow individuals over a relatively long time span, and can thus be used to study both developmental and historical change.

Longitudinal Panel Designs and the Study of Causal Relationships

In order to establish the existence of a causal relationship between any pair of variables, three criteria are essential: (1) the phenomena or variables in question must covary, as indicated, for example, by differences between experimental and control groups or by a nonzero correlation between the two variables; (2) the relationship must not be attributable to any other variable or set of variables—that is, it must not be spurious, but must remain nonzero even when other variables are controlled experimentally or statistically; and (3) the presumed cause must precede or be simultaneous in time with the presumed effect, as indicated by the change in the cause occurring no later than the associated effect it is supposed to produce. Evidence for covariation may easily be obtained from cross-sectional data. Evidence for nonspuriousness is never really sufficient (there is always something else that could have been controlled), but evidence for spuriousness or its absence in the presence of the controls used in a particular study can also be obtained from cross-sectional data. In some instances, it is also possible to infer temporal (and implicitly causal) order from cross-sectional data. For instance, whether an individual is male or female, along with other genetically determined characteristics, is determined at birth, and necessarily precedes any voluntary behavior on the part of the individual. Thus, although being male is a plausible cause of violent behavior (with respect to covariation, time ordering, and perhaps nonspuriousness), violent behavior is not realistically plausible as a cause of being male.

In the social sciences, however, we are often dealing with time-varying characteristics, and the order of change may not be readily ascertainable at the level of the individual research participant without longitudinal panel data. In the case of qualitative changes, with a short enough measurement interval (the time from one wave to the next), it should be possible to determine which of two changes occurred first (or that they occurred at the same time). That one change preceded another is not sufficient to support the claim that the first change must have caused the second (the “post hoc ergo propter hoc,” or “after therefore because of,” fallacy), because the criteria of covariation and nonspuriousness must also be

satisfied, but it does mean that the second change can probably be ruled out as a cause of the first. For example, in one study, the proposition that substance use (underage alcohol use and illicit drug use) caused other illegal behavior (violent and property crime) was examined; the findings were that the initiation of substance use typically came after, not before, other illegal behavior. Although this evidence does not establish other illegal behavior as a cause of substance use, it seriously weakens the case that initiation of other illegal behavior is a result of substance use, insofar as an effect cannot precede a cause. Besides initiation or onset of a behavior, other possible qualitative changes include escalation of attitudes or behaviors (entry of a higher state on an ordinal scale), de-escalation or reduction (entry of a lower state on an ordinal scale), and suspension (permanent or temporary exit from all states that indicate involvement in a particular kind of behavior or agreement with a particular attitudinal statement).

Issues in Longitudinal Panel Designs

Longitudinal panel designs have the same problems associated with cross-sectional research, and also have additional problems that are not encountered in cross-sectional designs, including problems of (1) changes in measurement over time, and the related problem of distinguishing unreliability in measurement from true change, (2) repeated measurement and panel conditioning, (3) respondent recall, and (4) missing data and panel attrition. In addition to the increased problems, however, longitudinal panel designs offer something that is not readily available in other research designs, i.e., the possibility of detecting and adjusting for these problems, particularly missing data.

Unreliability of Measurement and Measurement Change

In longitudinal panel research, the usual issues of internal and external validity and measurement reliability arise. Measurement reliability may be measured by either test–retest reliability, with a suitably short interval between test and retest, or by internal consistency measures, such as Cronbach’s alpha or factor analytic techniques. The issue of longitudinal reliability arises from the possibility that even when identical measurement instruments are used in different waves, and even more when they are not, differences in administration or life course changes may lead to the result that what is measured at one wave is not really comparable to what is measured at another. Four more specific issues within the broader

framework of longitudinal reliability illustrate the dilemmas that may arise: consistency of administration, consistency of observation, factorial invariance, and changes in measurement.

Even if the same survey or psychometric tests are administered in each wave of a panel study, how the questions are administered may vary in more obvious or more subtle ways. An example of this is the change from face-to-face to telephone interviews in the National Crime Victimization Survey and the Panel Study of Income Dynamics. More subtle changes may include changes in instructions to interviewers (or in the interviewers’ actual behavior, regardless of instructions); one example is whether certain responses elicit probes from the interviewer. The setting of a psychometric test may change, for example, from the researcher’s office to the respondent’s home or school. These changes in administration all represent inconsistencies in administration, and raise the question of whether any apparent change (or absence of change) in responses from one wave to another represents real changes (or their absence) in characteristics of the research participants, or merely changes in how the participants respond to the administration of the survey or test. Observational inconsistency closely parallels inconsistency in administration. When the observer becomes the measurement instrument, as in ethnographic research, the question arises whether reported changes represent true change in the individuals being observed, or merely changes in the perceptions or perspective of the observer.

When the same sets of items on a scale have the same relationship to the scale (and thus to one another) in each wave of a panel study, the result is called factorial invariance. Strict factorial invariance insists that the numerical relationship be identical across waves; a weaker form of factorial invariance insists only that the same items “belong” to the same scale (as indicated by some numerical criterion, but the numerical relationship need not be exactly the same) at each wave. Factorial invariance is compromised when the relationship of one item to the scale changes. The first question that arises when factorial invariance is absent is whether we are measuring the same variable from one wave to the next, and hence whether it is possible to measure change in that variable, one of the core criteria of longitudinal panel research. If the variable being measured is not the same from one wave to the next, or even if it is the same variable, but measured differently, a second question that arises is whether any change in the relationship of this variable to other variables in the study (or, again, an apparent absence of change) can be attributed to real change (or its absence) or merely to a change in measurement.

In some instances, researchers may deliberately change the measurement instrument (including the observer, in ethnographic studies) from one wave of a panel to another. This may be done to incorporate a “new

and improved” measure, because questions that were appropriate at an earlier age or stage of the life course (e.g., how well a student is doing in school at age 14) may no longer be appropriate, or because new questions that would have been inappropriate at an earlier age or stage (e.g., how well an individual is doing at work at age 34) are now appropriate. Of course, it is possible that, for some individuals, work is an important context at age 14 or school is an important context at age 34, but what about ages 9 and 59? In this example, the introduction of new questions without eliminating old ones, or the elimination of old questions without adding new ones, would constitute a change in survey administration, adding to or subtracting from the length of the survey, but the inclusion of the same set of questions at all waves, regardless of their appropriateness to the age or stage of the respondent, could risk unwillingness of the respondent to participate in a survey that seems irrelevant. Unless the same questions are asked in the same order, in the same way, at every wave, the question of comparability of administration arises. Yet at the same time, if the survey covers a substantial span of the life course, the same question at different ages or stages may not have the same meaning for the respondent, either subjectively or in its empirical relationship with other scale items or variables.

Repeated Measurement and Panel Conditioning

Panel conditioning (or in experimental and quasi-experimental research, the effect of testing) refers to the empirical observation that past experience with a psychometric test or a survey questionnaire may lead a respondent to respond differently, compared to how he or she would have responded had the same test been administered at the same time, but without any prior experience on the part of the respondent with the test or survey. For example, different responses to the same question on a survey may lead either to (1) skipping a series of questions or to (2) additional follow-up questions. Respondents may be tempted to answer in a way that avoids the follow-up questions if they regard the follow-ups as burdensome. Alternatively, they may be tempted to give an inappropriate answer that does lead into the follow-up questions if they find the questions particularly interesting! Study participants may also experience real changes as a result of the research, above and beyond the effects that would be expected from their characteristics and environment. For one example, the questions in a survey may provoke a respondent to reflect explicitly and seriously on his/her behavior, and to reassess and attempt, perhaps successfully, to change that behavior. Another possibility is that ethical requirements for the treatment of human participants in mental health

research may lead researchers to offer to provide referrals to individuals who show evidence of severe mental health problems, and this in turn may lead to a change in the behavior or psychological condition that would otherwise not have occurred. The problem of panel conditioning appears to be more severe for relatively shorter measurement intervals (for example, 6 months as opposed to a year or more), but it is not clear whether the length of the test or interview has a substantial impact on panel conditioning.

Respondent Recall

Research on short- versus long-term retrospective data typically indicates that (1) memories tend to fade with time; (2) short- and long-term recall data on more salient events or attitudes tend to be more consistent compared to data on less salient events or attitudes; (3) short- and long-term recall data on objective events or characteristics tend to be more consistent compared to data on attitudes or other psychological data; and (4) differences between short- and long-term recall data indicate that the long-term recall data tend to be biased to reflect respondents' current views and attitudes. Regarding this last point, people tend to reconstruct and reinterpret their memories to reflect their current life situations and attitudes, in effect constructing a consistent “life story” for themselves. The potential consequence of this is to generate inconsistencies when prospective (or short-term recall) and retrospective (or long-term recall) data are compared for the same respondents, and the evidence appears to indicate that the prospective data are more valid, both with respect to whether certain events actually occurred, and also with respect to the precise timing of those events. This is not to say that long-term recall data are consistently unreliable or invalid, but it does suggest that they should be used with caution, and that, whenever possible, the shorter term recall data characteristic of prospective longitudinal designs are to be preferred. Attempts have been made to reduce errors associated with long-term recall, but research on the effectiveness of these attempts is generally inconclusive.

Panel Attrition and Missing Data

Missing data can occur in both cross-sectional and longitudinal research, but longitudinal panel research involves more possible types of missing data and more ways in which to address the problem. In longitudinal data, it is possible to have data missing (1) for a single item on a multiple-item scale, (2) for an entire scale, (3) for a particular case at a particular wave but not for all waves (wave nonresponse), (4) for a particular case after the first, second, or subsequent waves [that is, the individual is permanently lost to the study (panel

attrition)], or (5) for a particular case for all waves, (for example, as a result of initial nonresponse). Regardless of the type of missing data, there is always a risk that it will lead to biased estimation of predictive or causal models, or inaccurate estimation of descriptive statistics such as means, standard deviations, or trends.

For missing items, if most items in a scale are available, it may be relatively simple to substitute the respondent's scale mean for the missing item, with some confidence that the resulting estimate is likely to be better than just deleting the case with the missing data from the analysis. When a whole scale is missing, there are several choices; none of them is entirely satisfactory, but some at least offer the prospect of improvement over dropping the case entirely. For longitudinal panel data in particular, one possibility is interpolation of data, using data from previous and subsequent waves to estimate the missing data, but this approach, although potentially useful for causal analysis, is problematic for the analysis of change in the variable that has the missing data. For wave nonresponse or initial nonresponse, if there is a clear pattern of "missingness" by a variable that has been measured (e.g., ethnicity or socioeconomic status), weighting cases so that the cases most like the missing cases "count" a little more is a frequently used option; this will reduce potential bias, but it depends on the degree to which the cases that are missing are similar to the nonmissing cases with the same characteristics (again, e.g., ethnicity or socioeconomic status), with respect to other variables and relationships. Alternatively, for wave nonresponse, it is possible to attempt to model the nonresponse, or to interpolate or extrapolate data based on previous or subsequent waves. Insofar as respondents are lost in later waves of data collection, the measurement of change may be confounded because those respondents who are lost may differ from those who are retained in some systematic way (they may have had different average values on variables to begin with, or they may have changed in ways different from the rest of the sample). This is especially serious if losses come disproportionately from those with extreme values on the variables on which the research focuses (for example, the most frequent illicit drug users or the most serious criminals in studies of illegal behavior). It is thus not only the magnitude of attrition, but also the pattern of attrition with respect to critical variables in the study, that may be problematic. It may be possible to use standard statistical tests to see whether, for example, individuals who continued in later waves differed significantly from individuals who were lost in later waves with respect to (1) values on particular variables, (2) strength of relationships (e.g., correlations) among variables, or (3) the structure of relationships (e.g., multiple regression equations or covariance structure) among sets of three or more variables. Still, it remains possible that some source of sample var-

iability that significantly affects the substantive outcome of the analysis may be overlooked. For example, individuals with different behavioral trajectories (e.g., increasing as opposed to decreasing drug use) may be differentially likely to remain in or drop out of the panel, and this may not be readily detectable using the previously suggested methods. This could seriously bias substantive results such as the estimation and explanation of developmental trends in behavior, and may be extremely difficult to detect.

In retrospective panel designs, the problem of attrition takes a different form, one not amenable to assessment by the use of tests of statistical significance. Instead of problems associated with respondents leaving the panel after the first wave of data collection, retrospective studies may have problems of selection. Especially for long-term studies, retrospective studies may miss individuals who, for example, died or moved out of the area from which the sample was drawn, and who did so during the period for which the data were collected. Those individuals may differ systematically from the rest of the population. For example, frequent users of illicit drugs may have higher mortality than the rest of the population. If this is so, then frequent illicit drug users will be undersampled for the period of the study, and this may bias estimates of change in rates of illicit drug use. In effect, this is a problem of attrition, but attrition that takes place before the sample is drawn. It is much more difficult to detect and measure this type of attrition compared to the attrition that arises in conjunction with prospective panel designs.

Analysis of Longitudinal Panel Data

Longitudinal data analysis confronts two major issues: first, the separation of developmental (age) and historical (period) change and their possible interaction, and second, the interdependence among observations of the same variable for the same individual at different times. If we operationalize age as the year of birth, period as calendar year, and cohort as the year of birth, then any one of these three variables is completely determined by the other two; for example, cohort = calendar year – age. Because they are linearly dependent, it is difficult to separate age, period, and cohort effects analytically. Possible solutions to this problem are (1) the use of dummy variable regression models, (2) reconceptualizing the cohort in terms of an event other than birth (for example, entry into the labor force, which may eliminate the linear dependency), or (3) replacing cohort, measured as year of birth, with some characteristic of the cohort (for example, cohort size) in which we are really interested.

Although we are sometimes specifically interested in the effect of being a certain age at a certain time, it is more often the case that it is not the year of birth, but some other characteristic of the cohort in which we are interested, or else that we are only concerned with the cohort effect as a nuisance variable, i.e., something that may confound our analysis of developmental and historical change. An important point is that although age and a period are both measures of time, a cohort is not; it is an aggregation of individuals, a unit of analysis, rather than a continuum along which change can be measured.

Regarding the issue of mutually dependent observations, longitudinal panel data by definition involve two or more observations on the same individuals. Many statistical techniques assume that the observations or measurements of variables are mutually independent, but this is clearly unlikely when the same individual is measured on the same variable more than once, especially for relatively shorter as opposed to longer measurement intervals. Yet additional observations on the same variable for the same individual do provide additional information for causal analysis and especially for the measurement and analysis of intraindividual change, which is based on the expectation that the measure of a variable at one time for an individual is very likely to be related to a later measurement of the same variable for the same individual. One problem that may arise in the analysis of longitudinal panel data is bias in inferential statistics. The interdependence of the observations typically leads to underestimates of the standard errors of estimation, and this in turn increases the risk of Type I error (rejecting the null hypothesis when the null hypothesis is true). A second problem is that apparent intraindividual change (or stability) may be a result of positively (or negatively) correlated within-individual measurement error. This systematic, nonrandom error most typically leads to overestimation of stability and underestimation of the causal impact of other variables in models of change.

A wide range of techniques is available for longitudinal analysis, depending on the number of cases, the number of periods, and the specific research issue (causal analysis of differences; description and analysis of the occurrence and timing of change) for which the analysis is being performed. Specific to longitudinal panel studies, the number of cases is typically large and the number of waves ranges from relatively few (3–10) to relatively many (over 50). For relatively few waves, linear panel analysis and latent growth curve models using structural equation models are often employed, and are especially amenable to the analysis of correlated error structures. When there are many cases and many waves, structural equation models can, in principle, be used, but in practice, because of the technical requirements of structural equation analysis software, they tend to be used for shorter series (fewer waves); with many waves of data,

it may become difficult to obtain reliable estimates for complex models. For both relatively few and relatively many waves, event history or survival analysis methods and multilevel growth curve models may be used to model causal relationships and change. For a panel involving few cases and many periods, time series analysis may be appropriate. All of these analytical techniques statistically adjust for the fact that the observations in a longitudinal panel are not independent, but are repeated for individual research participants or cases.

Glossary

Central Statistical Organization (CSO) A government agency at the federal level to oversee data collecting and reporting activities at the national and state levels.

D^2 The Mahalanobis distance; a measure of dissimilarity between individuals or objects based on multiple measurements.

Indian Statistical Institute (ISI) A research and teaching institution established in 1931.

International Statistical Education Center (ISEC) An organization established in 1950 to train statistical personnel from Asian and other developing countries.

National Sample Survey (NSS) A large-scale sample survey started in India in 1950 to collect socioeconomic data on a continuing basis.

operations research (OR) A technique developed during the Second World War for optimum use of resources.

statistical quality control (SQC) Special statistical techniques developed for use in industry to maintain a specified quality of goods in production and in research and development programs.

The Professor, as Prasanta Chandra Mahalanobis was popularly known, was a physicist by training, a statistician by instinct, and a planner by conviction. He became a professor of physics at Presidency College (Calcutta) in 1922 after completing the Physics Tripos program at Cambridge University (United Kingdom) and taught physics for over 30 years. His statistical interests led him to found the Indian Statistical Institute (ISI) for advanced research and training in statistics and to start a new journal in statistics, *Sankhyā*, both of which enjoy an international reputation. Lack of formal training in economics did not prevent Professor Mahalanobis from

undertaking a major responsibility in drafting the Second Five Year Economic Plan for India. He believed in perspective planning and used simple logical ideas in deriving an econometric model for planning in underdeveloped countries. As a member of the Planning Commission, he advocated making large investments in heavy industries, setting aside other sectors of development, a policy that helped the country considerably in achieving rapid industrialization, although agricultural development received a temporary setback. That a physicist-turned-statistician, rather than professional economists, had played a more important role in India's national economic planning could only be true of Mahalanobis, with his sharp intellect and versatile interests.

Early Life

Prasanta Chandra Mahalanobis was born on June 29, 1893 into a family well established in Calcutta; the relatively wealthy family members were enterprising, adventurous, and imbued with liberal traditions. The contacts Mahalanobis had with the great intellectuals and social reformers of Bengal prepared him for the active life he was to lead over the next 79 years.

Mahalanobis received his early education in the Brahmo Boys School in Calcutta, where he passed the entrance (later called matriculation) examination in 1908. He entered Presidency College in Calcutta in the same year and passed the intermediate examination in science in 1910; he earned a Bachelor of Science degree with honors in physics in 1912.

Mahalanobis left for England in the summer of 1913 and joined King's College in Cambridge. He took part I of the Mathematical Tripos program in 1914, and part II of

the Physics Tripos program in 1915, which he passed with first-class honors. After finishing the Physics Tripos program, Mahalanobis arranged to work with C. T. R. Wilson at the Cavendish Laboratory in Cambridge and returned to India for a short vacation. But Mahalanobis did not go to Cambridge; during what was to be a brief vacation at home in India, he found a number of problems that so engaged his attention that he did not leave. The story of Mahalanobis would have been different if he had gone back to Cambridge and worked in physics. He might have contributed richly to our understanding of the universe, but the modern development of statistics, which is fundamental to all sciences for information gathering, information processing, and decision making under uncertainty, would have received a great setback. Soon after his return to India, Mahalanobis accepted a teaching position in Presidency College in Calcutta. It was still his intention to return to Cambridge to do research in physics, but he soon gave up the idea because he found so many issues in India that held his interest and absorbed all of his working time.

At the time that Mahalanobis was scheduled to depart from Cambridge to return to India, World War I was on and there was a short delay in his planned journey. Mahalanobis utilized this time browsing in the King's College library. His tutor, Macaulay, found him there one morning and drew his attention to some bound volumes of *Biometrika*, presented by the editor, Karl Pearson, an Honorary Fellow at King's. Macaulay asked Mahalanobis for his opinion of the volumes, and Mahalanobis got so interested that he bought a complete set of *Biometrika* published up to date and brought them to India. He started reading the volumes on the boat during his journey and continued to study and work out exercises on his own during his spare time after arrival in Calcutta. He saw that statistics, a new science connected with measurements and their analysis, had the potential for wide applications. He tried to look for problems where he could apply the new knowledge he was acquiring. Fortunately, he found some extremely interesting problems in educational testing, meteorology, and anthropology, and started working on them. This was the turning point in his scientific career.

It was an accident that brought Mahalanobis into statistics. But it proved to be a lifelong struggle to develop statistics in India the way he had visualized it. Statistics was known in India only in the sense of official data obtained as a by-product of administration. It was not recognized by the universities, research institutes, or academic bodies as a separate discipline, and other scientists did not take kindly to statistics. Government bureaucracy was quite opposed to the introduction of new methods or making changes in existing practices, thus Mahalanobis had to struggle on all fronts—with the scientists and with the government officials—to advance the cause of statistics in India.

Contributions to Statistics

Mahalanobis Distance

The first opportunity to use statistical methods came to Mahalanobis when N. Anandale (then director of the Zoological Survey of India) asked Mahalanobis to analyze anthropometric measurements taken on Anglo-Indians (of mixed British and Indian parentage) in Calcutta. This study led, in 1922, to the first scientific paper published by Mahalanobis, and it was followed by other anthropometric investigations, leading to formulation of the D^2 statistic. The D^2 statistic, known in the statistical literature as the “Mahalanobis distance,” is widely used in taxonomic classification.

Suppose each individual of a population is characterized by p measurements. The means (average) of the p measurements can be represented as a point in a p -dimensional space. Corresponding to k given populations, we have a configuration of k points in the p space. If $p = 2$, the points can be represented on a two-dimensional chart, and the affinities between populations, as measured by nearness of mean values, can be graphically examined. We may find that some populations are close to each other in the mean values of the characters studied, thus forming a cluster. The entire configuration of points may then be described in terms of distinct clusters and relations between clusters. We can also determine the groups forming clusters at different levels of mutual distances. Such a description may help in drawing inferences on interrelationships between populations and speculating on their origins.

If p is larger than 2, graphical examination becomes difficult or impossible. How might the difference between the mean vectors of, for example, populations 1 and 2 be sensibly measured? Call these vectors δ_1 and δ_2 . A direct approach (one that had been used by anthropologists) works with the squared length of the column vector $\delta_1 - \delta_2$,

$$(\delta_1 - \delta_2)'(\delta_1 - \delta_2),$$

but this approach pays no attention to internal population covariation among the coordinates, nor to heterogeneity of variances. A related disadvantage of this simple sum-of-squares distance is its noninvariance under linear transformations of the coordinate system.

Mahalanobis, perhaps motivated by his studies of mathematical physics, suggested a more useful kind of distance when the dispersion (variance–covariance) matrix of the two populations is the same, say Λ . The Mahalanobis distance, traditionally given in squared form and called D^2 , is

$$D^2 = (\delta_1 - \delta_2)'\Lambda^{-1}(\delta_1 - \delta_2),$$

so that D^2 is in a sense the standardized squared difference between δ_1 and δ_2 , generalizing the univariate

version of the standardized difference $(\mu_1 - \mu_2)^2/\sigma^2$, where σ^2 is the common variance and μ_1 and μ_2 are mean values. If Λ is a common dispersion matrix for all k populations, it is then possible to examine the $k(k-1)/2$ different D^2 values and apply on them various statistical analyses, including cluster analysis. One large-scale anthropometric cluster analysis was published by Mahalanobis and colleagues in 1949. Fuller and more precise statements of this exposition appeared in Mahalanobis' later writings.

Mahalanobis argued that inferences based on distances among populations might depend on the particular measurements chosen for study. The configuration may change, and even the order relations between distances may be disturbed, if one set of measurements is replaced by another set. In 1936, Mahalanobis therefore laid down an important axiom for the validity of cluster analysis, the dimensional convergence of D^2 .

When a comparison between two real populations is made, ideally all possible (relevant) measurements, typically infinite in number, should be considered. Consequently, cluster analysis of a given set of populations should ideally be based on distances computed on an infinite number of measurements. If D_p^2 and D_∞^2 denote Mahalanobis distances between two populations based on p characters and all possible characters, respectively, then it can be shown under some conditions that

$$D_p^2 \longrightarrow D_\infty^2 \quad \text{as } p \longrightarrow \infty$$

(naturally, after making that expression precisely). In practice, it is possible to study only a finite number p of characteristics, thus D_p^2 should be a good approximation to D_∞^2 if cluster analysis is to be stable. Mahalanobis showed that stability, in important senses, was possible if and only if D_∞^2 is finite.

Meteorological Research

Sir Gilbert Walker (then director general of observatories in India) referred to Mahalanobis some meteorological problems for statistical study. This resulted in two memoirs and a note on upper air variables in 1923. Correcting meteorological data for errors of observation, Mahalanobis established by purely statistical methods that the region of highest control for changes in weather conditions on the surface of Earth is located about 4 km above sea level (a result rediscovered later by Franz Bauer in Germany, from physical considerations).

Early Examples of Operations Research

In 1922, a disastrous flood occurred in North Bengal. An expert government committee of engineers was about to recommend the construction of expensive retaining

basins to hold back the flood water, when the question was referred to Mahalanobis for examination. A statistical study of rainfall and floods extending over a period of 50 years showed that the proposed retaining basins would be of no value in controlling floods in North Bengal. The real need was improvement of rapid drainage, not control of flood water. Specific remedies were recommended, many of which were implemented and proved effective.

A similar question of flood control in Orissa was referred to Mahalanobis, after a severe flood of the Brahmini River in 1926. An expert committee of engineers held the opinion that the bed of the Brahmini had risen, and they recommended increasing the height of river embankments by several feet. A statistical study covering a period of about 60 years showed that no change had occurred in the river bed and that construction of dams for holding excessive flood water in the upper reaches of the river would provide effective flood control. Mahalanobis pointed out that dams could also be used for the generation of electric power, much needed for the economic development of the region. He also gave first calculations for a multipurpose (flood control, irrigation, and power) scheme for the Mahanadi system in Orissa; this formed the basis of the Hirakud hydroelectric project inaugurated about 30 years later in 1957.

Large-Scale Sample Surveys

Large-scale sample survey techniques as practiced today owe much to the pioneering work of Mahalanobis in the 1940s and 1950s. He saw the need for sample surveys in collecting information, especially in developing countries, where official statistical systems are poor and data are treated as an integral part of an administrative system that is regulated by the principle of authority. A sample survey, properly conducted, would provide a wealth of data useful for planning and policy purposes; the survey could be conducted expeditiously, economically, and with a reasonable degree of accuracy, and at the same time would ensure the objectivity of the data.

The methodology of large-scale sample surveys was developed during the period from 1937 to 1944 in connection with the numerous surveys planned and executed by the Indian Statistical Institute. The survey topics included consumer expenditure, tea-drinking habits, public opinion and public preferences, acreage under a crop, crop yields, velocity of circulation of rupee coins, and incidence of plant diseases. The basic results on large-scale sample surveys were published in 1944 and were also presented at a meeting of the Royal Statistical Society. The 1944 *Philosophical Transactions* memoir on sample surveys is a classic in many ways, touching on fundamental questions: What is randomness? What constitutes a random sample? Can different levels of randomness be identified? The memoir gives the basic

theory of sample surveys and estimation procedures. Mahalanobis described a variety of designs now in common use, such as simple random sampling with or without replacement, and stratified, systematic, and cluster sampling. He was also familiar with multistage and multiphase sampling and with ratio and regression methods of estimation. He was, in a sense, conscious of selection with probability proportional to size (area); he pointed out that selection of fields on the basis of cumulative totals of the areas of millions of fields was difficult.

Mahalanobis made three notable contributions to sample survey techniques: pilot surveys, concepts of optimum survey design, and interpenetrating networks of samples. A pilot survey provides basic information on operational costs and the variability of characters, which are two important factors in designing an optimum survey. It gives an opportunity to test the suitability of certain schedules or questionnaires to be used in the survey. A pilot survey can also be used to construct a suitable framework for sampling of units.

From the beginning, Mahalanobis was clear about the principles of good sample design. He wrote in 1940 that "from the statistical point of view our aim is to evolve a sampling technique which will give, for any given total expenditure, the highest possible accuracy in the finale estimate and for given precision in the estimates, the minimum possible total expenditure." For this it is necessary to determine three things: (1) the best size of the sample units, (2) the total number of sample units that should be used to obtain the desired degree of accuracy in the final estimates, and (3) the best way of distributing the sampling units among different districts, regions, or zones covered by the survey. Mahalanobis constructed appropriate variance and cost functions in a variety of situations and used them in designing actual surveys.

As a physicist, Mahalanobis was aware of instrumental errors and personal bias in taking measurements, and consequently he stressed the need for repeating measurements with different instruments, different observers, and under different conditions. He maintained that a statistical survey was like a scientific experiment and that the planning of a survey required the same discipline and rigor as do other investigations. He advocated built-in cross-checks to validate survey results. For this purpose, he developed the concept of the interpenetrating network of subsamples (IPNS). A simple design using IPNS is as follows. Suppose that a given area is divided into four strata and that there are four investigators for the field-work. The normal practice is to assign one stratum to each investigator to cover all units (randomly) chosen from that particular stratum. With IPNS, however, each investigator works in all of the strata and covers a random quarter of the units. Thus the IPNS design provides four independent (parallel) estimates of the characteristic under study

for the region as a whole, corresponding to the four different investigators. The validity of the survey will be in doubt if the four estimates differ widely. In such a case, it may be possible, by further data analysis, to take the differences properly into account when reporting the final estimate. Such a comparison or critical study would not have been possible if the four different strata had been assigned to four different investigators, because stratum and investigator differences would have been confounded.

Fractile Graphical Analysis

Fractile graphical analysis is an important generalization of the method and use of concentration (or Lorenz) curves. A Lorenz curve for wealth in a population tells, for example, that the least wealthy 50% of the population owns 10% of the wealth. (If wealth were equally distributed, the Lorenz curve would be a straight line.) The comparison of Lorenz curves for two or more populations is a graphical way to compare their distributions of wealth, income, numbers of acres owned, frequency of use of library books, and so on.

One of Mahalanobis' contributions in this domain was to stress the extension of the Lorenz curve idea to two variables. Thus, it is possible to consider, for example, both wealth and consumption for families, and to draw a curve from which it may be read that the least wealthy 50% of the families consume 27% of total consumption, or a certain quantity per family on the average. Or, treating the variables in the other direction, it might be found that the 20% least-consuming families account for 15% of the wealth, or a certain value per family. (The numbers in these examples are hypothetical and only for illustration.) Such bivariate generalized Lorenz curves can, of course, also be usefully compared across populations.

Contributions to Economic Planning

Mahalanobis' acquaintance with economics was neither systematic nor complete. The economics he learned was connected with the problems he had to solve, and these came intermingled with problems in other fields. Mahalanobis initiated a number of family budget surveys in rural and urban areas during the 1940s. He also undertook a number of studies on consumer preferences. He even tried his hand at a census of rupees, i.e., estimating the life of a rupee note. A survey of the aftereffects of the great Bengal famine in 1943 made him acutely aware of the poverty of the country.

In 1949, Mahalanobis became the chairman of the Indian National Income Committee; at this time, he

began to think about the macroeconomic problems of India. There were gaps in information for computing national income. To fill this, he established the National Sample Survey (NSS) in 1950, and also organized a statistical unit devoted to the study of national income. When Mahalanobis was asked to help in the formulation of 5-year economic plans for India, he took up the study of planning models. He realized that the models suitable for advanced countries might not be applicable for underdeveloped countries. Setting for himself the twin objectives of doubling the national income and reducing unemployment considerably over a period of 20 years, he produced what are known as the Mahalanobis two- and four-sector models for economic development.

In a series of papers, Mahalanobis considered a two-sector model, where the net output of economy is conceived as originating in two sectors, one producing all investment goods and the other producing all consumer goods. Assuming that the total investment every year is split up in the ratio $\lambda_i : \lambda_c (\lambda_i + \lambda_c = 1)$, between the investment and the consumer goods sectors, and introducing income coefficients of investments, β_i, β_c for the respective sectors, Mahalanobis obtained the equation

$$Y_t = Y_0 \left\{ 1 + \alpha_0 \frac{\lambda_i \beta_i + \lambda_c \beta_c}{\lambda_i \beta_i} [(1 + \lambda_i \beta_i)^t - 1] \right\},$$

where Y_t is the national income at time t and α_0 is base period investment. Using this equation, Mahalanobis concluded that a value of λ_i of approximately 0.3 would lead to a plausible limiting investment rate of 18%, which was adopted in the Indian Second Five Year Plan. Mahalanobis also considered a four-sector model, distinguishing three types of consumer goods industries, that was used in formulating the Indian Second Five Year Economic Plan.

Mahalanobis' association with the planning commission and his involvement in the formulation of the Second Five Year Plan brought him into contact with problems of wider national and international importance. He wrote extensively on subjects such as (1) the priority of basic industries, (2) the role of scientific research, technical manpower, and education in economic development, (3) world peace and the industrialization of poorer countries, and (4) labor problems, unemployment, and demographic problems. Mahalanobis considered scientific advance as a prerequisite of sustained economic development. He believed that economic progress entailed technological change that could be brought about only by engineers and technologists and that sustained technological research could prosper only in an atmosphere in which science in general flourished. In his writings on scientific research, technical manpower, education, etc., traces of a theory of economic growth are detectable. The role of innovations in economic development has

been stressed by Schumpeter and others, but Mahalanobis emphasized the connection between scientific advance and technological innovations and the role of decision making at the appropriate time.

Promotion of Statistics in India and the Asian Region

Mahalanobis will be remembered not only for the outstanding contributions he made to statistical theory and practice, but also for promoting national statistical systems for collection of data that are needed by governments for short-range policy decisions and long-range economic planning, and for promoting statistical quality control (SQC) techniques for use in industry. He was primarily responsible for the establishment of (1) the Central Statistical Organization (CSO) in 1951 to serve as a National Statistical Office at the all-India level, (2) statistical bureaus in each state to collect data at the state level, and (3) an independent National Sample Survey (NSS) organization for collecting socioeconomic data on a continuing basis. Mahalanobis was also responsible for creating consultation services located in different parts of India, for implementing SQC and operations research (OR) techniques in industrial establishments to increase productivity and improve the quality of manufactured goods.

Mahalanobis saw the need for developing statistics in the Asian region for socioeconomic planning. To train the statistical personnel needed in the countries of the Asian region, an International Statistical Educational Center (ISEC) was started at the Indian Statistical Institute in 1950 with the support of the United Nations Educational, Scientific, and Cultural Organization (UNESCO), the government of India, and the International Statistical Institute.

Honors and Awards

Mahalanobis was elected a fellow of the Royal Society of London in 1945, of the Econometric Society (United States) in 1951, and of the Pakistan Statistical Association in 1961; an honorary fellow of the Royal Statistical Society (United Kingdom) in 1954 and of King's College (Cambridge) in 1959; honorary president of the International Statistical Institute in 1957; and a foreign member of the (former) United Soviet Socialist Republics Academy of Science in 1958. He received the Weldon medal from Oxford University in 1944, a gold medal from the Czechoslovak Academy of Sciences in 1963, the Sir Deviprasad Sarvadhikari gold medal in 1957, the Durgaprasad Khaitan gold medal in 1961, and the Srinivasa Ramanujan

gold medal in 1968. He received honorary doctorates from Calcutta, Delhi, Stockholm, and Sofia universities and one of the highest civilian awards, Padmavibhushan, from the government of India.

Life With a Mission

The 79 years of Mahalanobis' life were full of activity. His contributions were massive on the academic side as the builder of the Indian Statistical Institute, founder and editor of *Sankhyā*, organizer of the Indian Statistical Systems, pioneer in the applications of statistical techniques to practical problems, promoter of the statistical quality control movement for improvement of industrial products, architect of the Indian Second Five Year Plan, and so on (see Table I).

During his life, he held several distinguished posts, many of them simultaneously. He was the chief executive of the Indian Statistical Institute, serving as secretary and

director continuously from the founding of the Institute in 1931; he was honorary statistical advisor to the government of India from 1949; and he was associated with the work of the Planning Commission as a member (1955–1967). He also served as head of the statistics department of Calcutta University (1941–1945) and statistical advisor to the government of Bengal (1945–1948). He was a member of the United Nations Statistical Subcommittee on Sampling from the time it was founded in 1946 and served as chairman from 1954 to 1958; he was general secretary of the Indian Science Congress (1945–1948) and, later, its treasurer (1952–1955) and president (1949–1950); and he was president of the Indian National Science Academy (1957–1958) and editor of *Sankhyā: The Indian Journal of Statistics*, from the time of its foundation in 1933.

Statistical science was a virgin field and was practically unknown in India before the 1920s. Developing statistics was like exploring a new territory; it needed a pioneer and adventurer like Mahalanobis, with his indomitable

Table I Chronology of Important Works by Mahalanobis

Year	Contribution
1922	Anthropological observations on the Anglo-Indians of Calcutta: Part 1. Analysis of the Male Stature (<i>Records of the Indian Museum</i> 23 , 1–96)
1923	Correlation of upper air variables (<i>Nature</i> 112 , 323–324)
1927	Report on rainfall and floods in North Bengal, 1870–1922 (submitted to the government of Bengal—volume 1, text; volume 2, 28 maps)
1930	On tests and measures of group divergence: Part 1. Theoretical formulae (<i>Journal and Proceedings of the Asiatic Society of Bengal, New Series</i> 26 , 541–588)
1931	Statistical study of the level of the rivers of Orissa and the rainfall in the catchment areas during the period 1868–1928 (report submitted to the government of Bihar and Orissa)
1936	On the generalized distance in statistics (<i>National Institute of Science, India, Proceedings</i> 2 , 49–55)
1940	A sample survey of the acreage under jute in Bengal (<i>Sankhyā</i> 4 , 511–530); The application of statistical methods in physical anthropometry (<i>Sankhyā</i> 4 , 594–598); Rain storms and river floods in Orissa (<i>Sankhyā</i> 5 , 1–20)
1944	On large scale sample surveys (<i>Royal Society of London, Philosophical Transactions, Series B</i> 231 , 329–451)
1946	Recent experiments in statistical sampling in the Indian Statistical Institute (<i>Journal of the Royal Statistical Society A</i> 109 , 325–378)
1949	Anthropometric survey of the United Provinces, 1941: A statistical study (<i>Sankhyā</i> 9 , 89–324)
1953	Some observations on the process of growth of national income (<i>Sankhyā</i> 12 , 307–312)
1955	Draft plan-frame for the Second Five-Year Plan, 1956/57–1960/61: Recommendations for the formulation of the Second Five-Year Plan (<i>Sankhyā</i> 16 , 63–90); The approach of operational research to planning in India (<i>Sankhyā</i> 16 , 3–62)
1958	Industrialization of underdeveloped countries: A means to peace (<i>Bulletin for Atomic Scientists</i> 15 , 12–17; also in <i>Sankhyā</i> 22 , 173–182); A method of fractile graphical analysis with some surmises of results (<i>Bose Research Institute Transactions</i> 22 , 223–230)
1960	A method of fractile graphical analysis (<i>Econometrica</i> 28 , 325–351; also in <i>Sankhyā, Series A</i> 23 , 41–64); A note on problems of scientific personnel (<i>Science and Culture</i> 27 , 101–128)
1961	Experiments in statistical sampling in the Indian Statistical Institutes (Calcutta: Asia Publishing House and Statistical Publishing Society; also in <i>Journal of the Royal Statistical Society, Series A</i> 109 , 325–378); Statistics for economic development (<i>Operations Research Society of Japan, Journal</i> 3 , 97–112)
1965	Statistics as a key technology (<i>American Statistician</i> 19 , No. 2, 43–46)

courage and tenacity to fight all opposition, clear all obstacles, and open new paths of knowledge for the advancement of science and society. The Mahalanobis era in statistics, which started in the early 1920s, ended with his death in 1972. It will be remembered as a golden period of statistics, marked by an intensive development of a new (key) technology and its application for the welfare of mankind.

Mail Surveys

Don A. Dillman

Washington State University, Pullman, Washington, USA

Glossary

response rate The percentage of sample units returning completed questionnaires.

response rate improvement techniques Individual procedures that are applied during the implementation of surveys primarily for the purpose of improving response rates.

tailored design Modifying the procedures used for conducting surveys on the basis of differences in population, purpose, and/or topic, with the goal of improving response rates and response quality.

visual communication Transmission of information through the sense of sight.

visual survey languages The words, symbols, numbers, and graphics used to transmit the meaning of questions that rely on visual communication.

Mail surveys are a means of collecting information from individuals, households, or other units of interest, whereby potential respondents are sent a paper questionnaire by postal mail or other courier. Individuals are asked to complete the questionnaires by self-administration and to return the surveys to the sender. Such surveys have been conducted for hundreds of years; as one of the oldest type of survey methods, the mailed questionnaire remains among the most prevalent procedures for collecting large quantities of information, especially from geographically dispersed respondents.

Introduction

Origins

The origin of mail surveys is unknown. However, in 1577, King Philip II of Spain conducted a census of his New World possessions using 38 written questions sent by

official courier. In addition, the first volume of the *Journal of the Royal Statistical Society* published in 1837 included a mail survey of Church of England clergymen. More than a century later, in Volume 124 of the same journal, a lengthy analysis of response rate research became the first of several meta-analyses that attempted to identify the major determinants of response to mail surveys.

Mail surveys are sometimes used for complete censuses. For example, the U.S. Census Bureau used mail surveys as the primary means of collecting population count information in the 2000 decennial census. More than 70 million households responded by mail, with visits from enumerators being used to collect information from nonrespondents. However, the most prevalent use of mail surveys is for scientifically drawn samples of large populations in which attempts are made to produce estimates for the entire population. Mail sample surveys and surveys by telephone or face-to-face methods are subject to the same sources of error—coverage, sampling, measurement, and nonresponse.

Coverage Concerns

In the United States, mail surveys were used extensively in the first half of the 20th century. However, as a method of collecting information from general populations, it was widely criticized. Compared to face-to-face interviews, the standard method for conducting most important surveys from the 1940s through the 1970s, mail surveys suffered from significant coverage problems. Lists did not exist for drawing samples of the general public such that all households (and individuals) would have a known, nonzero chance of being sampled, guaranteeing that scientifically based estimates could be made for that larger population. This shortcoming was demonstrated in an embarrassing way by the infamous *Literary Digest* survey that was conducted by mail in 1936. That survey collected

responses from more than 2 million respondents and predicted a landslide victory for Alf Landon (55% to 41%); in the actual election, Franklin Roosevelt beat Landon by an even wider margin (61% to 37%). The coverage problem stemmed from relying on telephone directories and automobile registrations for selecting households to receive their poll, and voters for Roosevelt were less likely than Landon supporters to have either. Coverage remains a major problem that limits the use of mail surveys for conducting surveys of the general public. Surveys of the general public require giving all households a known non-zero chance of being sampled, and it is rare to find lists that would fulfill this goal. In addition, it is important to select randomly the adult household member who responds. It is very costly, if not prohibitive, to achieve fully these requirements for such surveys. However, it is not a problem for more specialized populations, e.g., teachers, organization members, magazine subscribers, union members, and licensed professionals, for which complete address lists can often be obtained.

Response Rate Concerns

A second problem that has limited the use of mail surveys has been their reputation for producing low response rates. However, considerable progress has been made in finding solutions for this concern. In the 1970s, two publications on mail surveys provided research-based advice for improving response rates. The first book, *Professional Mail Surveys*, by Paul Erdos, emphasized the use of mail surveys in marketing research and provided detailed procedures for designing and implementing them. The second book, *Mail and Telephone Surveys: The Total Design Method*, emphasized the use of social exchange theory to design all aspects of the questionnaire and procedures experienced by respondents in ways that reduce perceptions of the social costs of responding (e.g., a sense of subordination) and increase perceptions of social rewards (e.g., a sense of doing something interesting) and trust (e.g., the likelihood that the results would be reported in a useful way). The total design method, or TDM as it is often called, was oriented toward university, government, and private foundation survey sponsors in much the same way that Erdos' procedures were oriented to private-sector organizations. The TDM also emphasized using quite similar procedures for most surveys. Both books established the idea in the 1970s that mail surveys using questionnaires of modest lengths, for most survey situations, could achieve response rates that were close to those normally obtained by other survey methods.

Reasons for Current Use

Mail surveys continued to be used heavily throughout the remainder of the 20th century. A 1981 review of all

U.S. government surveys revealed that of the 2137 active government surveys, 69% relied exclusively on self-administered methods (mostly done by mail), compared to 2.2% by telephone and 9.4% by face-to-face interviews; an additional 11% used self-administered questionnaires in combination with other methods.

Several factors have contributed to the heavy use of mail surveys. One of them is lower cost, especially in comparison to face-to-face interviews. Use of mail procedures made it possible to conduct large-scale surveys of thousands or tens of thousands of units; procedures on this scale otherwise would have been prohibitively costly to do. Although the cost of conducting mail surveys has been less than the cost of conducting telephone interviews, that gap narrowed significantly during the late 1980s and 1990s as computer-assisted telephone methods combined interviewing with data entry, thus eliminating a separate activity that is still required for most mail surveys. Another important contributor to the use of mail methods has been the ability of many organizations to use existing personnel and resources to conduct the surveys. Most mail surveys are simple enough to implement, so many organizations conclude that they can do it themselves. Whereas the skills needed for printing questionnaires and making multiple contacts exist in most organizations, the skills and software for conducting structured telephone interviews generally do not. In addition, improvements in list management software and printing capabilities have eased the task of implementing large-scale mail surveys for virtually any user.

In recent years, increased interest has developed for using mail surveys as one of two or more modes for collecting information in a particular survey. Concern over lower response rates, compared to telephone surveys, and coverage problems with the recently developed and less expensive Internet surveys are leading to the use of mail surveys as a way of reaching respondents who cannot be contacted or convinced to respond to the other interview modes.

Factors that Influence Response Rate

Factors that are Often Manipulated

Since the 1940s, hundreds of studies have investigated procedures that affect response rates to mail surveys. Two factors, multiple contacts and token financial incentives sent with the survey, stand out as being particularly effective for improving response rates. Other manipulations found to have a smaller, but significant, positive impact on response rates include respondent-friendly questionnaire design, stamped return envelopes, a request sent by

special contact (e.g., courier service or telephone), and personalization of correspondence.

A typical mail protocol might begin with a personalized prenotice letter, followed in a few days with a mail-out package that includes another personalized letter, a respondent-friendly questionnaire, \$2 cash incentive, and stamped return envelope. That in turn may be followed in a week by a thank-you/reminder postcard. Then, after waiting 2–3 weeks, a replacement questionnaire with a different explanatory letter and a stamped return envelope is sent. Finally, after a wait of a few more weeks without a response, a final effort might be made using a mailer that has contents similar to the fourth mailing, except for a new letter and being sent by overnight courier delivery. Such procedures consistently produce response rates near 60% or higher for many populations and situations.

Factors Less Subject to Manipulation

Response rates are also influenced by a number of considerations that are not usually subject to design manipulation. For example, it has been shown that salience or interest of respondents in the questionnaire topic has a substantial effect on response rates. The same study showed that questionnaire length, sponsorship by a market research firm, and survey of general populations had negative affects on response rates, whereas government sponsorship and the survey of school and army populations had positive effects. Also, completing mail questionnaires is difficult for people whose reading and writing skills are not well developed. Extensive research on this factor was conducted by the U.S. Bureau of the Census during the 1990s for decennial census test questionnaires. It was shown that response rates in areas of the United States with high proportions of lower income and minority populations (where about 11% of the U.S. population resides) and where education levels are low averaged 16–26 percentage points lower, compared to the remaining areas (where 89% lived). It was also determined that only one factor, i.e., respondent-friendly questionnaire design, of 16 potential response-inducing factors tested across several large-scale experiments, improved response more in the lower responding areas. These data provide evidence that response rates to mail surveys are limited by the characteristics of survey populations.

Tailored Design

Recognition that different survey sponsorship, the survey topic, and the nature of the population being surveyed may discourage the use of some response-inducing techniques and permit others has led to the development of a tailored design approach to improving survey response.

Tailored design uses the tenets of social exchange to shape survey implementation features somewhat more precisely for different survey populations and situations. For example, whereas token financial incentives are generally seen as appropriate for many private-sector surveys, they may be seen as quite inappropriate for establishment surveys and certain government-sponsored surveys.

The 2000 decennial census, to which all households are required by law to respond, is an example of tailored design. Extensive experimentation showed that placing a notice on the outside of the envelope, i.e., “U.S. Census Form Enclosed: Your Response is Required by Law,” improved response by nearly 10 percentage points. However, such a notice would be inaccurate, as well as inappropriate, on most other surveys. Other contrasts encouraged by a tailored design perspective might include concentrating six to eight contacts within a period of several weeks when asking people to complete a radio or TV diary, but stretching a smaller number of contacts out over many months in a government survey of manufacturers. Tailored strategies have even been used effectively to conduct election surveys, the traditional province of telephone survey methods. For example, for Ohio elections, it has been shown that results from a mail election survey conducted regularly since 1980 have been more accurate than comparable surveys conducted by telephone.

Increasingly, tailored design approaches are being used to ensure that good response is achieved in most mail survey situations. Improvements in response rates do not guarantee that nonresponse error, i.e., differences between respondents and nonrespondents on a variable of interest, will be reduced. However, the higher the response rates, the lower will be the potential biasing effect of even substantial differences in respondents and nonrespondents.

Measurement Considerations

Mail and Telephone Differences

Evidence exists that people answer mail surveys and telephone surveys somewhat differently; these two types of surveys have been most frequently compared, and at least four types of measurement differences have been noted by researchers. One difference is the tendency for mail surveys to be less prone to question-order effects, i.e., the possibility for answers to certain questions to be affected by other items, whether they appear before or after the affected items. Second, a consistent body of research has shown that respondents are less likely to offer socially desirable answers, i.e., answers that reflect attitudes or behaviors approved by the culture, in self-administered surveys than they are in surveys that require respondents

to give verbal answers to interviewers. For example, in one of the most recent publications that verifies this tendency, it was found that prostate surgery patients gave more positive answers about their current health by telephone interview than they did by mail.

There is a third type of measurement difference related to mail versus telephone: it has been hypothesized that in mail or self-administered surveys, respondents are more likely to choose from the first answer choices presented. This is called a primacy effect;—in telephone surveys, respondents are more likely to choose the last categories presented, known as a recency effect. Primacy is believed to occur because respondents tend to use their early answers as a base of comparison with others and work down the list only until they have found a satisfactory answer. Recency effects are thought to occur because under conditions of aural communication, the first categories read by an interviewer are less likely to be retained in short-term memory. However, an analysis of 82 experiments involving both mail and telephone surveys found no differences between methods in the occurrence of either primacy or recency effects.

Yet another tendency observed in past research is for mail survey respondents to give less extreme answers compared to those offered over the telephone. For example, on a series of community and neighborhood perception questions deemed to have low, if any, social desirability attributes, telephone respondents were much more likely to choose the extreme positive categories by a substantial margin.

Some Effects of Dependence on Visual Communication

The process of answering mail questionnaires differs in several significant ways from the manner in which telephone surveys are answered. One of these is the complete reliance on visual, rather than aural, communication. Information on self-administered questionnaires is communicated through four languages: words (also used in interviewer-administered questionnaires), numbers (which provide guidance on things such as in which order questions should be read and answered), symbols (e.g., arrows and answer boxes, which communicate navigation and response expectations), and graphics. Variations in graphical language, the conduit through which the other languages are expressed, includes considerations such as variations in size, brightness, color, and location, which communicate how information presented on self-administered questionnaires should be grouped and interpreted by respondents. A theory of how these elements may affect whether information on self-administered gets read and followed has been developed and tested. Results show that answers to mail surveys can

be significantly changed by manipulating symbols and the graphical display of information on questionnaire pages. These visual design concepts have also been used in an attempt to reduce certain errors that are much more likely to occur in self-administered questionnaires than in interview surveys—namely, the tendency for respondents to follow branching instructions incorrectly. Branching instructions direct respondents to different questions, depending on which answer choice was selected for a preceding question. It has been shown in a national test of census questionnaires that the effectiveness of branching instructions can be substantially improved through better use of the language constructs (words, numbers, symbols, and graphics) in a way that makes the language constructs more mutually supportive.

Although the use of visual languages plays an obvious role in how respondents interpret and use information in mail questionnaires, much remains to be learned about how differences in answers to specific questions result from differences in graphical composition. It also remains to be determined how important the visual aspects of questionnaire design are in comparison with others for explaining the frequently observed differences in answers to interview questionnaires, such as primacy and extremeness effects.

Effects of Technology

Many of the processes associated with obtaining high response rates to mail surveys, e.g., use of personalized correspondence and repeated mailings, are labor intensive. Development of word processors in the 1970s began to reduce the time and costs required for such efforts, and facilitated keeping track of returns to avoid duplicate mailings. However, most mail questionnaires, even today, require manual data entry, a separate step in processing that is not required for telephone surveys collected through computer-assisted methods.

Since the 1960s, it has been possible to use optical scanning as a means of avoiding manual data entry. However, these early methods relied on a reflective mark technology that required respondents to fill in circles or ovals completely on specially designed questionnaires for which special colors of (drop-out) inks were used to print the questions and the answer spaces. Such questionnaires were often inflexible (answers had to go on certain portions of the pages and be printed in pastel colors) and have been judged not to be respondent friendly. Dramatic changes have occurred in these technologies. Today, instead of being limited to scanning questionnaires under colored lights to read pencil marks in ovals, it is possible to import complete images of questionnaires into computers and to automate further the process of summarizing answers. Software exists for recognizing check marks, numbers, and characters, so

they can be read directly during computer processing. The ability to recognize numbers and letters has been improved significantly through the use of visual principles for design. For example, white spaces for answers can be set against colored backgrounds, and segmentation marks can be added to divide internally the answer spaces. As a result, respondents are more likely to print rather than use cursive writing, and to stay within confined spaces, both of which facilitate faster processing. It remains to be seen how these developments will affect the general use of mail surveys.

Future Uses of Mail Surveys

The future use of mail surveys appears somewhat unclear. On the one hand, the high costs of face-to-face interviews and declining response rates to telephone surveys suggest that more surveyors may consider using mail surveys. On the other hand, the ability to conduct self-administered surveys over the Internet, for which costs are substantially less than for mail, especially for large samples, suggests that Web surveys may replace those by mail. The situation is complicated by the fact that for many, if not most, survey populations, access to the Internet is limited. In addition, telephone surveys exhibit an increasing coverage problem, as in some advanced industrial countries the telephone becomes more of a personal device, and some people forgo the traditional household telephone.

It seems likely that surveyors will attempt to deal with these issues through the increased use of mixed-mode surveys, which means that some individuals in a sample will be surveyed by one mode while others respond by alternative modes. This in turn raises the issue of whether mail surveys and surveys using other modes will obtain the same answers to questions, an issue that will no doubt command the attention of researchers for many years to come.

Marketing Industry

Maria Anne Skaates

Aarhus School of Business, Aarhus, Denmark

Glossary

database marketing The creation and use of databases and other information management systems to find potential customers, service them, and monitor their preferences.

interaction marketing Activities concerned with the development of supplier and customer relationships to ensure better creation and delivery of the products or services offered.

marketing The process by which products and services of value to customers and potential customers are created, communicated, and delivered.

marketing industry The collective composed of all firms, organizations, groups, and individuals who collect and analyze information about the needs, preferences, and current and potential future demands of current and potential customers for use in creating, communicating, and delivering goods and services in a way that will ensure sufficient returns.

marketing information system An information management system composed of people, equipment, and methods for collecting and analyzing information about customers and potential customers and delivering the analysis to decision makers.

network marketing The development of relationships to multiple stakeholders, including customers, to enable the optimal offering delivery as well as the optimal coordination of offering-related activities among the stakeholders in the network of relationships.

relationship marketing Activities concerned with creating and optimizing customer relationships. May encompass database, interaction, and/or network marketing practices.

segmentation The subdivision of a market into groups of consumers that have different needs, preferences, or user behavior and thus can be addressed through separate offerings or advertisements.

test market A small, most often geographically defined section of a market with members who are believed to have the same characteristics as are found in the entire

market. A test market is used for marketing experiments with, e.g., product design, pricing, or advertising.

transaction marketing A type of marketing that is primarily concerned with optimizing product or service characteristics connected to an individual transaction such as quality, price, promotion, place of sale, etc., in relation to customer preferences.

The marketing industry encompasses firms, organizations, groups, and individuals involved in conducting research about markets and about the needs, preferences, and current and potential future demands of customers. These aspects are examined in this article, first by briefly describing the marketing industry and its areas of focus. Thereafter, research questions and methods pertaining to the marketing industry are discussed. Finally, future developments in the research done by and methods used by the marketing industry are addressed.

The Marketing Industry and its Areas of Focus

Marketing is a process of activities by which firms, organizations, groups, or individuals create, communicate about, and deliver offerings of value to other firms, organizations, groups, or individuals. The offerings may include any combination of goods, property, services, and other intangibles (e.g., brand name, corporate reputation, supplier and customer relationships, value propositions, experiences, events, individual expertise, or knowledge). In order to create, communicate about, and deliver offerings, marketers must have a profound understanding of the needs, preferences, and current and potential

future demands of current and potential customers and of the offerings of competitors. However, in order to make the long-term creation, communication about, and delivery of offerings feasible, sufficient returns need to be obtained on the offerings. Marketers are therefore also necessarily concerned about the economics of the creation, communication, and delivery of current and potential offerings, yet marketers often work with other business researchers, such as those persons responsible for accounting measures or business performance measurement, or technical professionals (logisticians or production engineers), to map the economics of offerings.

The marketing industry encompasses all firms, organizations, groups, and individuals involved in conducting applied social science research by collecting and analyzing information about markets and the needs, preferences, and current and potential future demands of current and potential customers for use in creating, communicating, and delivering offerings that will achieve sufficient returns. From this it follows that the marketing industry includes individuals and groups from private enterprises, governmental institutions, and not-for-profit organizations as well as entire organizational units (e.g., firms specialized in market research or export promotion offices of states, provinces, or countries). However some of these individuals, groups, or organizational units perform marketing only on a part-time basis, in that they also are involved in other organizational tasks such as managing production or service delivery, hiring new staff, or keeping records of income and expenses.

In their marketing research, marketers examine specific issues related to the creation, communication, and delivery of offerings in a way that ensures sufficient returns. In connection with these issues, they pose specific research questions, then gather and analyze data using various methods and research designs. These points are elaborated on further in the following sections of this article.

Marketing Research Questions

Questions Pertaining to the Levels of Business Strategy

In large organizations, business strategy is commonly developed at the levels of the organization as a whole, the business unit, and the operating line. In contrast, in smaller organizations, strategy is often developed at only one level, and the strategy development process may occur either during or after the market-related information is gathered and analyzed. The roles that marketers fulfill in relation to strategy formulation in large organizations have been specified as follows: At the level of the organization as a whole, marketers work with the

assessment of market attractiveness and at ensuring that top management understands customer demands. Furthermore, at this level, marketers are involved in the development of a specific global policy concerning the interlinked issues of (1) which types of offerings the organization should develop, (2) which types of customers it should aim to serve, and (3) which types of underlying internal resources and capabilities it should develop. Possible research questions that correspond to these themes are found in Fig. 1, which also lists research questions relevant to the other levels of strategy formulation in large firms.

At the level of the business unit, questions that marketers commonly address include how to target potential customers (including the possible use of market segmentation and relational marketing techniques); how to position the offerings in relation to, e.g., competitors' offerings or the requirements of distributors; and what areas of offering-related development, production, advertisement, and delivery should be outsourced to other firms. At the level of the operating line, marketers are involved in formulating and implementing the quality of specific offerings and the pricing, promotion, and distribution policies; in managing relationships to end customers and distributors; and in problem solving in relation to previous marketing policy mistakes or misjudgments. In relation to the levels of the business unit and the operating line, it is relevant to note that there is some overlap between the types of research questions and research methods used by marketers and those used by practitioners in the field of communication.

Questions Pertaining to Four Types of Marketing Activities

The marketing practices of organizations influence the research questions that their marketers pose. In a study of practices of firms in five countries, Coviello, Brodie, Danaheer, and Johnston (2002) took their point of departure in four different types of marketing activities:

1. Transaction marketing: activities concerned with optimizing product characteristics such as quality, price, promotion, place of sale, etc.
2. Database marketing: the creation and use of databases and other information management systems to find potential customers, monitor customers' preferences, and ensure optimal customer service.
3. Interaction marketing: activities concerned with the development of supplier–customer relationships to ensure, e.g., a better creation and delivery of the offering seen from viewpoint of the customers.
4. Network marketing: the development of multiple relationships to enable the optimal offering delivery as

Level of the organization as a whole:

- How much economic benefit would our corporation get out of establishing our own sales subsidiary in Australia?
- Should our fast food chain continue to target business professional eating lunch worldwide?
- Would the largest individual customers of our civil engineering design services also value our company developing facility management services so much that they would ask us to manage the facilities that we have designed for them, if we developed such facilities management capabilities?
- If we divest our own production activities and instead enter production contracts with firms X and Y, will this have a positive or negative effect on our sales to major industrial customers?

Level of the business unit:

- What should characterize our line of specialty drills if we are to differentiate them from those currently sold to do-it-yourselfers in Germany?
- What sorts of salads sell best to our repeat lunchtime customers who use their loyalty program card?
- How should the employees in our shops inform individual customers of the types of fashion trends that this line of clothing seeks to mirror?
- How much of the after-sales service on our product line should we make a specific external provider of such services responsible for?

Level of the operating line:

- If we increase the price of drill X by Y, how will this affect total sales in Germany?
- Does this fat-reduced sandwich appeal to those lunchtime business professionals who are part of our loyalty program?
- To better meet a specific customer's needs, should we arrange for special deliveries and if so, what should we charge this customer for this extra service?
- To what extent do teenagers introduce each other and their parents to the fun of playing this mystery video game by using its "solve the mystery as a group" function?

Figure 1 Examples of marketing research questions at the levels of business strategy.

well as optimal coordination of offering-related activities among the actors of the network of relationships.

In larger organizations, these four types of marketing activities may pertain to all three levels of business strategy formulation mentioned previously, i.e., the levels of the organization as a whole, the business unit, and operating line. Therefore, in Fig. 2, the research questions listed in Fig. 1 have been regrouped to illustrate to which of the four types of marketing activities they pertain. The manner in which the data are presented in Fig. 2 does not represent the only way in which marketing activities may be categorized. For example, looking at an individual offering, i.e., a specific product or service, it would also be possible to categorize the marketing activities according to phases: (1) development of the offering, (2) introduction of the offering to the market, (3) further development or maintenance of the offering on the marketing, and (4) removal of the offering from the market. Nevertheless, the focus on the classifications presented in Fig. 2 is maintained in this article because these classifications deal with the more general, multiple-offering situation. The results of the five-country study indicate that transaction and interaction marketing practices are much more widespread than database and network marketing are. However, this may change in the future, if hardware, software, and methods for database and network marketing develop in coevolution with the increasing levels of

knowledge richness and acknowledgment of diversity in advanced societies. Furthermore, the five-country study results showed that firms that sell to consumers focus to a greater extent on transaction and database marketing than do firms that sell to businesses, and that firms that sell goods are generally more transactional than are firms that sell services. However, the results also indicate that there is substantial variation among firms. It is possible to find examples of both transactional and relationship (i.e., database, interaction, or network) marketing practices in all firm types, and around one-third of the firms in the five-country sample combine transactional and relational practices.

The Link between Marketing Research Questions and Views on Measuring Human Behavior

As in other social research, the aims of marketing research questions vary. They may, for example, seek to increase exploration of specific instances of human behavior in relation to a particular offering or to explain trends or patterns in market share or consumer acceptance by documenting relations of causality or teleology. Similarly, the views of marketing researchers and their customers on the possibilities of measuring human behavior vary. Some marketing researchers and marketing research customers

Transaction marketing:

- How much economic benefit would our corporation get out of establishing our own sales subsidiary in Australia?
- What should characterize our line of specialty drills if we are to differentiate them from those currently sold to do-it-yourselfers in Germany?
- If we increase the price of drill X by Y, how will this affect total sales in Germany?

Database marketing:

- Should our fast food chain continue to target business professionals eating lunch worldwide?
- What sorts of salads sell best to our repeat lunchtime customers who use their loyalty program card?
- Does this fat-reduced sandwich appeal to those lunchtime business professionals who are part of our loyalty program?

Interaction marketing:

- Would the largest individual customers of our civil engineering design services also value our company developing facility management services so much that they would ask us to manage the facilities that we have designed for them, if we developed such facilities management capabilities?
- How should the employees in our shops inform individual customers of the types of fashion trends that this line of clothing seeks to mirror?
- To better meet a specific customer's needs, should we arrange for special deliveries and if so, what should we charge this customer for this extra service?

Network marketing:

- If we divest our own production activities and instead enter production contracts with firms X and Y, will this have a positive or negative effect on our sales to major industrial customers?
- How much of the after-sales service on our product line should we make a specific external provider of such services responsible for?
- To what extent do teenagers introduce each other and their parents to the fun of playing this mystery video game by using its "solve the mystery as a group" function?

Figure 2 Examples of marketing research questions by type of marketing activity.

believe strongly in the quest for objectivity and are therefore less open to phenomenological research. Others may be more open to phenomenological marketing research and more critical of efforts to determine cause or correlation through quantitative research; this may be due, for example, to the ongoing discussions about the possibilities of achieving content validity, about the validity of hypotheses tests and proof, and about statistical versus substantive data interpretations.

Marketing Research Methods

Operationalization of Research Questions

Research questions such as the ones presented in Figs. 1 and 2 have to be operationalized, i.e., reformulated to allow for measurement using secondary data and/or primary data (including communication with the persons whose behavior and opinions are to be examined by the marketing researchers via surveys, focus groups, participant observation, or interviews). In connection with this communication, it is paramount that the persons whose behavior and attitudes will be examined understand the questions posed in the same way as the marketing researchers believe they are understood. This can be

especially problematic for marketing researchers if cross-cultural data are to be collected and interpreted. Especially if the marketing researchers do not have sufficient knowledge of foreign market and foreign customers, there are risks of ethnocentrism and poor translation equivalence in the formulation of research questions and in the interpretation of responses. Methodologies from anthropology, communications, and linguistics may, however, be used by marketers to minimize ethnocentrism and translation problems in marketing research.

Ethical issues, such as ensuring anonymity and confidentiality of respondents and taking into consideration issues concerning their personal risks, consent, and privacy, are also considered by marketers in connection with the operationalization of research questions as well as with the rest of the marketing research process. In connection with these issues, marketers are subject to substantial national and supranational (e.g., European Union) variations in data protection legislation, and the marketing research industry's own rules, recommendations, and norms also vary from country to country.

Marketing Information Systems

Individuals or organizations that collect and analyze information about the needs, preferences, and current and

potential future demands of current and potential customers on a regular basis often make use of previously established marketing information systems. Such systems for marketing information management are composed of individuals, equipment (such as data-mining and data-warehousing software), and methods for collecting and analyzing information about customers and potential customers and then delivering the analysis to relevant decision makers. Thus, with specific regard to the marketing industry, customer listening systems or, in some instances, systematized customer feedback systems can be considered. In contrast, organizations that conduct marketing research only occasionally usually do not develop marketing information systems. Instead, they rely on the more *ad hoc* use of some of the qualitative and quantitative methods discussed in the following sections.

Qualitative Methods of Marketing Research

Marketing research studies using qualitative methods most often explore and describe the nature of offering- or market-related phenomena without using stratified or random samples. This is in contrast to marketing research studies using quantitative methods, which normally seek to measure and explain patterns of predefined offering-related phenomena in an entire population using established sampling methods. Thus, qualitative methods are especially relevant when marketers are concerned with in-depth understanding of phenomena and with “whys” and “hows.” Examples of the application of the marketing research questions that were listed in Figs. 1 and 2 to qualitative methods are given in Fig. 3. It is important to note that some of the research questions in Fig. 3 can also be applied to quantitative methods. In fact, there is

often the option of doing either qualitative or quantitative research or combining the two research approaches. Qualitative research methodologies used by marketing practitioners include case study-based research, ethnographic and field study research, individual interviews, focus group research, and observational studies.

Case study methodology is especially appropriate for capturing current or recent phenomena in circumstances when the boundaries between the phenomenon and its context cannot be predetermined and when there are multiple sources of empirical data (e.g., interview data and firm-internal documents) available for inspection. Thus, an Irish marketing bureau specializing in helping Irish high-technology firms communicate about their products and services to potential North American customers and capital-providers might undertake case study research of previous Irish high-tech firm internationalizations to North America. Similarly, a South African marketing consulting firm specializing in helping local retailing operations expand nationally might do a case study of the changes in the delivery function during a successful national expansion. Ethnographic and field study research are often used in international marketing research and in research into subcultures in societies. In these cases, one or more researchers also participate actively in the activities of the culture or subcultures, to gain an insider understanding. For example, a market researcher of a new light ale targeted at young adult women on its domestic market might frequent bars and cafés in a foreign country to learn more about the drinking habits and preferences of the young adult women there. This participant observation would enable the researcher to determine reasons why the light ale could/could not be targeted in the same way in the foreign market.

Interviewing of individuals is a major source of information in qualitative research, and as such it is most often

- Would the largest individual customers of our civil engineering design services also value our company developing facility management services so much that they would ask us to manage the facilities that we have designed for them, if we developed such facilities management capabilities?
- If we divest our own production activities and instead enter production contracts with firms X and Y, will this have a positive or negative effect on our sales to major industrial customers?
- What should characterize our line of specialty drills if we are to differentiate them from those currently sold to do-it-yourselfers in Germany?
- What sorts of salads sell best to our repeat lunchtime customers who use their loyalty program card?
- How should the employees in our shops inform individual customers of the types of fashion trends that this line of clothing seeks to mirror?
- How much of the after-sales service on our product line should we make a specific external provider of such services responsible for?
- Does this fat-reduced sandwich appeal to those lunchtime business professionals who are part of our loyalty program?
- To better meet a specific customer's needs, should we arrange for special deliveries and if so, what should we charge this customer for this extra service?
- To what extent do teenagers introduce each other and their parents to the fun of playing this mystery video game by using its “solve the mystery as a group” function?

Figure 3 Examples of marketing research questions suitable for qualitative inquiry.

also used in case studies, ethnographic, and field study research, yet it may also be used alone. For example, a U.S. Chamber of Commerce seeking to increase the demand for its services among its members may conduct market research interviews with selected individuals from member firms. On the other hand, focus group research involves inviting a small group of respondents to a meeting where they will be asked about their attitudes and behavior. In focus group research, group interaction effects may produce data and viewpoints that would not have been accessible through individual interviews. Thus the aforementioned U.S. Chamber of Commerce effort seeking to increase the demand for its services among its members might also have conducted its market research by arranging for a small number of individuals from member firms to participate in focus groups.

Two types of observational studies, participant and passive, are used by the marketing industry. Participant observation, has already been discussed in relationship to ethnographic and field study research. Passive observation is a more unobtrusive method and a method that should guarantee greater neutrality in data collection in that it involves collecting data without interaction with the persons being studied. Passive observation is very much used in consumer research. For example, the marketing department of an Italian company that develops children's toys may conduct passive qualitative observational studies of how children play with various prototype versions of the toys.

Quantitative Methods of Marketing Research

Quantitative methods seek to measure various offering-, consumer-, or market-related phenomena in an entire population and to explain patterns of predefined offering-, consumer-, or market-related phenomena through causal inference or teleological explanation. Such quantitative

measurements enable, among other things, segmentation, i.e., the subdivision of a market into groups of consumers that have different needs, preferences, or user behavior and thus can be addressed through separate offerings or advertisements. Those marketing research questions listed in Figs. 1 and 2 that are suitable for quantitative methods of research are shown in Fig. 4. It is important to remember that many of these research questions could have also been studied using qualitative methods. In connection with this point, quantitative methods have the advantage of generating results that can be generalized to larger populations, whereas qualitative methods enable marketing researchers to go into specific instances in great depth.

In quantitative research, the marketing industry most often uses sample research designs; however, occasionally, censuses of entire populations are used. In quantitative international marketing research, marketing researchers must seek to achieve construct equivalence, measurement equivalence (through scale transformation, for example), and sampling equivalence as well as comparability between national research designs. Because markets, consumers, and offerings change over time, the marketing research industry, similar to the polling industry, conducts a substantial portion of both its domestic and international research at intermittent intervals, using either longitudinal panel studies or cross-section data.

Instead of primary data, the marketing research industry very often uses suitable, valid, and reliable secondary data if they are available, because it is usually more expensive to generate primary data. Types of secondary data commonly used by marketers include demographic, psychometric, labor market, polling industry, consumption and saving, household behavior and family economics, and tourism statistics data; census-derived retail trade, wholesale trade, inter- and intraindustry trade, and international trade data; and industry-, nation-, or region-specific data on economic development, technological

- How much economic benefit would our corporation get out of establishing an own sales subsidiary in Australia?
- Should our fast food chain continue to target business professionals eating lunch worldwide?
- What should characterize our line of specialty drills if we are to differentiate them from those currently sold to do-it-yourselfers in Germany?
- What sorts of salads sell best to our repeat lunchtime customers who use their loyalty program card?
- How should the employees in our shops inform individual customers of the types of fashion trends that this line of clothing seeks to mirror?
- How much of the after-sales service on our product line should we make a specific external provider of such services responsible for?
- If we increase the price of drill X by Y, how will this affect total sales in Germany?
- Does this fat-reduced sandwich appeal to those lunchtime business professionals who are part of our loyalty program?
- To what extent do teenagers introduce each other and their parents to the fun of playing this mystery video game by using its "solve the mystery as a group" function?

Figure 4 Examples of marketing research questions suitable for quantitative inquiry.

change, and growth. Such data may be acquired by marketers from governmental organizations at the local, regional, national, or supranational [e.g., European Union (EU), North Atlantic Free Trade Association (NAFTA), Organization for Economic Cooperation and Development (OECD), World Bank, and World Trade Organization (WTO)] levels, from industry or business organizations, or from private firms specializing in publishing market research reports. However, in general, there are fewer available secondary data on markets and consumers from the developing countries.

In cases in which it is necessary for marketers to generate their own primary data, the marketing industry utilizes surveys, quantitative observations, and pre-experimental, quasi-experimental, and true experimental designs. Surveys have traditionally been conducted over the telephone, through personal interviewing, or via mailings to potential respondents. In recent years, the Web-based survey has become increasingly important, especially in countries in which a substantial portion of businesses and most of the general population have access to the Internet. Surveys are appropriate to determine opinions of customers and potential customers about pricing, packaging, promotion, points of sale, and the quality of offerings and the quality of their relationship to the producer or the retailer or to determine general patterns of household behavior and family economics. However, industry experts may also be surveyed for strategic marketing purposes; in this case, these experts are commonly asked about their beliefs concerning future industry or market developments.

Passive observation is used as a quantitative method, too. In quantitative observation, the measurement may concentrate on the number of times something occurs or the amount of time or money spent on something. Human researchers are sometimes involved in quantitative observation, e.g., when a marketing researcher working in a Brazilian shopping center records the number of customers who visit a shop for formal men's attire, the times of day that these customers arrive, and the parts of the shop that they visit. However, quantitative human observation research may also take the form of an audit of stocks. For example, a marketer in a Japanese supply firm that supplies its business-to-business customers according to their materials management policies may take an inventory of the number of the customer's preferred brands, the customer's current quantities of products and packaging, and general size of the customer's storage facilities. A great deal of quantitative observation is also undertaken electronically. Examples of electronic means of recording activity include the use of tracking "cookies" (information stored on a computer user's hard disk, by the server, following a client/server interaction) to monitor consumers' Internet use, the use of "loyalty cards" by retail shops, hotel chains, or airlines to monitor

customer purchase patterns, and installation of the A. C. Nielsen audiometer in a consumer's television set to record which channels are accessed.

Pre-experiments do not control for extraneous factors through randomization. For example, through the use of a one-shot case study design, the attitudes of a number of respondents may be measured by marketing researchers immediately after a critical, yet unforeseeable, event such as a company winning a prestigious award or a large-scale product recall. Alternatively, if an event is foreseeable, such as the introduction of new product features, the single group may be exposed to a pretest/posttest design, in which group attitudes are measured before and after the change. Quasi-experiments are characterized by the researcher being able to control when, on whom, or what measurement is to be undertaken, yet not being in total control of the extraneous stimuli that those persons or objects to be measured will experience. Most marketing research field experiments, such as the use of test markets or computer-simulated test markets, are quasi-experiments. A test market is a small, most often geographically defined section of a market with members who are believed to have the same characteristics as are found on the entire market. A test market may be used for marketing experiments with product design, pricing, or advertising. For example, a Pakistani producer of radio commercials wants to test the effectiveness of a commercial jingle by broadcasting it and subsequently surveying two test panels, one located in the area of where the commercial is to be broadcast and the other in a neighboring area. Because the producer cannot be certain of the number of members of the first panel who have heard the jingle or that all the members of the second panel have not heard the jingle, the producer is not in total control of extraneous stimuli.

True experiments are marked by both randomization with regard to the assignment to test units to groups and by a large level of control for extraneous variables. For example, a bank located in a country such as Finland, where consumer Internet banking is very widespread and where the vast majority of I-banking customers use a single bank's I-banking interface, would be able to conduct true experiments concerning variations in its Internet banking interface. For this field experiment to be a true experiment, the Finnish customers involved in the experiment would have to be randomly assigned to the experimental and control groups. Additionally, a high level of control of extraneous variables could be achieved because the Finnish customers would access only the specific I-banking interface and thus would not be subject to uncontrollable communication from competing banks.

Laboratory experiments are sometimes used in marketing research. In these cases, the laboratory may be a restaurant, place of entertainment, shop, or trade fair environment designed exclusively for experimentation

purposes. The possibilities for controlling extraneous variables tend to be higher in such laboratories. However, human subjects of research may still respond differently to the stimuli in such laboratories than they would in other situations, especially if they are aware that they are a part of a test and/or are present in a laboratory.

Future Developments in the Marketing Industry

The future of the marketing industry will be influenced by broader societal developments, including the evolution of production and distribution structures, further innovations in the area of information technology, and continued public debate and governmental regulation concerning international trade and the protection of sensitive person-related data. As concerns the evolution of production and distribution structures, in some industries, marketers are faced with increasingly short product development and launch periods. This occurs in industries that are highly influenced by fashion or fads, such as the clothing industry or the entertainment industry. In these cases, the marketing research and its resulting product or service adjustments are often done on a real-time basis, i.e., on the basis of data accumulated in marketing information systems and/or through the use of universal product code (UPC) bar codes, "loyalty cards" in retail shops, or monitoring devices that record the consumer's use of the Internet, the television, or video game equipment. It is expected that this trend toward "real-time" marketing research will continue in the future. In service industries (such as chartered travel, hotels and motels, retailing, airlines, and, in some countries, rail travel), special systems of real-time pricing based on marketing information on achieved sales are being implemented. These systems have revolutionized the marketing industry's possibilities for determining an optimal price at a certain place and time.

The production and distribution structures used by the marketing industry to distribute its market- and customer-related information are also evolving due to new information technology possibilities. Marketers within many multinational companies communicate with each other on a daily basis via either the Internet or an internal network, and they also hold meetings using teleconferencing facilities. Additionally, relationships between client firms and the marketing industry's consulting firms are often reinforced by such telecommunication. These developments are expected to become even more prevalent in the future, as is the trend toward the increased use of Internet (and perhaps even mobile) services in transmitting surveys to and from respondents. Finally, in the future, respondents may also be interviewed individually

or in focus groups via teleconferencing, just as Internet discussion groups may also be used for research in many of the same ways that focus groups are currently being used. However, the methodologies for conducting communicative marketing research electronically are not yet as well developed as the corresponding traditional, face-to-face methods are.

Evolutions in information technology have also allowed for more advanced statistical and econometrical analysis than was previously possible, as well as very advanced business information software programs that contain data-mining and data-warehousing features. In many of these business information software programs, the marketing information systems related to customer listening are regarded as just one part of more general management information systems, which also encompass financial planning systems, materials and production management systems, human resource management systems, and systems for monitoring specific competitors' activities. Thus, marketing research and marketing decisions, and here especially the marketing research and decisions at the level of the whole organization, are increasingly also being assessed by business information gatherers who are experts in other fields of business administration. This increases the need for members of the marketing industry as well as all other types of business specialists to have sound generalist knowledge of all of the main areas of decision making in organizations and of the interdependencies between these areas.

The demand for international marketing research is related to the extent of trade liberalization and the harmonization of product requirements in relation to national or international standards, consumer protection issues, and environmental policy. However, due to the progression of trade liberalization talks in the WTO and the General Agreement on Trade in Services (GATS), for example, as well as the creation and further strengthening of trade blocks such as the EU and NAFTA, it can be expected that the marketing industry will be even more involved in international marketing research than it has been. Thus, there will also be a need in the future for marketers who have skills in the methods used to conduct market- and customer-related social measurement in more than one country.

Regarding the protection of person-specific data, it is much more difficult to predict the future, because public opinion and the actions of lawmakers will very likely be influenced by specific events. Such events include possible media disclosure of the illegal use and/or perceived unethical use of such data or, to the contrary, stories in the media of successful product or service improvements that would not have been possible without the generation and combination of such person-specific data. However, it can be said with a high degree of certainty that this is an area that is being watched intensively in many democratic

countries by the media as well as by consumer rights organizations and organizations concerned with civil liberties.

Glossary

Bernoulli variable A random variable that takes only two values, usually designated by 0 and 1.

factor analysis A method of statistical analysis designed to show how far a set of correlations between variables can be explained by its dependence on a smaller set of unobserved variables.

factor score The predicted (or “estimated”) value of an unobservable variable.

Gini coefficient A scale-free measure of dispersion for a positive random variable.

indicator A directly observable random variable that depends on an unobservable variable and thus “indicates” something about its value.

intelligence quotient (IQ) A widely used measure of cognitive ability.

latent variable A random variable that cannot be directly observed; also known as a hidden variable or a factor.

logit If p lies between 0 and 1, then $\text{logit } p = \log_e[p/(1-p)]$.

manifest variable A random variable that is directly observable.

Markov chain A process, developing over time, in which the probability of moving to a new state at any time depends only on the current state.

Social measurement poses particular problems because many of the quantities occurring in social discourse cannot be measured directly. Indirect methods based on mathematical or statistical models provide an important way out of this impasse. This approach enables many measurement problems to be posed as problems of statistical estimation or prediction.

Introduction

Social Measurement

Measurement is the cornerstone of science. Laws of nature typically express the relationship between measured quantities. Ohm’s law, for example, states that the voltage divided by the current flowing in a circuit is equal to a constant called the resistance. Physicists have invented instruments for measuring the basic variables of the physical world—length, mass, time, and electric charge. In the social sciences, the position is much more complicated, although social scientists often aspire to the standards of measurement set by their natural science colleagues. In some areas, especially in economics, it is sometimes possible to quantify the concepts in a way that allows them to be measured directly. Time and money, for example, are two variables for which measurement poses relatively few problems. This is “direct” measurement because the quantity of interest is directly expressible in terms of some readily measurable quantity. However, a great many other variables are not so readily captured. For example, cost of living, quality of life, arithmetical ability, or social mobility are all spoken of quantitatively, yet there are no simple measuring instruments to measure them in the direct way that is usual in the natural sciences. What is usually available in such cases is a set of indicators—that is, a collection of directly measurable quantities that are believed to reflect the underlying quantity of real interest to some degree. The problem of measurement is then to distill from this collection of indicators the essence of the variable of interest. Put in another way, the task is to assign numbers to objects in a way that corresponds to the intuitive notion of their “magnitude.” Measurement of this kind may be described as *indirect*. It is in indirect measurement that mathematical and statistical methods come in to play.

Examples

Before proceeding, it will help to have a variety of examples in mind. Common examples arise in most of the social sciences and in related areas such as medicine. In economics, quantities such as the cost of living or industrial production need to be measured so that comparisons can be made over time and so that the quantities can be used as inputs to econometric models. Many indicators (for example, of the cost of living) are usually expressed as price relatives (that is, current prices expressed in terms of the prices at some earlier time). Some kind of average (usually weighted) then serves as a measure of the unobserved quantity.

In sociology, a large amount of work (much originating with Karl Schuessler of the University of Indiana) has focused on the measurement of “social life feelings.” This covers attitudes such as feeling “down,” job satisfaction, and disillusionment with government. One of the main interests of quantitative sociologists has been in social or occupational mobility. Intergenerational mobility is concerned with the movement of family lines between social classes (usually defined by occupation). Sociologists are interested in comparing the mobility of different societies and of the same society at different times. For this they need measures of mobility.

Psychologists have been prominent in the field of social measurement through their interest in human abilities and attributes. First, and most controversial, among these has been the measurement of intelligence, to which we shall return later. The whole field of intelligence assessment has become an area of study in its own right, known as psychometrics.

Finally, but without exhausting the list of examples, there is the issue of quality of life. This is a particularly interesting case because it straddles several disciplines and falls into both of the main categories of measurement that we are about to define. As used in medicine, for example, it usually refers to a characteristic of an individual. It arises in the context of treatment for disabling conditions, when the decision to treat the condition may depend on the quality of life that the patient will expect to enjoy subsequent to treatment. This usually refers to the degree of mobility, the ability to feed and wash oneself, and so on. In other contexts, it refers to the quality of the environment, which is something shared by a whole population. The indicators in this case will include the concentration of atmospheric pollutants, the quality of drinking water, and so on.

Population and Individual Level Measurement

Social measures fall into two broad categories that require different treatment. Some relate to populations

and others relate to individuals. Social mobility, for example, is a characteristic of a human population. Such a population is made up of many individuals, or family lines, each pursuing a different path over the generations. However, it is not the individual movements that are of interest, but the collective behavior of the population. Some populations show more movement than others, and that is what a measure of mobility is designed to capture.

A cost-of-living index is, likewise, a population measure, though this time it is the population of commodities purchased. Population measures refer to aggregates and so may be referred to as aggregate measures. Other variables relate to individuals. Abilities or attitudes, for example, are individual characteristics. They may be thought of as if they were real (but unobservable) characteristics of the individual, just like the indicators. To distinguish them from the indicators, they are called “latent” (or hidden) variables.

Mathematical and Statistical Approaches

Formal Statement of the Problem

Many measures in current use have been derived without any overarching theory. In some cases, the way to construct them has seemed so obvious as to make a formal theory unnecessary. For example, the “summated rating scales” widely used in ability scaling simply require the addition of the indicator scores in each row of the data matrix (see later). Teachers have done this kind of thing for generations because it seemed the natural thing to do.

In mobility measurement, there exists, a wide range of similarly *ad hoc* measures that seem to measure mobility in an obvious way. Examples include the proportion of family lines that move to a different class from one generation to the next, or, if the classes are designated by numbers, the correlation between the classes in the first and second generations. Even at this rudimentary level there are indications that intuition may not be enough. There are, in fact, many measures of mobility available, and this fact raises the question of their relative merits. A general theory of measurement should enable making rational choices between existing measures. More importantly, it should enable devising new measures for new situations. As part of this process, it helps to clarify the concept behind the measure.

A convenient way of setting out the unity of the measurement problems is to start with the form of the data from which the problems originate. The differences arise from the differing ways in which the data are supposed to

have been generated. Imagine the data for the problem to be set out in a standard data matrix as follows:

	Indicators			
	x_{11}	x_{12}	\dots	x_{1p}
	x_{21}	x_{22}	\dots	x_{2p}
Individuals	\vdots	\vdots		
	x_{n1}	x_{n2}	\dots	x_{np}

There is one column for each indicator, of which we assume there to be p altogether. The rows are referred to as “individuals.” In many applications, these will be persons, but they could be firms, farms, or families. These n individuals will often be sampled randomly from some population, but this need not necessarily be so. There may be missing values, because not all indicators need be observed for all individuals. Posed mathematically, the problem is to find some function of the elements of this table to serve as the measure. The data matrix will be denoted by \mathbf{X} .

First look at the matrix from the aggregate measure point of view, taking the simplest possible case when there is only one column. Such an example arises when measuring inequality. Suppose that the income of n families is observed and a measure of inequality is to be constructed. The problem is then to find some function of the elements in the first (and only) column of the table that summarizes what is meant by inequality of income. If the column represents the whole population, this immediately provides the measure. If it is a random sample, an inference must be made from the sample to the population.

The case of social mobility is more complicated, but the same general principles apply. The x values in the first column might represent the class to which each family line belongs in the first generation. The second column would then indicate the class occupied by the next generation, and so on, across the table. In practice, there will often be only two columns to the mobility table. Each row provides information about the mobility pattern of a particular family line. An aggregate measure of mobility must then be obtained by aggregating these patterns in some way.

Next look at the data matrix from the individual measurement point of view. In educational testing, the rows would represent the individuals whose ability is to be measured. In each row are the scores obtained by that individual on a series of p tests. Thus, for example, the x values might be marks out of 100. The individual measurement problem is to use each individual's test scores to arrive at an ability score. In other words, we wish to attach a score, y_i , say, to the i th row that can be regarded as a measure of the ability of individual i . This value, y_i , is a predictor or estimate of the latent variable we seek to measure.

Individual level measurement is thus the problem of extracting a relevant summary of the sample of variables represented by the columns. In this case, it will not be

justified, or necessary, to regard them as a random sample. They do need, however, to be representative, in some sense, of the population (or domain) of items that are indicators of the latent variable.

Axiomatic Approaches

The measurement problem can be posed as that of finding a scalar function of the elements of the data matrix, $m(\mathbf{X})$ say, which captures the essence of what it is desired to measure. It may be possible to specify constraints on the function $m(\mathbf{X})$ that restrict the range of functions necessary to consider. Ideally, if there were only one function that met all the requirements, the measurement problem would be solved. This is called the axiomatic approach because it starts with a set of properties (axioms) that any measure must satisfy. More realistically, the method may serve to restrict the search for suitable measures. Used retrospectively, it provides a means of judging the validity of measures arrived at by other means (see section on Validity). The approach has been used in the construction of index numbers and, in an extended form, for social mobility.

In order to illustrate the idea, consider how it might be applied to the construction of a measure of income inequality. In this case, suppose the data matrix has only one column in which the values of income are recorded. Dropping the second subscript, look for a function $m(x_1, x_2, \dots, x_n)$ that measures the degree on inequality. Inequality is a quantity that is necessarily non-negative. Therefore, limit the class of functions to those for which $m(x_1, x_2, \dots, x_n) \geq 0$. Second, if all x values were equal, there would be no inequality. Thus, if $x_1 = x_2 = \dots = x_n = x$, say, then $m(x, x, \dots, x) = 0$ is required. Third, inequality does not depend on the units in which income is measured. It does not matter whether rupees, dollars, or yen are used. The third axiom then becomes

$$m(ax_1, ax_2, \dots, ax_n) = m(x_1, x_2, \dots, x_n) \quad \text{for any } a > 0.$$

Proceeding further along these lines narrows down the range of options. For example, it might be required that if the distance between any pair of x values increased, the measure of inequality should increase also. However, the procedure has gone far enough to indicate what the approach involves. In practice, it is far less useful than the model-based approach.

Model-Based Approaches

The key idea behind the approach advocated here is that of a statistical model. The model provides the link between the data and the underlying concept. The modeling approach requires specifying the joint probability distribution of the random variables, the observed values of which are given in the data matrix. This specification must include any latent variables. The quantity to be

measured is then identified either as a latent variable or as a parameter of this distribution. The measurement problem then resolves itself into the prediction of a random variable or the estimation of a parameter of the distribution. All measurement problems are then reduced to problems of prediction or estimation, which can be tackled by standard statistical methods. In the following sections, it is shown how this simple idea works out in practice.

Modeling Individual Behavior

The basic idea is first introduced by pointing out that it is already implicit in the summated rating scale. Suppose a child is asked to perform a number of tasks, 10, say, as a test of arithmetical ability. What is the rationale behind the idea that a sum of task-performance scores gives a good indication of the child's ability? Because a sum of scores would obviously be much better than any score taken individually, a likely answer would be as follows: the score on any particular task might be affected by many extraneous factors peculiar to the circumstances at the time. The task might, by chance, happen to be one the child had encountered before. Or the child's attention might have been distracted by something happening in the room or by the recollection of some incident that caused daydreaming. Some of these extraneous factors might work in one direction, and some in the other. However, it would not be expected that all factors were present all of the time and for all people. Different factors on different occasions would be likely to produce a haphazard perturbation of the scores. Given enough items, it would confidently be expected that the pluses and the minuses will roughly balance out, thus providing a better idea of the true ability of the child.

This argument may be expressed algebraically as follows. Let there be p items yielding scores x_1, x_2, \dots, x_p . Suppose that the major determinant of x_i is the child's ability, denoted by a . This gives

$$x_i = a + e_i \quad (i = 1, 2, \dots, p), \quad (1)$$

where e_i is the effect of all the extraneous factors acting on this occasion. Because each e_i is presumed to be the cumulative effect of many separate factors, it is expected that some are negative and some are positive. Overall, they should approximately "balance out." This idea can be taken further by making assumptions about the frequency distribution of the e_i values, and that, in turn, will indicate whether straight addition is, indeed, the best way of "extracting" a . When extended to include distributional assumptions, Eq. (1) is sometimes referred to as the classical measurement model. Although it is limited in its scope, it incorporates the key elements in any measurement model—namely, (1) a quantitative

link between the indicators (the x values and the thing to be measured, a) and (2) a probabilistic statement about the deviations of the indicators from the thing to be measured. In an individual-level measurement problem, it is assumed that each individual (represented by a row of the matrix) is located at a different point on a one-dimensional scale. This means that the rows will all have different distributions. There is, therefore, no way to estimate those distributions directly. Instead, some assumption will have to be made about their form. This is made easier by the fact that the distributions can be broken down into component parts.

The starting point for a model is still the joint probability distribution of the elements in the i th row. (The concern is only with a single row because the focus is only on the value of y linked to that row.) However, this distribution is now conditional on the latent variable, denoted by y . If some way of estimating this distribution can be found, then the roles of y and \mathbf{x} can be inverted by Bayes' theorem to give

$$f(y | \mathbf{x}) = \frac{f(y)f(\mathbf{x} | y)}{f(\mathbf{x})}, \quad (2)$$

where, for convenience, the subscript i has been omitted from \mathbf{x} . To keep things simple, all variables have been treated as continuous, but the idea is perfectly general. All that is known about y , after \mathbf{x} is observed, is contained in $f(y | \mathbf{x})$. The value of y is clearly not certain, but its value can be predicted using Eq. (2). There are several ways of doing this, but a natural predictor is $E(y | \mathbf{x})$. In principle, this solves the individual measurement problem, but only after selection of $f(\mathbf{x} | y)$ and $f(y)$. The relationship between the three distributions appearing on the right-hand side of Eq. (2) is

$$f(\mathbf{x}) = \int_{-\infty}^{+\infty} f(y) f(\mathbf{x} | y) dy. \quad (3)$$

Once $f(y)$ and $f(\mathbf{x} | y)$ have been chosen (by whatever means), that they are consistent with the data can be checked using Eq. (3). Here $f(\mathbf{x})$ is the marginal distribution of \mathbf{x} that can be estimated from the data. However, there are infinitely many pairs $\{f(y), f(\mathbf{x} | y)\}$ that lead to the same $f(\mathbf{x})$. Once one pair is available, others can be generated simply by making a one-to-one transformation of y . This has no effect on the integral and hence on $f(\mathbf{x})$. Another way of saying this is that $f(y)$, the prior distribution, is arbitrary, and any choice that is made is, therefore, a matter of convention.

This still leaves $f(\mathbf{x} | y)$ to be chosen, and here the choice can be narrowed by invoking a variety of considerations. If \mathbf{x} is to tell us anything at all about y , it must be because each individual x_i depends on y . This common dependence on y means that the x values will be correlated among themselves. Conversely, it may be inferred that, if the x values are independent, then, when we condition on y , there are

no further latent variables influencing the x values. This means that it is necessary only to choose the form of a univariate distribution rather than a multivariate distribution.

A second criterion for choosing $f(x_i | y)$ ($i = 1, 2, \dots, n$) is based on the notion of sufficiency. If it turned out that $f(y | \mathbf{x})$, given by Eq. (2), depended on \mathbf{x} only through a single statistic t , say, then this would serve as a substitute for y in the sense that, once t is known, the data would provide no more information about y . In other words, any measure of y should be a function of t .

An example is provided by the case when all the x values are binary variables. This is often the case in educational and attitude testing when the responses are YES/NO or RIGHT/WRONG. Each x_i is then a Bernoulli variable defined by the probability of getting a positive response, $\pi_i(y)$, say. The problem is then to choose a suitable functional form for $\pi_i(y)$. As a probability, it must obviously lie between 0 and 1. Further, it should be monotonic in y because the “more y ” there is, the greater (or lesser) should be the probability of a positive response. Also, symmetry arguments can be brought into play. Which of the two responses are labeled as 1 and as 0 is quite arbitrary, and the choice of direction to measure y is likewise arbitrary. Any function chosen, therefore, should retain the same form under transformations of this kind. These constraints are not sufficient to determine uniquely $\pi_i(y)$, but they severely limit the range of choices. If it is now asked that the sufficiency condition should also be satisfied, the choice is

$$\text{logit } \pi_i(y) = \alpha_{i0} + \alpha_{i1}y \quad (i = 1, 2, \dots, n). \quad (4)$$

This is known as the logit model and the function $\pi_i(y)$ is S-shaped, increasing from 0 to 1 as y ranges from $-\infty$ to $+\infty$. The sufficient statistic turns out to be

$$t = \sum_{i=1}^p \alpha_{i1}x_i. \quad (5)$$

It is very interesting to note that this approach has led to a weighted sum of x values that is very close to the summated rating scale idea, which owes nothing to the general ideas presented here. The only difference lies in the weights $\{\alpha_{i1}\}$. A large value of α_{i1} means that the corresponding probability changes relatively rapidly with y . In other words, x_i is a good indicator of y and hence it is appropriate that it should receive more weight. The form of the argument here is largely dictated by the fact that x_i was assumed to be a binary variable. Similar reasoning can be used if x_i is polytomous or continuous.

Modeling Collective Behavior

In modeling collective behavior, it is necessary to estimate the joint distribution of the row elements of the data matrix. This is because all rows have the same distribution,

because they have been generated by random sampling from some population, the aggregate properties of which are of interest. The previous example of inequality can be used to illustrate how a measure may be derived from this. That is, suppose there is a situation with a single observation on each individual. Suppose, again, that this observation measures the income of the individual and that constructing a measure of income inequality is of interest. That is, it is desired to locate the particular distribution on a scale that can be regarded as measuring inequality. In this case, it is immediately recognized that a measure such as the standard deviation indicates variability, and hence inequality. In passing, note also that the first two axioms are then satisfied but the third is not. Changing the scale of each indicator changes the scales of the standard deviation by the same factor. For example, if income is measured in monetary units such as euros, the standard deviation will be in the same units. The degree of inequality should not depend on such arbitrary units, so the problem might be solved by using instead standard deviation/mean. This would then serve as a measure of inequality. There is thus a way of mapping the possible distributions of income onto a one-dimensional scale extending from zero upward.

Of course, there are other measures of dispersion and other ways of normalizing the incomes so as to make the measure independent of scale. One interesting alternative is to use the Gini coefficient, which ranks the distributions according to their degree of dispersion (inequality) on a scale from 0 to 1 by a measure derived directly from the distribution. Leaving aside the question of how, precisely, to measure scale-free dispersion, this simple example reveals that any measure will be a parameter of the distribution. Most distributions will depend on several parameters, so choosing the right parameter may involve selecting some function of the parameters in terms of which the distribution is specified—as in this case. Constructing a measure thus resolves itself into two stages: (1) determining an appropriate distribution to describe the variation of the data and (2) identifying the relevant (appropriate) parameter of that distribution to serve as a measure.

The case of mobility is much more complicated but the same principles apply. If the classes of the family line are observed over $(p - 1)$ generations, it is possible to estimate the joint distribution $f(\mathbf{x}_i)$, where \mathbf{x}_i represents the i th row of the data matrix. The question now concerns what parameter of that distribution best reflects what is meant by “mobility.” To keep things simple, suppose that $p = 2$, so that there is only one generation to consider. The joint distribution $f(\mathbf{x}_i)$, which can be factorized into $f(x_{i2} | x_{i1}) f(x_{i1})$. The set $\{f(x_{i1})\}$ is concerned with how family lines are distributed across classes and it can be plausibly argued that this distribution reveals nothing about mobility that is concerned with transitions between

classes. Therefore, only the conditional distributions $\{f(x_{i2} | x_{i1})\}$ should be considered. These determine how family lines are distributed across classes at the first step. A simple hypothesis, for which there is empirical evidence, is that the distribution is multinomial with parameters $\pi_{i1}, \pi_{i2}, \dots, \pi_{ip}$, say $(\sum_{j=1}^p \pi_{ij} = 1) (i = 1, 2, \dots, n)$. If that is accepted, mobility is governed by the transition matrix:

$$\mathbf{P} = \begin{bmatrix} \pi_{11} & \pi_{12} & \dots & \pi_{1p} \\ \pi_{21} & \pi_{22} & \dots & \pi_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ \pi_{p1} & \pi_{p2} & \dots & \pi_{pp} \end{bmatrix} \quad (6)$$

The joint distribution obviously has very many parameters; therefore, it has to be decided what single-valued function of those parameters best represents what is meant by mobility. Much work on measuring mobility has centered on finding a suitable one-dimensional summary of this matrix (this question will be further addressed later).

Constructing a joint distribution involves making assumptions and the quality of the resulting measure will depend on the realism of these assumptions. An important part of the measurement process is the validation of the model by testing the assumptions.

Two Examples

Intelligence

The measurement of intelligence has a long and controversial history. There are two distinct strands, both originating independently at the beginning of the 20th century. The first began with Alfred Binet, whose tests were originally devised to identify children who might benefit from remedial education. The basic idea was refined and developed, leading to what became known as the Binet–Simon scale and the Binet–Stanford scale. The latter was largely the work of Lewis Terman. A key figure here was David Wechsler, whose name is still linked with a family of tests in use today. The second strand began with Charles Spearman, whose interest gave birth to factor analysis. Subsequent developments were made on both sides of the Atlantic by Thurstone, Thomson, Cattell, and many others. It is this second strand that falls within the general framework described herein. In the third section, the general approach for the case where the manifest variables are binary was illustrated. Items in intelligence tests are usually treated as continuous variables. In that case, the model becomes a set of regression equations of the x_i values on the latent variables, but the general idea is essentially the same. It is still the case, for example, that information about

latent variables is contained in linear combinations of the manifest variables. When scores for test items, such as those in the Wechsler scales, are factor analyzed, it turns out that they cannot be adequately described by a model with only one latent variable. It seems to be necessary to include at least three. This means that the idea of intelligence that lies behind those scales is not a unidimensional quantity, as is commonly supposed. This accounts for much of the confusion and dispute that have surrounded this matter. Spearman, for his part, recognized that the term “intelligence,” as used in ordinary discourse, was too imprecise for scientific purposes. He therefore coined the term “ g ” for the major dimension of latent variation. Spearman and his followers regarded this as corresponding to a general dimension of cognitive ability. By identifying those test items that are particularly good indicators of this latent dimension, it is possible to get a more precise idea of what this dimension represents. Items that require abstract problem solving, especially those depending on patterns in numbers and shapes, seem to be close to what this factor measures.

The quantity g is, of course, a latent variable and cannot, therefore, be directly observed. Thus, it has to be estimated from the data. These estimates (or factor scores, as they are known) are linear combinations of the item scores. Once again, therefore, the intuitive idea of summing (possibly with weights) turns out to have theoretical support.

Because these g scores are linear combinations of indicators, they have the same form as the intelligence quotient (IQ) indices constructed by Wechsler, among others. It may be asked what is the difference between the two. The answer is that IQ reflects the compromise position of the individual on several different dimensions of ability, whereas the g score relates to the single dimension identified as general cognitive ability.

The case of intelligence provides another example of the advantages of a model-based approach to measurement. It serves to resolve much of the confusion that has bedeviled the subject for almost a century. Further, it provides a technique for generating a measure with a much clearer meaning.

Social Mobility

Return again to the question of measuring mobility, at the point where the transition matrix \mathbf{P} had been identified as the set of parameters containing the information about mobility. The next question is how to summarize this information in a single number. If this is possible, it will serve to rank matrices according to the degree of mobility that they represent. A good way to begin is to fix the end points representing the maximum and minimum amount of mobility. The lower limit presents no problems. When $\mathbf{P} = \mathbf{I}$, there is no movement at all and

this matrix therefore corresponds to 0 on the mobility scale. The upper limit is not so straightforward. In the case of zero mobility, the son's social class is identical with the father's and so depends on the father's social class to the greatest degree possible. The opposite extreme, when viewed from this angle, is a situation in which the son's class is totally independent of the father's. The condition for this to be so is that the rows of the transition matrix be identical. There are infinitely many matrices having this property, and all should therefore map onto the extreme upper end point of the scale.

A little reflection suggests that the upper limit might be defined in another way. The point may be made by inspecting the following three matrices:

$$\begin{array}{ccc} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} & \begin{pmatrix} 2/3 & 1/3 \\ 2/3 & 1/3 \end{pmatrix} & \begin{pmatrix} 1/3 & 2/3 \\ 2/3 & 1/3 \end{pmatrix} \\ \text{(i)} & \text{(ii)} & \text{(iii)} \end{array} \quad (7)$$

The second matrix is a 2×2 matrix with identical rows. But the third matrix will produce more changes of class than the second will, because $2/3$ of the first class move compared with $1/3$ in the middle case. This example reveals an ambiguity in the concept of mobility. If it is desired to measure the amount of movement, the upper extreme would occur when

$$\mathbf{P} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

because then all family lines move. The intermediate case, whereby the rows are identical, is actually measuring what might be more accurately described as social inheritance—the extent to which the class of the child is dependent on that of the father. For matrices intermediate between matrices (i) and (ii), the concepts of movement and social inheritance are not easy to distinguish. It is only with movement to the upper extreme that the two diverge. This example illustrates how the modeling process may bring to light subtle distinctions that are easily missed in less formal approaches.

The foregoing discussion can be recognized as an example of the axiomatic approach, but this time it is applied to the parameters rather than to the data. This process was carried further by Anthony Shorrocks, to the point where there was no single measure that satisfied all of the axioms that he proposed. This suggested that the concept needed further clarification. Many measures have been suggested. When the primary focus is on social inheritance, there is a whole class of measures based on the distance between the estimated transition matrix and either of the previously identified extremes. Measures of movement typically focus on the number of transitions made. In both cases, account needs to be taken of whether the classes are ordered. If not, all moves to a different

class are equivalent so far as the contribution they make to mobility is concerned. If the classes are ordered, a move from class I (the lowest class) to class III can be thought of as two moves—from I to II and from II to III—and so should carry more weight.

All of the measures derived in this way are model dependent. The Markov chain model used here is not the only model capable of describing mobility. It is almost always an oversimplification. In some contexts, another model, known as the vacancy-chain model, is more suitable. This is as it should be, because what is meant by mobility obviously depends on what drives the system. However, bearing in mind that one of the main purposes of measuring mobility is to make comparisons—between societies and within one society at different times—it may be better to settle for a simple model that will allow such comparisons.

Having decided on the appropriate parameter, the final step is to estimate it from the data matrix. This may, or may not, be a simple task but, in principle at least, it is a routine matter.

Validity and Reliability

Validity

Turning all measurement problems into statistical problems of estimation or prediction has also clarified two topics that figure prominently in the measurement literature, namely, validity and reliability. Validity is concerned with whether the measure is measuring the right thing. In a strict sense, it is impossible to answer this question because there is no “gold standard” with which a proposed measure can be compared. If there were, there would be no need of a new measure in the first place! There is no question that a population-based measure provides a measure of the parameter that has been identified as being the thing desired to measure. Equally, statistical theory ensures that the predictor of a latent variable does, indeed, predict the latent variable of interest.

The question of validity, therefore, resolves itself into the question of the appropriateness of the model. In the case of social mobility, for example, there are two aspects to this question. First, does the model adequately describe the movements between classes? Second, does the function of the parameters that were chosen adequately capture the notion of mobility. The first is a statistical question; the second is a matter of semantics. Essentially, it must be asked whether the measure varies in a way that corresponds to the usage of the term in social scientific discourse.

The axiomatic approach often provides a partial way of judging validity, as already noted. Axioms embody the

most basic features of the concept we are trying to capture. That a measure of inequality should be non-negative and independent of scale is a very limited but self-evident pair of properties that can be used to weed out totally unsuitable measures. In the case of social mobility, it is easily possible to propose sufficient axioms to identify a single measure. The same is true of index numbers. Roy Allen, for example, has described many desirable properties that, it turns out, cannot be satisfied simultaneously by any single index. Again, this points to lack of precision about what we are trying to measure but, by checking which axioms are satisfied, it is possible to judge how close a proposed measure comes to the ideal and to make a judgment about its validity.

Reliability

Reliability is, essentially, about the closeness of the estimate or predictor to the parameter or latent variable of interest. Appropriate measures of reliability, therefore, arise naturally from general statistical theory. The standard error of an estimator measures reliability. The predictive variance serves the same purpose for predictors. Thus, if we have a factor score $E(y|\mathbf{x})$ for y , then the conditional standard deviation $\sigma(y|\mathbf{x})$ measures the reliability of the score (as would any other measure of dispersion). In practice, there are a number of other measures in use, all closely related to $\sigma(y|\mathbf{x})$. An advantage of the statistical approach recommended here is that it requires nothing new but points directly to the core idea on which any reasonable measure of reliability must depend. For individual-level measurement, there are several reliability coefficients, one of which—Cronbach's alpha—is widely used. Such coefficients are constructed to range over the interval (0, 1), but they are essentially equivalent to measures of variability as defined here. So

far as the principles are concerned, therefore, they may be regarded as measures of variability, or unpredictability.

Glossary

carrying capacity The maximum sustainable population, which in the case of the logistic function is the value toward which the population levels off.

cohort A group of individuals sharing a common characteristic (e.g., born the same year).

continuous models Models in which time is any real number.

deterministic models Models in which all quantities are known.

discrete models Models in which time is counted at discrete points in time (0, 1, 2, etc.).

force of mortality at age x A measure of the risk of dying during a short time interval after age x conditional on surviving to age x .

Lexis diagram A schematic representation of the life course of an individual through time.

life expectancy at age x Average number of years to be lived beyond age x .

life table A table describing statistically the attrition through death (or other causes) of a group of individuals born the same year.

logistic function A function that describes a population that initially grows exponentially and then levels off.

stable population A population with constant age-specific mortality rates and a number of births growing exponentially.

stationary population A population with constant age-specific mortality rates and a number of births that is constant.

stochastic models Models in which all quantities have a certain degree of uncertainty (stochastic is synonymous with random).

strong ergodicity The long-run behavior of a population subjected to constant fertility and mortality rates.

weak ergodicity The long-run behavior of a population subjected to variable fertility and mortality rates.

Mathematical demography uses mathematical and statistical methods to study the size, distribution, composition, and dynamics of human populations. This definition can be broadened to include all biological populations (i.e., cells and animal populations).

Introduction

History up to 1900

It is generally accepted that the modern use of statistical methods for the study of human populations (at least in the Western world) started with the Englishman John Graunt in the 17th century. He produced a fairly detailed statistical description of the populations of London and England. His most important contribution was made in his single published work in which he described for the first time a life table (see [Table I](#)). The life table, which is a cornerstone of mathematical demography, describes the attrition through death over time in a cohort of, say,

Table I Graunt's 1662 Life Table

<i>Age</i>	<i>Survivors</i>
0	100
6	64
26	40
36	16
46	10
56	6
76	1
80	0

100 individuals born at the same time. Graunt's table makes clear the struggle for life in 17th century England, where only 16% of the population reached their thirty-sixth birthday.

Another cornerstone of mathematical demography is the stable population, first introduced in the 18th century by the Swiss mathematician Leonard Euler. A stable population has a constant age-specific death rate and an annual number of births growing exponentially. A stationary population is a special case of stability with a zero growth rate for births.

Perhaps the first mathematical theory of population growth can be found in the work of the English clergyman Thomas Malthus. Although Malthus's much debated ideas are beyond the scope of this entry, their mathematical expression is laid out simply in his celebrated and controversial 1798 essay. Malthus argues that "Population, when unchecked, increases in a geometric ratio," whereas "Subsistence increases only in an arithmetical ratio." Notwithstanding its naïveté by today's standards, this was the first mathematically formulated attempt at linking population and economic growth.

It was not difficult to realize that a population could not grow indefinitely at an exponential rate. Pierre-François Verhulst was a 19th century Belgian mathematician who first proposed the logistic function, which avoids the pitfall of indefinite growth. This function describes a population that initially grows exponentially, then slows down, and finally levels off to its carrying capacity (i.e., the maximum population that can be sustained).

20th Century Mathematical Demography

A modern integral equation formulation for a continuous-time deterministic population-growth model was first introduced in 1911. The classical matrix and renewal equation models were developed shortly after World War II. Sophisticated mortality and forecasting models arose during the last third of the 20th century. These models are described in some detail later.

Mathematical demography is a young science that developed only during the second half of the 20th century. This development was made possible because only then were university courses offered in the discipline. Another important factor that contributed to the expansion of the field was the availability of digital computers. Although primitive in the early years following World War II, computers became an increasingly important and indispensable tool for anyone interested in tracking, understanding, and projecting the growth of human and other populations.

Model Types

Important distinctions need to be made between deterministic and stochastic (or random) models and also between continuous and discrete formulations.

Deterministic versus Stochastic

Deterministic models assume that known average rates with no random deviations are applied to large populations. For example if 10,000 individuals each have a 95% chance of surviving 1 year, then we can be reasonably certain that 9500 of them will indeed survive. In stochastic models, in contrast, there are random variations due either to uncertainties on the parameter or to small population sizes for which it may not be reasonable to apply average rates. Consider for example a population of 20 centenarians, each having a probability 0.7 of surviving another year. The average number of survivors will be $20 \times 0.7 = 14$. However, due to the small size of the population, there will be random variations, and a probabilistic description of the population at the end of the year would be preferable. In this case, we would use a binomial model to describe the population. The binomial model provides the probabilities of having zero survivors, one survivor, two survivors, and so on, up to 20 survivors at the end of the year. In other words, a probability distribution is given for the number of survivors, not just an average number.

Continuous versus Discrete

In a continuous model, events can take place at every point in time. For example, the time between birth and death can be any positive decimal number. In a discrete model, events are categorized within time intervals. For example we might count the numbers of deaths between ages 0 and 1, between 1 and 5, between 5 and 10, between 10 and 15, and so on. (This example, which is typical, also shows that the lengths of the intervals need not be the same.) Both deterministic and stochastic models can be either continuous or discrete.

The life table and its applications are first presented. The classical linear and non-linear deterministic models follow. The entry closes with stochastic models, most of which were developed since the 1970s.

The Life Table

Basic Definitions

The Discrete Formulation

Table I is one of the earliest life tables. Table II provides a modern example, an excerpt from the 1989–1991 table for U.S. females. Such tables are typically calculated using census data. The ℓ_x columns gives the number of survivors at exact age x (this corresponds to the "Survivors" column

Table II Life Table for U.S. Females, 1989–1991^a

Age x	q_x	ℓ_x	d_x	L_x	T_x	e_x
0	0.00828	1,000,000	828	99,341	7,881,156	78.81
1	0.00068	99,172	67	99,139	7,781,815	78.47
2	0.00042	99,105	42	99,084	7,682,676	77.52
3	0.00032	99,063	32	99,047	7,583,592	76.55
4	0.00025	99,031	25	99,019	7,484,545	75.58
⋮	⋮	⋮	⋮	⋮	⋮	⋮
20	0.00052	98,597	51	98,571	5,902,842	59.87
⋮	⋮	⋮	⋮	⋮	⋮	⋮
60	0.00895	89,742	803	89,341	2,055,538	22.90
⋮	⋮	⋮	⋮	⋮	⋮	⋮
99	0.27957	3124	873	2688	8363	2.68
100	0.29635	2251	667	1917	5675	2.52

^a Source: National Center for Health Statistics. Nine years presented.

in Table I). The initial size of the cohort ℓ_0 (the radix) is an arbitrary number that is usually taken for convenience to be equal to a multiple of 100 (here $\ell_0 = 1,000,000$ female newborns). The other columns are derived from the ℓ_x as explained next.

The d_x column gives the number of deaths between ages x and $x + 1$:

$$d_x = \ell_x - \ell_{x+1} \quad (1)$$

The q_x column gives the probability of death during the x th year and is the number of deaths d_x during that year divided by the number ℓ_x of survivors at the beginning of the year:

$$q_x = \frac{d_x}{\ell_x} = \frac{\ell_x - \ell_{x+1}}{\ell_x} \quad (2)$$

The variable L_x is the average number of people alive during the time interval between ages x and $x + 1$. If people die uniformly during the interval, then L_x is the average between the numbers alive at the beginning and at the end of the year:

$$L_x = 0.5(\ell_x + \ell_{x+1}). \quad (3)$$

Finally we define the sum:

$$T_x = L_x + L_{x+1} + \cdots + L_{\omega} \quad (4)$$

where ω is the maximum life span, and T_x is the total future number of years lived by the ℓ_x individuals alive at exact age x . If ω is the maximum life span then $L_{\omega} = T_{\omega} = 0$, and we work recursively back from the oldest ages with the formula:

$$T_x = T_{x+1} + L_x \quad (5)$$

Finally, the average future numbers of years lived by those alive at exact age x is:

$$e_x = \frac{T_x}{\ell_x} \quad (6)$$

which is better known as the life expectancy at age x , that is, the average number of years to be lived by those who have reached age x .

Useful information can be obtained from a life table. The value ℓ_{36} (not shown) is 97,497, which means that 97.5% of the female population will survive to be 36—a great improvement compared to the 16% estimated by Graunt. A newborn can expect to live $e_0 = 78.81$ years, but a centenarian will live on average only another $e_{100} = 2.52$ years.

Various probabilities can be calculated from the table. For example the probability that a girl alive at age 4 lives to be 100 is the number of centenarians divided by the number alive at age 4, $2251/99,031 = 0.0227$.

The Continuous Formulation

The life table provides an intrinsically tabular, discrete, description of mortality over the life span. However, the survivorship function ℓ_x can also be viewed as continuous, that is, as having a value for any real (not only integer) value between 0 and, say, 120. The average number L_x of people alive between x and $x + 1$ and the number T_x of people older than x are then:

$$L_x = \int_{t=0}^{t=1} \ell_{x+t} dt \quad T_x = \int_{t=0}^{t=\infty} \ell_{x+t} dt \quad (7)$$

The life expectancy at age x is:

$$e_x = \frac{\int_0^{\infty} \ell_{x+t} dt}{\ell_x} \quad (8)$$

If ℓ_x has a derivative, then the continuous equivalent of the number of deaths d_x between exact ages x and $x + 1$ is d_x^* , which is the opposite of the instantaneous rate of change in the population (i.e., the derivative):

$$d_x^* = -\frac{d\ell_x}{dx} \quad (9)$$

The continuous equivalent of the probability of death q_x between ages x and $x + 1$ is the force of mortality $\mu(x)$, defined as:

$$\mu(x) = -\frac{d_x^*}{\ell_x} = -\frac{d\ell_x}{\ell_x dx} \quad (10)$$

The probabilistic interpretation of the quantity $\mu(x)$ (which is not necessarily less than 1) is that, for a very small time interval dx , then $\mu(x)dx$ is the infinitesimally small probability that a person alive at age x will die between ages x and $x + dx$. The relation between $\mu(x)$ and ℓ_x is then:

$$\ell_x = \ell_0 \exp \left[-\int_{u=0}^x \mu(u) du \right] \quad (11)$$

Oftentimes the force of mortality $\mu(x)$ is known and many useful calculations can be performed with Eq. (11). For example the probability that a person alive at age 40 will still be alive at 60 is:

$$\frac{\ell_{60}}{\ell_{40}} = \exp \left[-\int_{u=40}^{60} \mu(u) du \right] \quad (12)$$

As a numerical illustration, suppose that between 40 and 60 the force of mortality $\mu(x)$ increases approximately as a straight line, say from 0.005 to 0.03. Therefore $\mu(x) = 0.00125x - 0.045$ and

$$\frac{\ell_{60}}{\ell_{40}} = \exp \left[-\int_{u=40}^{60} (0.00125u - 0.045) du \right] = 0.705 \quad (13)$$

This means that a person alive at 40 has a 70.5% chance of being alive at 60.

Life Tables, Stationary/Stable Populations and Lexis Diagrams

The life table describes the attrition within one cohort of individuals born at the same time. There is however a dynamic way of looking at the life table. Suppose that 1,000,000 females are born during each year. Thereafter, they die according to the schedule in Table II. The result is a stationary population, that is, a population characterized by a constant annual arrival of births and an unchanging schedule of mortality. The life table provides information on the corresponding population in a straightforward manner, best explained with a Lexis diagram. (A stable population generalizes this by considering that births increase exponentially, with still unchanging mortality.)

The Lexis diagram has horizontal and vertical axes that represent time and age. The trajectory over time of a particular individual is represented by a line starting at the time of birth and at a 45° angle, because time and age increase in the same manner. The line continues until the time of death. In our example, there are 1,000,000 lines that start off during each 1-year interval.

Figure 1 Lexis diagram.

Because $\ell_1 = 99,172$ and $\ell_2 = 99,105$ there will 99,172 lines crossing a segment of length 1 at age 1 and only 99,105 of those crossing the horizontal line at age 2. (There were 67 deaths, i.e., 67 lines were interrupted between ages 1 and 2.)

The population at age 1 is the number of trajectories crossing any vertical line (e.g., at time 3) for ages between 1 and 2 (i.e., the number of lines crossing the segment from a to b in Fig. 1). Two such lines are depicted in Fig. 1, but in reality there are approximately $0.5(\ell_1 + \ell_2) = (99,172 + 99,105)/2 = L_1 \approx 99,139$ such lines, which is therefore the population at age 1 in the stationary population. More generally then, L_x is the number of individuals at age x in the stationary population; T_x is therefore the population at age x and above.

Applications: Life Insurance and Pension Funds

The life table and the corresponding stationary population have many important applications in actuarial sciences. Two oversimplified but typical examples are given next.

Life Insurance

Suppose a 20-year-old woman has a risk of dying at each age given by Table II. What annual premium can she expect to pay if she wants to buy \$10,000 worth of life insurance? Table II reveals that she can expect to live 59.87 years. A break-even annual premium is simply $\$10,000/59.87 = \167 a year. If the woman lives her average 59.87 years, then at that rate she will have paid out exactly the capital that goes to her estate upon her death. If the insurance company wants to make an annual 5% profit, it must charge $167 \times 1.05 = \$175.35$ per year. If the woman is 60, she has only 22.9 years, on average, to live, and her break-even premiums are $\$10,000/22.9 = \436.68 .

This is a highly simplified example that ignores inflation and a person's individual risks. In reality, calculations are more complicated than this and are done with life tables that incorporate the specific risks of a person (e.g., cancer history in the family, smoking, and risks of catastrophic diseases such as AIDS).

Pension Funds

Every year a company hires 100 young women age 20, whose risks of dying are again given in Table II. These women retire at 60 and collect \$30,000 a year in pension. Management wants to know how much has to be paid by the pension fund every year. It also wants to know what capital K is needed in order to make these payments entirely from the income earned with a safe return of 5%.

The retired women consist of the population over 60 in the stationary population given by Table II, but with a survivorship function ℓ_0^* equal to the previous one multiplied by the constant $100/\ell_{20}$ (in order to have $\ell_{20}^* = 100$):

$$\ell_x^* = \ell_x(100/\ell_{20}) \quad x = 0, 1, \dots \quad (14)$$

The average population of women 60 and older is then T_{60} multiplied by the same corrective factor $100/\ell_{20}$:

$$T_{60}100/\ell_{20} = 2084.79 \quad (15)$$

The amount paid out every year is therefore:

$$\begin{aligned} 30,000 \times T_{60}100/\ell_{20} &= 3 \times 10^6 \times T_{60}/\ell_{20} \\ &= \$62,543,627 \end{aligned} \quad (16)$$

If this amount is 5% of a capital K , then K must be:

$$K = 3 \times 10^6 \times T_{60}/\ell_{20}/0.05 = \$1,250,872,542 \quad (17)$$

Again, this is an oversimplified example that ignores inflation and many other factors; but it does illustrate the importance of the life table in concrete everyday business applications.

Extensions

The basic life table described so far has many important extensions that make it a fundamental tool of analysis in demography, public health, and sociology. Multiple-decrement life tables recognize the possibility of attrition through different causes. For example, the number of deaths d_x may be decomposed into $d_x = d_x^1 + d_x^2 + d_x^3$, where these three numbers are deaths by cardiovascular disease, cancer, and all other causes. Attrition can be due to causes other than death. For example, we may be interested in the attrition through death and first marriage. Life tables may become even more complicated with possibilities of reentry or movements between different regions or categories. For example, we may wish to

track entries into and exits from the labor market or contraceptive use.

Deterministic Models

Aggregate Models

The simplest population dynamics models consider the whole (aggregated) population, without distinguishing between age and sex.

Exponential Model

Let $P(t)$ be the population at time t and $b(t)$, $m(t)$ be the prevailing crude birth and death (mortality) rates at time t . The population at time $t + 1$ is then:

$$P(t + 1) = P(t)(1 + b(t) - m(t)) \quad (18)$$

When birth and death rates are constants b and m , then the growth rate is $r = b - m$ and Eq. (11) becomes:

$$P(t + 1) = P(t)(1 + r) \quad (19)$$

Therefore:

$$P(t) = P(0)(1 + r)^t \quad (20)$$

This is the exponential (or Malthus's "geometric") model—the simplest possible model of population growth. It assumes a constant growth rate r that can be positive, zero, or negative (although not smaller than -1).

The continuous equivalent to Eq. (18) is the differential equation:

$$\frac{dP(t)}{dt} = P(t)r \quad (21)$$

which has the solution:

$$P(t) = P(0)e^{rt} \quad (22)$$

The exponential model is of theoretical interest because it describes the growth of a population under the simplest circumstances, namely with constant birth and death rates.

Perhaps the *raison d'être* of population models is their use for demographic forecasts. However, the exponential model is of limited use for that purpose (beyond the short term) because the resulting population either goes to infinity when $r > 0$ (which is not realistic) or to 0 when $r < 0$ (which is not desirable). When $r = 0$, the population is stationary (constant). An alternative to the exponential model is provided by the logistic function, which always approaches an upper limit over time.

The Logistic Function

Although the logistic function has met with mixed results and has mostly fallen out of favor, it is of interest

historically and pedagogically because it has been used extensively as a forecasting tool.

The logistic function is derived from a simple differential equation similar to Eq. (21). Instead of assuming a constant growth rate, the logistic model postulates that the growth rate decreases linearly as the total population increases:

$$\frac{dP(t)}{dt} = P(t)r \left[1 - \frac{P(t)}{A} \right] \quad (23)$$

where $r > 0$ and A is a constant that is larger than the initial value $P(0)$. Equation (23) expresses the saturation of a population whose growth rate decreases as $P(t)$ approaches A . The solution to this differential equation is:

$$P(t) = \frac{A}{1 + (A/P(0) - 1)e^{rt}} \quad (24)$$

This function at first grows exponentially, then levels off and converges to the carrying capacity A (i.e., the maximum sustainable population).

The logistic function can be used for forecasting purposes by first finding the parameters A , $P(0)$, and r for which the modeled population $P(t)$ approximates as closely as possible a population series $P_o(t)$ observed in the past. Then the population is projected by extrapolating the modeled function $P(t)$ beyond the last observed value of $P_o(t)$. The parameters are found by minimizing the squared deviations between fitted and observed values; that is, we seek A , $P(0)$, and r such that:

$$\sum_t \left[\frac{A}{1 + (A/P(0) - 1)e^{rt}} - P_o(t) \right]^2$$

is minimized. As an example, the analysis was performed with decennial U.S. census data from 1790 to 2000. The minimization yields the following estimated parameter values:

$$\begin{aligned} A &= 440.81; \quad P(0) = 7.68; \\ r &= 0.02160 \implies A/P(0) - 1 = 56.38 \end{aligned} \quad (25)$$

Therefore the logistic function is:

$$P(t) = \frac{440.81}{1 + 56.38e^{0.02160(t-1790)}} \quad t = 1790, 1791, \dots \quad (26)$$

The observed population (census figures) and the modeled logistic population (with an extrapolation up to 2050) are presented in Fig. 2. The logistic function appears to fit the data well. In 2050, the population is projected to be 366 million. According to the model, the U.S. population will converge to the limit value $A = 440.81$ million by the end of the 21st century.

Extreme caution needs to be exercised with such simple extrapolations. If the model is fitted with the census

Figure 2 Census data and fitted logistic function for the United States from 1790 to 2000, with forecasts to 2050.

data up to 1960 only, the predicted population in 2000 is 216 million instead of the 281 million actually counted, a figure already larger than the estimated limit population $A = 253$ million we would have obtained in this case. Therefore, a projection made in 1960 using this approach would have severely underestimated the true population at the end of the 20th century.

The logistic function is not a reliable projection tool because the differential Eq. (16) does not express a biological, natural, or social law that a human population is known to follow (unlike, for example, the physical law of gravity, which provides an accurate prediction of the trajectory of an object thrown in the air). The logistic function is merely a convenient mathematical description of a population that levels off.

It should be noted that minimizing a nonlinear function of three variables is not a simple task and, as recently as the 1980s, would have been considerably more cumbersome. Today, however, the whole exercise, including the graphing and minimization of the sum-of-squares needed to estimate the parameters, can be done in a few minutes with an Excel spreadsheet on a PC.

Linear Age-Structured Models

Introduction

Aggregate models are too crude because they do not take into account the fact that mortality and fertility rates depend on age. Age-structured models are defined through the knowledge of $p(t, a)$, a function of two variables that represents the population at time t of age a . In a discrete formulation, t and a will typically be integers that represent years. The total population $P(t)$ at time t is the sum over all ages at time t :

$$P(t) = \sum_{a=0}^{\omega} p(t, a) \quad (27)$$

where ω is the maximum life span. In a continuous formulation, this sum is an integral:

$$P(t) = \int_0^{\omega} P(t, a) da \quad (28)$$

Discrete Population Dynamics

The Leslie Matrix Because it is females who give birth, we usually consider that the values $p(t, a)$ represent the female population. (The number of male births is close to that of females and is found by applying a male life table to the radix $p(t, 0)$.)

The number of female births at time $t + 1$ is $p(t + 1, 0)$ and is obtained by applying age-specific fertility rates $f(a)$ to each age group at time t (i.e., $f(a)$ is the number of girls born to each woman at age a):

$$p(t + 1, 0) = p(t, 0)f(0) + p(t, 1)f(1) + \cdots + p(t, \omega)f(\omega) \quad (29)$$

In human populations, the fertility rates $f(a)$ are 0 up to age $a = 15$, then increase rapidly to a maximum around 25, and then decrease to reach 0 around age 50.

The populations in other age groups at $t + 1$ are obtained by applying proportions surviving $\sigma(a)$ to each population $p(t, a)$. That is, $\sigma(a)$ is the proportion of those age a who survive to age $a + 1$ (the values $\sigma(a)$ are derived from a life table; each $\sigma(a)$ is essentially ℓ_{a+1}/ℓ_a):

$$p(t + 1, a + 1) = p(t, a)\sigma(a) \quad a = 0, 1, 2, \dots, \omega - 1 \quad (30)$$

The dynamics of the population are thus entirely defined by Eqs. (29)–(30). These equations can be formulated by considering the population vector $\pi(t)$, whose components are the populations $p(t, a)$ at each age a :

$$\pi(t) = (p(t, 0)p(t, 1) \cdots p(t, \omega))^T \quad (31)$$

where T denotes the transpose; $\pi(t)$ is a column vector that is the transpose of the row of $p(t, a)$.

We next define the Leslie matrix L having the fertility rates $f(a)$ in its first row and the survival rates $\sigma(a)$ below the main diagonal:

$$L = \begin{bmatrix} f(0) & f(1) & . & . & . & f(\omega) \\ \sigma(0) & 0 & 0 & . & . & 0 \\ 0 & \sigma(1) & 0 & . & . & 0 \\ . & . & . & . & . & . \\ 0 & . & . & \sigma(\omega - 2) & 0 & 0 \\ 0 & . & . & . & \sigma(\omega - 1) & 0 \end{bmatrix} \quad (32)$$

Equations (29)–(30) can now compactly be expressed in matrix notations as:

$$\pi(t + 1) = L\pi(t) \quad (33)$$

When L remains constant through time, we then have:

$$\pi(t + 1) = L\pi(t) = LL\pi(t - 1) = \cdots = L^{t+1}\pi(0) \quad (34)$$

which shows that the vector $\pi(t + 1)$ can be calculated from the knowledge of the powers L^t . Of particular interest is the long-term behavior of the vector $\pi(t)$ as t becomes very large. From the theory of nonnegative matrices, we know that L will have a positive dominant eigenvalue (spectral radius) ρ , where ρ is the positive root of the characteristic equation:

$$\text{Det}(L - \lambda I) = 0 \quad (35)$$

that dominates all other roots in modulus. (Det denotes the determinant of the matrix $L - \lambda I$, where I is the identity matrix). In the long run, each component $p(t, a)$ of $\pi(t)$ grows as ρ^t . In particular, the first component can be written $p(t, 0) \approx \alpha \rho^t$ for some $\alpha > 0$. If we define the survival rate $s(a)$ from age 0 to a :

$$s(a) = \sigma(0)\sigma(1) \cdots \sigma(a - 1) \quad a = 1, 2, \dots, \omega \quad (36)$$

then, in the long run:

$$p(t, a) = p(t - a, 0)s(a - 1) \approx \alpha \rho^{t-a}s(a - 1) \quad a = 1, 2, \dots, \omega \quad (37)$$

Equation (37) shows that after a long time all age groups grow exponentially with the same growth rate $\rho - 1$. Furthermore, the structure of the population is that of the stationary population defined by the survival rates $\sigma(a)$. Depending on whether $\rho > 1$, $\rho = 1$, or $\rho < 1$, the population will grow to infinity, converge, or go to extinction.

The Renewal Equation From Eq. (29) and the first part of Eq. (37) we derive a recurrence relation between births $p(t, 0)$ (with $s(0) = 1$):

$$\begin{aligned} p(t + 1, 0) &= p(t, 0)f(0)s(0) + p(t - 1, 0)f(1)s(1) \\ &\quad + p(t - 2, 0)f(2)s(2) \\ &\quad + \cdots + p(t - \omega, 0)f(\omega)s(\omega) \end{aligned} \quad (38)$$

If we call $B(t)$ the births $p(t, 0)$ and define the net maternity rates $m(a) = f(a)s(a)$, then Eq. (38) can be rewritten:

$$\begin{aligned} B(t + 1) &= B(t)m(0) + B(t - 1)m(1) \\ &\quad + B(t - 2)m(2) + \cdots + B(t - \omega)m(\omega) \end{aligned} \quad (39)$$

There exists a solution of this renewal equation of the form $B(t) = \alpha \rho^t$ if $\rho > 0$ satisfies the polynomial equation:

$$\begin{aligned} \lambda^{\omega+1} &= \lambda^{\omega}m(0) + \lambda^{\omega-1}m(1) + \lambda^{\omega-2}m(2) \\ &\quad + \cdots + \lambda m(\omega - 1)m(\omega) \end{aligned} \quad (40)$$

This equation is the same as the characteristic Eq. (35) and its single positive root ρ is therefore equal to the ρ of Eq. (37). The solution $B(t) = \alpha \rho^t$ to the recurrence Eq. (39) is therefore the same as the long-term solution obtained for the Leslie matrix. This is not surprising because those were two different formulations of the same problem.

The Leslie matrix model hinges on the assumption that a proportion $\sigma(a)$ of individuals survives to the next age group. This is a reasonable assumption when populations are large, and probabilities of survival applied to large numbers of people result in numbers surviving that are very close to the average number. If populations are small (say a few dozen), then the proportion $\sigma(a)$ should really be considered a probability and we then have a stochastic version of the Leslie matrix model.

Continuous Population Dynamics

If we consider a density of births $B(t)$, then the continuous equivalent of Eq. (39) is:

$$B(t) = \int_0^\omega B(t-x)m(x)dx \quad (41)$$

where $m(x) = f(x)s(x)$ as before. In a continuous analog of Eq. (34), a solution $B(t) = \alpha e^{rt}$ of Eq. (41) will exist if r is the unique real root of:

$$1 = \int_0^\omega e^{-rs}m(s)ds \quad (42)$$

The population density $p(t, a)$ at age a at time t is then the number born $t-a$ years prior multiplied by the proportion $s(a)$ surviving a years:

$$p(t, a) = \alpha e^{r(t-a)}s(a). \quad (43)$$

From Eq (22) the total population $P(t)$ is:

$$P(t) = \int_0^\omega p(t, a)da = \alpha \exp(rt) \int_0^\omega \exp(-ra)s(a)da \quad (44)$$

The population is thus stable; that is, mortality rates are constant and the population increases (or decreases) exponentially depending on the value of r relatively to 0; when $r = 0$, the population is stationary.

The age distribution $c(a)$ (proportion of population at age a) is constant and equal to:

$$c(a) = \frac{p(t, a)}{P(t)} = b e^{-ra} s(a) \quad (45)$$

where b is the birth rate:

$$b = \frac{1}{\int_0^\omega e^{-ra}s(a)da} \quad (46)$$

Coale and Keyfitz have investigated the process by which an arbitrary initial population subjected to the constant survival and fertility rates $s(a)$ and $f(a)$

converges to its stable state, defined by r and the age distribution of Eq. (45). They seek a solution $B(t)$ of the form:

$$B(t) = \sum_{k=0}^{\infty} Q_k \exp(r_k t) \quad (47)$$

where each r_k is a root of Eq. (42) and the values Q_k are chosen so as to satisfy initial conditions determined by the density of births by women alive at time 0, say. The first root r_0 is the only real root r defined here—other roots come in complex conjugate pairs whose real parts are less than r . The influence of these roots on the process of convergence to stability has been studied in detail. The convergence to stability is also known as the strong ergodic theorem of demography.

Applications of Stable Population Theory

Stable population theory has been one of the cornerstones of mathematical demography for two reasons. First the convergence to stability is the outcome of the simplest and most natural assumption we can make when projecting a population, namely that of constant mortality and fertility rates. Indeed, such constant-rates projections provide useful what-if scenarios in the absence of specific information on trends in mortality, fertility, and migration rates. (Stable population theory is easily generalized to incorporate migrations).

Second, stable population theory is of considerable importance when using indirect estimation methods to assess demographic parameters in countries with incomplete vital registration systems. For example, mortality rates or intrinsic growth rates can be estimated in such cases under the assumption that the population has reached stability.

Nonlinear Models

The simple population dynamics models of Eq. (39) or (41) are intrinsically linear. If the number of women of childbearing age doubles, the number of newborns will also double, all other forces remaining unchanged. Whether other forces remain unchanged, however, is precisely what has interested economists who believe that nonlinear feedbacks play an important role in population processes.

The best-known example is provided by the post-World War II baby boom. Easterlin and Condran in 1976 argued that such a boom (and possible echoed busts) could be explained by a feedback of the age structure on fertility rates (a relative scarce young population has better economic opportunities and will have a higher fertility, and *vice versa*).

Mathematical formulations of such feedbacks hinge on nonlinear versions of Eq. (39) or (41), in which the

maternity function $m(x)$ is a function of the age x but also of births $B(t - k)$ of women born in the recent past. The discrete equivalent of Eq. (33) with such a feedback might be of the form:

$$\begin{aligned} B(t + 1) = & B(t)m_0(\beta(t)) + B(t - 1)m_1(\beta(t)) \\ & + B(t - 2)m_2(\beta(t)) \\ & + \cdots + B(t - \omega)m_{t-\omega}(\beta(t)) \end{aligned} \quad (48)$$

where the maternity rates $m(a)$ are now functions $m_a(\beta(t))'$ of the vectors $\beta(t) = (B(t - \omega), B(t - \omega + 1), \dots, B(t))$ of births during the past $\omega + 1$ periods.

Models along the lines of Eq. (48) have attracted considerable attention in the last 30 years. Even when very simple, such models can exhibit complex behaviors that include bifurcations between stable, cyclic, and chaotic trajectories. These elegant constructions have yet to find their way into the arsenal of mainstream mathematical tools used for population forecasts.

Extensions and Applications

The Weak Ergodic Theorem

In practice, fertility and survival rates always change with time, which means that the matrix L of Eq. (33) is a function $L(t)$ of time. If the strong ergodic theorem provides information on the behavior of a population subjected to constant mortality and fertility rates, the weak ergodic theorem sheds light on the behaviors of two different populations subjected to the same but changing Leslie matrices $L(t)$. Two such populations have age structures that come closer and closer to one another with the passage of time. Cohen and Golubitsky *et al.* made important contributions to the same subject through the use of elegant mathematical tools, particularly the projective distance between vectors that measures how close they are to having the same structure.

Nonstable Extensions

The dynamics of a population subjected to changing vital rates have been formulated and analyzed in various ways. For example, Artzrouni derived approximate closed-form expression for population variables when vital rates change slowly. Kim and Schoen considered the possibility of sinusoidal or quadratically exponential birth trajectories. This latter case means that births $B(t)$ are of the form $B(t) = \exp(h_1 t + h_2 t^2)$.

Multiregional Models

Population geographers have extended the Leslie matrix model to systems that allow migratory flows between regions. Recently much work has dealt with spatial interaction patterns and the spatial structure of population growth. Time series techniques are used to model age-specific and origin-specific migration flows.

Stochastic Models

In recognition of the complexity and elusiveness of population processes, mathematical demographer interested in both mortality models and population forecasts have recently started to move away from deterministic models. Indeed, uncertainty (often arising from heterogeneity within a population) is one of the most important characteristics of population processes.

Stochastic Differential Equations

The simplest example of a stochastic differential equation is a variant of Eq. (21) in which the growth rate r is subjected to infinitesimally small, random fluctuations. The modified equation is then:

$$\frac{dp(t)}{dt} = P(t)[r + sW(t)] \quad (49)$$

where s is a constant and $W(t)$ is the generalized derivative $dB(t)/dt$ of the standard Brownian motion process. There are difficulties with the interpretation of the stochastic differential Eq. (49), which has at least two solutions, depending on whether the Ito or Stratonovich approach is used. With the Ito approach, the expected value $E(P(t))$ of the population at time t is $P(0)\exp(rt)$, which coincides with the solution in the deterministic case. With the Stratonovich approach, the term $s^2 t/2$ is added to rt in the exponential.

Frailty Models of Mortality

Recall that $\mu(x)$ denotes the force of mortality at age x ; that is, $\mu(x)dx$ is the probability of death between ages x and $x + dx$ for individuals alive at age x . However, much depends on the health, or frailty, of these individuals who have survived to age x . All else being equal, the healthier these individuals are, the smaller $\mu(x)dx$ will be. This simple premise led Vaubel, Yashin, and others to recognize the importance of individual frailty and of selection in any modeling of $\mu(x)$.

A simple mortality model that incorporates individual frailty stipulates that mortality is a function of age but also of a variable Y that captures each individual's indisposition, with $Y(x)$ being an individual's indisposition at age x . A possible construction of $\mu(x)$ is then:

$$\mu(x, Y) = \mu_0(x) + \lambda(x)Y^2(x) \quad (50)$$

where

1. $\mu_0(x)$ is a baseline mortality under optimal conditions.
2. $Y(x)$ is the indisposition that changes randomly from individual to individual.

3. $\lambda(x)$ is an age-dependent vulnerability that determines the extent of the excess mortality due to indisposition.

Each individual is assigned randomly an indisposition at birth $Y(0) = Y_o$; values $Y(x)$ at other ages are obtained through the following differential equation:

$$\frac{dY(x)}{dx} = a_0(x) + a_1(x)Y(x) \quad (51)$$

The overall average observed force of mortality among survivors at age x , denoted $\bar{\mu}(x)$, is then:

$$\bar{\mu}(x) = \mu_0(x) + \lambda(x)(m^2(x) + \gamma(x)) \quad (52)$$

where $m(x)$ and $\gamma(x)$ are the conditional mean and variance of $Y(x)$ among individuals surviving to age x . If Y_o is normally distributed with mean m_o and variance γ_o , then $m(x)$ and $\gamma(x)$ are the solutions of the following system of differential equations:

$$\frac{dm(x)}{dx} = a_0(x) + a_1(x)m(x) - 2\lambda(x)m(x)\gamma(x) \quad (53)$$

$$\frac{d\gamma(x)}{dx} = 2a_1(x)\gamma(x) - 2\lambda(x)\gamma^2(x) \quad (54)$$

Numerical solutions to these equations yield the quantities $m(x)$ and $\gamma(x)$ needed to obtain at least the average observed force of mortality $\bar{\mu}(x)$ at age x .

A natural extension has the deterministic $Y(x)$ replaced with a continuous path stochastic process $Y(x)$ obtained as the solution of the stochastic differential equation:

$$\frac{dY(x)}{dx} = b(x)W(x) \quad (55)$$

where $W(x)$ is as in Eq. (49) and $b(x)$ changes over age x .

This simple frailty model has been considerably expanded in the past 20 years and has spawned shared-frailty and correlated frailty models, which have been used extensively with bivariate data.

The Stationary Leslie Matrix

The deterministic Leslie matrix model has a straightforward stochastic version, which we denote as “stationary” to emphasize that probabilities do not change with time. The female population $p(t, a)$, age a at time t , is now a random variable with expected value $e(t, x)$ and variance $C(t, a, a)$. The covariance of $p(t, a)$ and $p(t, b)$ is denoted $C(t, a, b)$. The fertility and survival rates $f(k)$ and $\sigma(k)$ in Eq. (32) are now probabilities of giving birth to one girl and of survival to age k . If $\pi^e(x, t)$ is the vector:

$$\pi^e(x, t) = (e(t, 0) \ e(t, 1) \cdots e(t, \omega))^T \quad (56)$$

of expected (average) population counts, then as in Eq. (33) the vector $\pi^e(x, t)$ satisfies the matrix equation:

$$\pi^e(x, t+1) = L\pi^e(x, t). \quad (57)$$

There is also a simple linear relationship involving the vector $C(t+1)$ of the covariances $C(t+1, a, b)$ listed in the lexicographic order of the indices a and b :

$$C(t+1) = D\pi^e(x, t) + L \times LC(t) \quad (58)$$

where D is a constant nonnegative matrix (based on A) and $A \times A$ is the Kronecker (or direct) product of A by A . Stochastic equivalents of stable population theory follow fairly simply from Eqs. (57)–(58) (i.e., if ρ is as before the dominant positive eigenvalue of L , then $e(t, 0)/\rho^t$ converges with probability 1).

Stochastic Forecasting

In recent years, arbitrarily defined low, medium, and high variants obtained with deterministic models have come under criticism for not adequately capturing the inherent uncertainties of population forecasts. The stochastic differential equation approach reviewed here is useful only for the total population, as opposed to a population structured by age and sex. The stationary Leslie matrix model is of little use because it does not allow for secular changes in the forces of mortality or fertility, which need to be incorporated in any realistic population forecast. Time series methods have long been used to model and forecast specific demographic variables with statistically sound confidence intervals.

However, what is needed to project human populations is a statistical model that both captures the inherent linear nature of the demographic process (i.e., the Leslie matrix model) and takes into account the uncertainties due to the fluctuating nature of fertility, mortality, and migration rates. In 1986, Cohen proposed the first forecasts based on a nonstationary stochastic version of the Leslie matrix model. However, confidence intervals are provided only for the total population, which limits their usefulness.

In 1994, Lee and Tuljapurkar solved this problem with a method that feeds carefully forecast time series of age-specific mortality and fertility rates into a nonstationary Leslie matrix model that incorporates migrations. Their equation is:

$$\pi(t+1) = L(t+1)\pi(t) + I(t+1) \quad (59)$$

where the population vector $\pi(t+1)$ is now a random variable equal to $\pi(t)$ multiplied on the left by the now random Leslie matrix $L(t+1)$, to which is added the vector $I(t+1)$ of net immigration. Each $L(t)$ is assumed to be a sum $L(t) = M(t) + E(t)$ of a deterministic component $M(t)$ and of a (small) deviation $E(t)$. Complex perturbation methods are used to approximate

moments of the random vector $\pi(t+1)$ from which a confidence interval can be found for the predicted population in each age group. For example, the 95% prediction interval for the U.S. population under 20 years old in 2000 is 70.9–85.4 million. The 2000 census yielded 82.2 million for that population, which is in the interval, although on the high side. The interval for the total population in 2050 is 267.6–515.9 million. The predicted value for 2050 is 371.5 million, a figure quite close to the 366 million previously obtained by extrapolating the logistic function.

Confidence intervals reflect the uncertainty within a stochastic model that is assumed to be an accurate reflection of reality. In that respect, stochastic models as well as deterministic ones both depend heavily on the assumptions made concerning vital rates. Indeed, the previous interpretation of the confidence interval is that the actual population in 2050 has a 1 in 20 chance of being outside the (267.6, 515.9) interval, even if the model is correctly specified. However, if the population did fall outside the interval (which is unlikely given the interval's size) it may be the result of an unforeseen drop in fertility or increase in immigration rather than the result of an "unlucky" 1 in 20 realization of an otherwise accurate stochastic process.

Finding stochastic population forecasting models that are as accurate and useful as possible remains one of the major challenges for mathematical demographers of the 21st century.

Maximum Likelihood Estimation

Charles H. Franklin

University of Wisconsin, Madison, Wisconsin, USA

Glossary

asymptotic properties The properties of an estimator as the sample size goes to infinity.

consistent estimator An estimator that converges to the population parameter as the sample size goes to infinity.

Cramér-Rao lower bound The minimum variance possible for an estimator in the class of consistent estimators.

data generating process The probability function or density describing the distribution that characterizes the data.

efficient estimator An estimator whose variance-covariance matrix achieves the Cramér-Rao lower bound.

likelihood The joint density of the observed data, treating the parameters as variable and the data as fixed.

maximum likelihood (ML) estimator The value of the parameter(s) at which the likelihood is maximized.

Maximum likelihood (ML) is a method of estimation and inference for parametric models. The ML estimator is the value of the parameter (or parameter vector) that makes the observed data most likely to have occurred given the data generating process assumed to have produced the variable of interest. ML estimates have several desirable asymptotic properties: consistency, efficiency, asymptotic normality, and invariance over continuous transformations. These are asymptotic properties, however, and the small-sample properties of ML estimators are not known in general, although they may be derived for some specific applications. The advantages of ML estimation are that it fully uses all the information about the parameters contained in the data and that it is highly flexible, allowing easy extension to incorporate complex parametric specifications. Most applied ML problems

lack closed-form solutions and so rely on numerical maximization of the likelihood function. The advent of fast computers has made this a minor issue in most cases. Hypothesis testing for ML parameter estimates is straightforward due to the asymptotic normal distribution of ML parameter estimates and the Wald likelihood ratio and Lagrange multiplier tests for ML estimates.

Specifying the Data Generating Process

The likelihood approach to statistical estimation and inference begins with the specification of a probability model that represents the process generating the data. The specification of this process rests on scientific knowledge about the phenomena and the observable characteristics of the data, such as whether the variable of interest is discrete or continuous, binary or ordered, and so on. It should be recognized that the choice of model is seldom dictated by theory alone. All models are simplifications of complex reality. Our goal is to make the best model we can consistent with what we know about the phenomena and with the recognition that models must also be tractable to be useful.

Let \mathbf{y} represent the observed variable of interest. The probability model is characterized by a density function (for continuous variables) or probability function (for discrete variables) $f(\mathbf{y} | \theta)$, where θ is a vector of one or more parameters that characterize the distribution. For example, if \mathbf{y} is generated by a Poisson process, then

$$f(\mathbf{y} | \theta) = \frac{e^{-\lambda} \lambda^{y_i}}{y_i!}$$

with a single parameter, $\theta = \lambda$.

If \mathbf{y} is normally distributed, then θ contains two parameters, μ and σ^2 :

$$f(\mathbf{y} | \theta) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-1/2((y_i - \mu)^2/\sigma^2)}$$

The density, $f(\mathbf{y} | \theta)$, is often called the data generating process for the variable \mathbf{y} . The specification of this process is central to likelihood estimation because without it there can be no likelihood function. Theoretical considerations may help with this specification. For example, processes that generate events over time may suggest a Poisson distribution or one of its relatives. Although social science may lack the strong theories of some physical sciences, there is often more theoretical basis to suggest a particular distribution than a casual first impression might admit.

The nature of the variable \mathbf{y} may also place some constraints on the data generating process. If \mathbf{y} is discrete and nonnegative, then this rules out the normal distribution as a potential data generating process because the normal distribution describes variables that are both continuous and unbounded. However, within the class of discrete and nonnegative distributions there may be considerable room for uncertainty as to which data generating process is appropriate. For example, both Poisson and binomial distributions describe discrete and nonnegative variables. In these circumstances, the researcher must be guided in the specification of the data generating process by a combination of substantive theory, observed characteristics of the data, and practicality.

The specification of the data generating process encourages the researcher to be explicit about the assumptions being made and to justify the decision to use one distribution rather than another. This encourages the interaction between the theoretical questions being asked and the statistical specification of the model.

This interaction may be seen in an example. Suppose we wish to model the number of bills approved by a committee of the U.S. House of Representatives during a 2-year-long Congress. The institutional rules of Congress requires that bills be referred to a single committee for consideration. The committee may then modify the bill (or not) and report the bill back to the full House, or it may fail to report the bill, in which case the legislation dies in the committee. We might consider using a binomial distribution:

$$f(\mathbf{y} | \theta) = \binom{N}{y} \pi^y (1 - \pi)^{N-y}$$

where $\theta = \pi$ is the probability that a bill is approved by the committee, and N is the number of bills referred to the committee. Because a bill cannot be reported back unless it is first referred to the committee, this model captures an element of the institutional rules of the

House. Our knowledge of those rules suggests part of the probability model.

On the other hand, it may make sense to think that members of a committee behave as legislative entrepreneurs who generate legislation rather than passively awaiting bill referrals. In this case, the number of bills referred to a committee has no inherent upper limit. If too few bills are submitted, members will generate new bills. We might prefer to ignore the institutional referral constraint and model the process as a Poisson distribution that places no upper limit on the number of bills a committee might report over a 2-year period. In this case, we adopt a data generating process that captures the entrepreneurship behavior rather than focusing on institutional limits on bills. Which of these distributions, or others, we might prefer is partially a statistical question, but it is also a result of the substantive perspective we bring to the problem. By asking ourselves what the substantive model requires and by asking how different probability models would represent that substance, we benefit from a conversation between the substantive and statistical models. This conversation is very helpful when specifying the data generating process. It informs both the substantive and statistical models.

Definition of the Likelihood

The likelihood of a sample of N observations, \mathbf{y} , is defined as the joint density of the data, with the parameters, θ , taken as variable and the data as fixed, multiplied by any arbitrary constant or function of the data but not of the parameters:

$$L(\theta | \mathbf{y}) = c(\mathbf{y}) f(y_1, y_2, \dots, y_n | \theta)$$

where $f(\bullet)$ is the probability density function (for continuous \mathbf{y}) or the probability mass function (for discrete \mathbf{y}). The parameter θ may be a scalar for a single parameter model or a vector for functions of multiple parameters, as is the more common case in practice. The arbitrary constant, $c(\mathbf{y})$ means that the likelihood is proportional to the density of the data given θ :

$$L(\theta | \mathbf{y}) \propto f(y_1, y_2, \dots, y_n | \theta)$$

This means that $c(\mathbf{y})$ can be readily ignored when we move on to estimation and inference. This was one of the key insights in Fisher's development of the likelihood notion. The elements of $c(\mathbf{y})$ need not concern us because they do not depend on the parameter, θ . If we compare ratios of likelihoods, the $c(\mathbf{y})$ will cancel in numerator and denominator and so relative likelihoods depend only on the joint density of the data given the parameter.

If the observations are independently distributed, then the likelihood of the sample reduces to the product of the likelihoods for each observation:

$$L(\theta | \mathbf{y}) \propto \prod_{i=1}^N f(y_i | \theta)$$

If the observations are not independent, we can use the general rule for joint probability, $P(ABC) = P(A) \times P(B|A) \times P(C|A,B)$, to write the joint likelihood of a sample as:

$$L(\theta | \mathbf{y}) \propto f(y_1 | \theta) \times f(y_2 | \theta, y_1) \times f(y_3 | \theta, y_1, y_2) \\ \times \cdots \times f(y_N | \theta, y_1, y_2, \dots, y_{N-1})$$

Although there are practical difficulties with the most general forms of such a likelihood, in many empirical cases it is possible to condition on only a few terms, as, for example, in a time series that is autoregressive for only a small number of lags, say AR(1) or AR(2). Once the data generating process has been specified and the data are observed, our problem is to estimate the parameters of the model based on the likelihood function.

Maximum Likelihood Estimation

The key intuition for estimation in likelihood problems is that the most reasonable estimate is that value of the parameter vector that would make the observed data most likely to occur. More formally we seek a value of θ that maximizes:

$$L(\theta | \mathbf{y}) = c(\mathbf{y})f(y_1, y_2, \dots, y_n | \theta)$$

or, in the case of independent observations, that maximizes:

$$L(\theta | \mathbf{y}) = c(\mathbf{y}) \prod_{i=1}^N f(y_i | \theta)$$

Because $c(\mathbf{y})$ does not depend on the parameter θ , it does not change as θ changes. Any value of θ that maximizes $f(y_1, y_2, \dots, y_n | \theta)$ also maximizes $c(\mathbf{y})f(y_1, y_2, \dots, y_n | \theta)$. This means we can ignore $c(\mathbf{y})$ in solving for the maximum likelihood (ML) estimate of the parameters. More formally, $c(\mathbf{y})$ will drop out of the derivative of the likelihood with respect to θ and hence not affect the solution for the ML estimator. For this reason we drop $c(\mathbf{y})$ and the proportionality relation in subsequent discussion.

Maximizing the likelihood can be seen graphically in the following example. Assume that the number of appointments to the U.S. Supreme Court made during each presidential term follows a Poisson distribution (there are various reasons why this may or may not be

Table I Appointments to the U.S. Supreme Court 1961–2000

<i>Years</i>	<i>Number appointed</i>	<i>Years</i>	<i>Number appointed</i>
1961–1964	2	1981–1984	1
1965–1968	2	1985–1988	3
1969–1972	4	1989–1992	2
1973–1976	1	1993–1996	2
1977–1980	0	1997–2000	0

the case in fact, but we assume it here for the sake of illustration.) The data for the period 1961 through 2000 are listed in [Table I](#).

Assuming independent observations the likelihood for these data is:

$$L(\theta | \mathbf{y}) = \prod_{i=1}^N \frac{e^{-\lambda} \lambda^{y_i}}{y_i!}$$

For the 10 observations in this data set, we can complete the product, yielding:

$$L(\theta | \mathbf{y}) = \frac{e^{-N\lambda} \lambda^{\sum_{i=1}^N y_i}}{\prod_{i=1}^N y_i!} \\ = \frac{e^{-10\lambda} \lambda^{17}}{2304}$$

This likelihood function is plotted in [Fig. 1A](#) for values of λ between 0 and 5. The likelihood peaks between about 1.5 and 2. In [Fig. 1B](#), the likelihood is plotted for a narrower range of values of λ , between 1.5 and 2, to show that the maximum appears to be close to 1.7.

It is usually simpler mathematically to find the maximum of the log of the likelihood rather than the likelihood itself. Because the log is a monotonic transformation, the log-likelihood will be maximized at the same parameter value that maximizes the likelihood. This is illustrated in [Fig. 1C–D](#) for the Supreme Court appointments example. Although the shape of the log-likelihood is different from that of the likelihood, it is clear that both are maximized at approximately 1.7.

We may solve analytically for the ML estimator. To maximize any function, we find the value of the parameters that make the first derivatives of the function with respect to the parameters equal to zero. We also check that the second derivatives are negative to ensure that this is a maximum rather than a minimum. To maximize a likelihood function in general we solve the derivative:

$$\frac{\partial L(\theta | \mathbf{y})}{\partial \theta} = 0$$

where ∂ denotes partial differentiation of the likelihood with respect to the parameter vector θ .

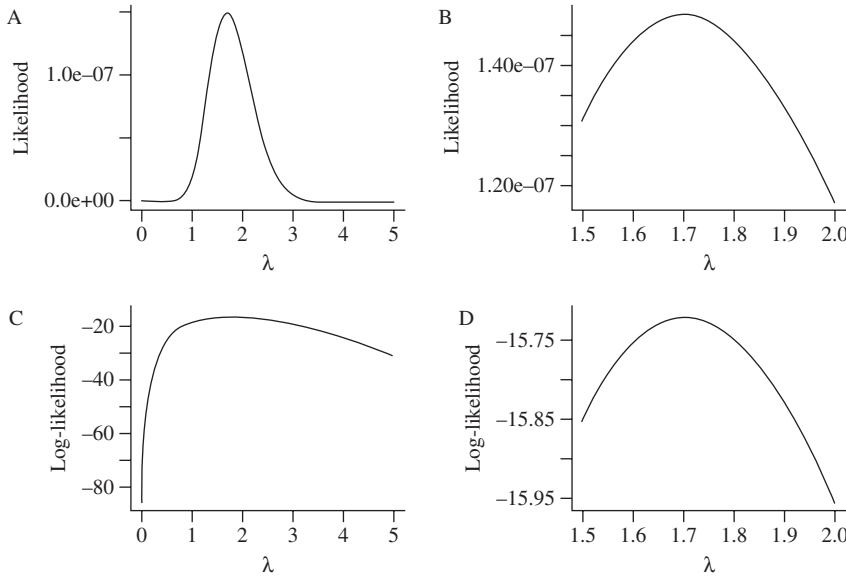

Figure 1 Likelihood and log-likelihood functions for a Poisson model of U.S. Supreme Court appointments, 1961–2000. Both likelihood and log-likelihood functions are maximized at $\lambda = 1.7$.

It is easier to maximize the log-likelihood, written $l(\theta | \mathbf{y}) = \log L(\theta | \mathbf{y})$. Because the log of a product is the sum of the logs, this simplifies the log-likelihood to a sum:

$$\begin{aligned} \log L(\theta | \mathbf{y}) &= \log \prod_{i=1}^N f(y_i | \theta) \\ &= \sum_{i=1}^N \log f(y_i | \theta) \end{aligned}$$

Because the derivative of a sum is just the sum of the derivatives, it is easier to differentiate the log-likelihood rather than the likelihood; the latter would involve the more complicated derivative of a product. Because the log transformation is monotonic, any value of the parameter vector that maximizes the log-likelihood will also maximize the likelihood.

For the Poisson example this results in:

$$\begin{aligned} \frac{dl(\lambda | \mathbf{y})}{d\lambda} &= \frac{d}{d\lambda} \left(\sum_{i=1}^N \left(\log \frac{e^{-\lambda} \lambda^{y_i}}{y_i!} \right) \right) \\ &= \frac{d}{d\lambda} \left(\sum_{i=1}^N (-\lambda + y_i \log(\lambda) - \log(y_i!)) \right) \\ &= -N + \frac{1}{\lambda} \sum_{i=1}^N y_i \end{aligned}$$

Setting the last line equal to zero and solving for λ yields:

$$\lambda = \frac{\sum_{i=1}^N y_i}{N}$$

In the Supreme Court appointments data, $N = 10$ and $\sum y_i = 17$, so the ML estimate is $\lambda = 17/10$ or 1.7, which coincides with the apparent maximum in Fig. 1.

To check that this is a maximum, we take the second derivative of the log-likelihood:

$$\begin{aligned} \frac{d^2 l(\lambda | \mathbf{y})}{d\lambda^2} &= \frac{d}{d\lambda} \left(-N + \frac{1}{\lambda} \sum_{i=1}^N y_i \right) \\ &= -\lambda^{-2} \sum_{i=1}^N y_i \end{aligned}$$

which is always negative because λ and $\sum y_i$ must both be positive. Because the second derivative is always negative, this shows that the log-likelihood has a single maximum value.

This illustrates the general process of maximizing any likelihood. We write the likelihood of the data, based on our model specification of the data generating process. We then differentiate the log of the likelihood with respect to the parameters. Setting this derivative equal to zero and solving for the parameters results in an expression for the ML estimator for the model. The second derivative test must be negative to demonstrate that we have found a maximum.

Once we move beyond the simplest models, explicit solutions for the parameters are unlikely to exist. Often the ML estimator is a nonlinear function that does not have an explicit closed-form solution. In this case, we resort to numerical maximization of the likelihood. The widely used logit model for binary dependent variables is an example of this. The derivative of the log-likelihood of the logit model with independent variables \mathbf{x} is:

$$\frac{\partial l(\beta | \mathbf{y}, \mathbf{x})}{\partial \beta} = \sum \left(y_i - \frac{e^{\mathbf{x}_i \beta}}{1 + e^{\mathbf{x}_i \beta}} \right) \mathbf{x}_i$$

which is nonlinear in β , which precludes an explicit solution for β . There are a number of numerical methods that provide solutions in these cases.

Multiparameter Likelihoods

Aside from classroom examples, there is usually more than a single parameter in the model. In this case, the first derivatives produce a vector of partial derivatives and the second derivatives produce a matrix.

This is easy to see with the normal distribution as an example. In general, we write the parameters as a vector:

$$\theta = \begin{bmatrix} \theta_1 \\ \vdots \\ \theta_k \end{bmatrix}$$

The normal log-likelihood, $l(\sigma^2 | \mathbf{y})$, depends on two parameters, μ and σ^2 , so this becomes:

$$\theta = \begin{bmatrix} \mu \\ \sigma^2 \end{bmatrix}$$

To simplify the notation we write the log-likelihood function as $l \equiv l(\theta | \mathbf{y}) \equiv \log L(\theta | \mathbf{y})$. This notation is common in works on likelihood. We also assume that summations are over all cases from $i = 1, \dots, N$ unless otherwise noted. The likelihood depends on the parameters. The derivative of a likelihood function with respect to a parameter vector, θ , produces a vector of partial derivatives:

$$\frac{\partial l}{\partial \theta} = \begin{bmatrix} \frac{\partial l}{\partial \theta_1} \\ \frac{\partial l}{\partial \theta_2} \\ \vdots \\ \frac{\partial l}{\partial \theta_k} \end{bmatrix}$$

Recall that the likelihood for a normal distribution is:

$$L(\theta | \mathbf{y}) = \prod_{i=1}^N \frac{1}{\sqrt{2\pi\sigma^2}} e^{-1/2((y_i - \mu)^2/\sigma^2)}$$

so the log-likelihood is:

$$\begin{aligned} l &= \sum \left(-\frac{1}{2} \log(2\pi) - \frac{1}{2} \log \sigma^2 - \frac{1}{2} \frac{(y_i - \mu)^2}{\sigma^2} \right) \\ &= -\frac{N}{2} \log(2\pi) - \frac{N}{2} \log \sigma^2 - \frac{1}{2} \frac{\sum (y_i - \mu)^2}{\sigma^2} \end{aligned}$$

The first derivative of this log-likelihood, where $\theta = (\mu, \sigma^2)'$, is:

$$\begin{aligned} \frac{\partial l}{\partial \theta} &= \begin{bmatrix} \frac{\partial l(\mu, \sigma^2 | \mathbf{y})}{\partial \mu} \\ \frac{\partial l(\mu, \sigma^2 | \mathbf{y})}{\partial \sigma^2} \end{bmatrix} \\ &= \begin{bmatrix} \frac{1}{\sigma^2} \sum (y_i - \mu) \\ -\frac{N}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (y_i - \mu)^2 \end{bmatrix} \end{aligned}$$

The vector of partials with respect to θ is called the gradient vector, or just the gradient. It tells us how the log-likelihood function is changing as each element of θ changes. We can solve the gradient vector to find the ML estimators for the normal likelihood:

$$\begin{bmatrix} \frac{1}{\sigma^2} \sum (y_i - \mu) \\ -\frac{N}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (y_i - \mu)^2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

so

$$\mu = \frac{1}{n} \sum y_i$$

$$\sigma^2 = \frac{1}{n} \sum (y_i - \mu)^2$$

Regardless of how many parameters enter into a model, the basic steps of ML estimation remain the same—use the derivatives of the log-likelihood to find the values of the parameters that maximize the likelihood of the sample. This may be done analytically or with numerical methods. These point estimates are of interest, but for statistical inference we must also know how these estimates vary. For this, we turn to the problem of finding the variance-covariance matrix for ML estimators.

Variance-Covariance Matrix of the Maximum Likelihood Estimator

Any estimator will vary across repeated samples. We must be able to calculate this variability in order to express our uncertainty about a parameter value and to conduct

statistical inference about the parameters. This variability is measured by the variance-covariance matrix of the parameters or, more briefly, the covariance matrix. This matrix provides the variances for each parameter on the main diagonal while the off-diagonal elements estimate the covariances between all pairs of parameters. In least-squares regression, this covariance matrix is $\sigma^2(X'X)^{-1}$. In ML, the matrix of second derivatives of the log-likelihood is the key.

Fisher showed that the covariance matrix for ML estimators is the inverse of what he called the information matrix:

$$[I(\theta)]^{-1} = \left(-E \left[\frac{\partial^2 \ln L(\theta)}{\partial \theta \partial \theta'} \right] \right)^{-1}$$

In words, the covariance matrix of the ML estimator is the inverse of the negative of the expected value of the matrix of second derivatives of the log-likelihood with respect to the parameters.

An intuition into why this makes sense is that the second derivatives measure the rate of change in the first derivatives, which in turn determine the value of the ML estimate. If the first derivatives are changing rapidly near the maximum, then the peak of the likelihood is sharply defined and the maximum is easy to see. In this case, the second derivatives will be large and their inverse small, indicating a small variance of the estimated parameters. If on the other hand the second derivatives are small, then the likelihood function is relatively flat near the maximum and so the parameters are less precisely estimated. The inverse of the second derivatives will produce a large value for the variance of the estimates, indicating low precision of the estimates.

In the case of a typical multiparameter likelihood, we need to find the matrix of second derivatives, then take the expected value of this, and invert to get the covariance matrix. As with single-parameter models, the second partial derivative is the derivative of the first partial derivatives with respect to θ . The first derivatives produce a column vector:

$$\frac{\partial l}{\partial \theta} = \begin{bmatrix} \frac{\partial l}{\partial \theta_1} \\ \frac{\partial l}{\partial \theta_2} \\ \vdots \\ \frac{\partial l}{\partial \theta_k} \end{bmatrix}$$

To get the second derivatives, we differentiate each element of the gradient vector with respect to each element in θ' , a row vector. This results in a square matrix of second derivatives:

$$\frac{\partial}{\partial \theta'} \left(\frac{\partial l}{\partial \theta} \right) = \frac{\partial^2 l}{\partial \theta \partial \theta'}$$

or

$$\frac{\partial}{\partial \theta'} \begin{bmatrix} \frac{\partial l}{\partial \theta_1} \\ \frac{\partial l}{\partial \theta_2} \\ \vdots \\ \frac{\partial l}{\partial \theta_k} \end{bmatrix} = \begin{bmatrix} \frac{\partial^2 l}{\partial \theta_1 \partial \theta_1} & \frac{\partial^2 l}{\partial \theta_1 \partial \theta_2} & \cdots & \frac{\partial^2 l}{\partial \theta_1 \partial \theta_k} \\ \frac{\partial^2 l}{\partial \theta_2 \partial \theta_1} & \frac{\partial^2 l}{\partial \theta_2 \partial \theta_2} & \cdots & \frac{\partial^2 l}{\partial \theta_2 \partial \theta_k} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial^2 l}{\partial \theta_k \partial \theta_1} & \frac{\partial^2 l}{\partial \theta_k \partial \theta_2} & \cdots & \frac{\partial^2 l}{\partial \theta_k \partial \theta_k} \end{bmatrix}$$

This matrix of second derivatives is called the Hessian matrix, often abbreviated as H . It is always of dimension $k \times k$, where k is the length of the θ parameter vector. The off-diagonal elements are called the cross-partial derivatives and Young's theorem guarantees that:

$$\frac{\partial^2 l}{\partial \theta_i \partial \theta_j} = \frac{\partial^2 l}{\partial \theta_j \partial \theta_i}$$

which assures us that the Hessian, and hence the covariance matrix, will be symmetric.

In the previous section we found the first derivatives for the two-parameter normal distribution. Here we continue that example to find the covariance matrix for the normal likelihood.

The gradient vector for the normal likelihood is:

$$\frac{\partial l}{\partial \theta} = \begin{bmatrix} \frac{1}{\sigma^2} \sum (y_i - \mu) \\ -\frac{N}{2\sigma^2} + \frac{1}{2\sigma^4} \sum (y_i - \mu)^2 \end{bmatrix}$$

The Hessian is the matrix of second derivatives of this likelihood:

$$\frac{\partial^2 l}{\partial \theta \partial \theta'} = \begin{bmatrix} \frac{\partial^2 l}{\partial \mu \partial \mu} & \frac{\partial^2 l}{\partial \mu \partial \sigma^2} \\ \frac{\partial^2 l}{\partial \sigma^2 \partial \mu} & \frac{\partial^2 l}{\partial \sigma^2 \partial \sigma^2} \end{bmatrix}$$

Take the appropriate derivatives of the gradient to get:

$$\begin{aligned} \frac{\partial^2 l}{\partial \mu \partial \mu} &= -\frac{N}{\sigma^2} \\ \frac{\partial^2 l}{\partial \mu \partial \sigma^2} &= -\frac{1}{\sigma^4} \sum (y_i - \mu) \\ \frac{\partial^2 l}{\partial \sigma^2 \partial \sigma^2} &= \frac{N}{2\sigma^4} - \frac{1}{\sigma^6} \sum (y_i - \mu)^2 \end{aligned}$$

Young's theorem takes care of the other cross-partial derivative. So:

$$H = \begin{bmatrix} -\frac{N}{\sigma^2} & -\frac{1}{\sigma^4} \sum (y_i - \mu) \\ -\frac{1}{\sigma^4} \sum (y_i - \mu) & \frac{N}{2\sigma^4} - \frac{1}{\sigma^6} \sum (y_i - \mu)^2 \end{bmatrix}$$

Because the sum of deviations about the mean is always zero, the off-diagonal terms vanish leaving:

$$H = \begin{bmatrix} -\frac{N}{\sigma^2} & 0 \\ 0 & \frac{N}{2\sigma^4} - \frac{1}{\sigma^6} \sum (y_i - \mu)^2 \end{bmatrix}$$

Taking expected values leaves us with:

$$E(H) = \begin{bmatrix} -\frac{N}{\sigma^2} & 0 \\ 0 & -\frac{N}{2\sigma^4} \end{bmatrix}$$

And the inverse of the negative of this gives us the covariance matrix for the normal likelihood parameter estimates:

$$I(\theta)^{-1} = \begin{bmatrix} -\frac{\sigma^2}{N} & 0 \\ 0 & -\frac{2\sigma^4}{N} \end{bmatrix}$$

The first element in the covariance matrix is the well-known variance of the sample mean. The second element is the less widely discussed variance of the estimated variance parameter, $\hat{\sigma}^2$. The zero covariances in the off-diagonals show that in the case of a simple normal model the estimates of the mean and variance are uncorrelated.

With these results in hand, we know how to find the ML estimator and the variance-covariance matrix for that estimator. It remains to discuss the properties of the ML estimator.

Properties of Maximum Likelihood Estimators

The nearly universal acceptance of ML as a method of estimation and inference rests on the properties of ML estimators. These major properties are:

- Consistency
- Efficiency
- Asymptotic normality
- Invariance under reparameterization

If a ML estimator exists, it is guaranteed to have these properties. This may be ML's greatest strength. The properties need not be proved repeatedly for each application of ML. Amazingly, Fisher discussed all these properties in his 1922 and 1925 papers. ML was born almost full grown (although rigorous proofs did await developments by Cramér, Wald, and Rao during the 1940–1960 period.)

It is important to note that these are asymptotic properties that hold only as the sample size becomes indefinitely large. It is impossible to say in general at what point a sample is large enough for these properties to apply.

This, in turn, is a significant limitation of ML. Although some small-sample properties may be derived for specific models, no general results have been discovered. Thus, when applications involve small samples, the use of ML should be carefully evaluated before relying on inferences based on the ML estimates.

Consistency

There are several definitions of consistency, but an intuitive version is that as the sample size gets large the estimator is increasingly likely to fall within a small region around the true value of the parameter. This is called convergence in probability and is defined more formally as follows. A random variable x_n converges in probability to a constant, c , if:

$$\lim_{n \rightarrow \infty} \text{Prob}(|x_n - c| > \epsilon) = 0$$

for any positive ϵ .

For example, if we think of c as the population value of a parameter and x_n as an ML estimator of c based on n cases, then this says that as the sample size increases the probability that we fall outside a small ϵ region around c goes to zero. We are certain to be within ϵ of the true value as long as the sample size is allowed to be large enough.

In 1946, Cramér proved that ML estimators are consistent; Fisher had reached this conclusion less rigorously in the 1920s. From a practical perspective, this means that as long as the likelihood is properly specified we can be confident that the estimates of the parameters will converge to the population parameter values as the sample size becomes sufficiently large.

As an example of consistency, consider the ML estimator for the variance in a normal likelihood. We have already seen that this estimator has a closed form and is:

$$\sigma^2 = \frac{1}{n} \sum (y_i - \mu)^2$$

But it is well known from elementary statistics that this is a biased estimate of the population variance and that:

$$\sigma^2 = \frac{1}{n-1} \sum (y_i - \mu)^2$$

is the unbiased estimator.

This example shows that ML estimators may be biased in finite samples, even though they are consistent in large samples. The convergence of the ML estimator in this case can be seen in Fig. 2. The figure plots the distribution of the ML estimator of σ^2 for four sample sizes when the population variance is set to 10. The small-sample estimates are noticeably biased, but as the sample size increases the distribution of the ML estimator converges toward the true value and the variability of the estimator also decreases.

Figure 2 The ML estimator for the variance in a normal likelihood is biased downward in finite samples. As the sample size increases, the estimator converges toward the population value (10 in this example) and the variance of the estimator decreases.

Efficiency

The Cramér-Rao lower-bound theorem shows that (given certain regularity conditions concerning the distribution) the variance of any estimator of a parameter θ must be *at least* as large as:

$$\text{Var } \hat{\theta} \geq \left(-E \left[\frac{\partial^2 \ln L(\theta)}{\partial \theta \partial \theta'} \right] \right)^{-1}$$

Therefore any estimator that achieves this lower bound is efficient and no “better” (in the sense of smaller variance) estimator is possible.

But this lower bound is exactly the variance-covariance matrix of the ML estimator that we have previously found. Therefore, all ML estimators achieve the Cramér-Rao lower bound. In this sense then, ML estimators are optimal. No other consistent estimator can have a smaller variance. Another way to think of this is that ML estimators incorporate all the available information about the parameters that is contained in the data.

Asymptotic Normality

Combining consistency and the ML covariance result with the Lindberg-Feller central limit theorem produces:

$$\hat{\theta}_{ML} \stackrel{a}{\sim} N[\theta, \{I(\theta)\}^{-1}]$$

This says that ML estimators converge in distribution to a normal with mean equal to the population value of the parameter and covariance matrix equal to the inverse of the information matrix. The proof of normality is quite involved and not covered here.

The practical implications of this, however, are quite apparent. This means that regardless of the distribution of the variable of interest the ML estimator of the parameters will have a multivariate normal distribution. Thus, a variable, \mathbf{y} , may be Poisson distributed, but the ML estimate of the Poisson parameter λ will be normally distributed, and likewise for *any* distribution of \mathbf{y} . This is particularly valuable for inference and hypothesis testing because it means we can always count on a very simple distribution of the parameter estimates, no matter how complex the underlying likelihood.

Invariance

How does the parameterization of a likelihood affect the resulting inference? ML has the property that any transformation of a parameter can be estimated by the same transformation of the ML estimate of that parameter. This provides substantial flexibility in how we parameterize our models while guaranteeing that we will get the same result if we start with a different parameterization.

The invariance property can be stated formally. If $\gamma = c(\theta)$, where $c(\theta)$ is a one-to-one transformation, then the ML estimator of γ is $c(\hat{\theta}_{ML})$.

To make this more concrete, consider the example of a normal distribution. The usual parameterization is in terms of the mean and variance but an alternative parameterization is in terms of precision, which is the inverse of the variance. If we adopt this parameterization and derive the ML estimator for the precision, how is this related to the ML estimator for the variance?

We reparameterize the normal log-likelihood in terms of precision, $\tau^2 = 1/\sigma^2$:

$$l(\mu, \tau^2 | \mathbf{y}) = - (N/2) \ln(2\pi) + (N/2) \ln \tau^2 - \frac{\tau^2}{2} \sum (y_i - \mu)^2$$

The log-likelihood equation for τ^2 is now:

$$\partial l(\mu, \tau^2 | \mathbf{y}) / \partial \tau^2 = \frac{1}{2} \left[N/\tau^2 - \sum (y_i - \mu)^2 \right] = 0$$

which has the solution $\hat{\tau}^2 = N / \sum (y_i - \hat{\mu})^2 = 1/\hat{\sigma}^2$. We see that the invariance property holds. We are free to choose either parameterization, estimate that parameter, and then transform the ML estimate into an alternative parameterization. The results will be consistent with one another regardless of the choice of parameterization. Fisher noted this property in his 1925 paper. In the process he pointed out that Bayesian approaches do not share the invariance property. A Bayesian posterior is sensitive to the parameterization and different parameterizations may lead to different inferences when transformed.

Inference and Hypothesis Tests

Standard hypothesis tests about parameters in ML models are handled quite easily, thanks to the asymptotic normality of the ML estimator. For any single ML parameter estimate, $\hat{\theta}_j \stackrel{a}{\sim} N[\theta_j, \{I(\theta)\}_{jj}^{-1}]$ and therefore:

$$z = \frac{\hat{\theta}_j - \theta_j}{\{I(\theta)\}_{jj}^{-1}} \stackrel{a}{\sim} N(0, 1)$$

This is the familiar z score for a standard normal variable developed in all introductory statistics classes. The normality of ML estimates means that our testing of hypotheses about the parameters is as simple as calculating the z score and finding the associated p value from a table or by calling a software function.

In a regression, for example, the hypothesis test that a slope is zero is based on the z score of the slope divided by its standard error. In ordinary least-squares (OLS), this is calculated as a t distribution. However, because the ML properties are all asymptotic we are unable to address the finite sample distribution. Asymptotically, the t distribution converges to the normal as the degrees of freedom grow, so clearly the ML test is the same as that for OLS as long as the number of cases are large enough. However, for small samples the OLS estimator is known to have a t distribution, whereas the small-sample properties for the ML estimator are generally unknown.

In addition to the test of hypotheses about a single parameter, there are three classic tests that encompass hypotheses about sets of parameters as well as one parameter at a time. All are asymptotically equivalent, but they differ in the ease of implementation depending on the particular case: the likelihood ratio (LR), Wald, and Lagrange multiplier (LM) tests.

- The LR test asks, “Did the likelihood change much under the null hypotheses versus the alternative?”
- The Wald test asks, “Are the estimated parameters very far away from what they would be under the null hypothesis?”
- The LM test asks, “If I had a less restrictive likelihood function, would its derivative be close to zero here at the restricted ML estimate?”

The first two are most commonly used. The LM test is particularly useful in specification tests that are beyond the scope of this entry.

The LR test is based on the relative likelihoods between a full and a restricted (or reduced) nested model with fewer parameters. The restricted model must be nested within (i.e., a subset of) the full model. The LR

test is actually based on the log of the likelihood ratio, $\ln L_r - \ln L_f$. The test statistic is:

$$-2(\ln L_r - \ln L_f) \sim \chi^2$$

with degrees of freedom equal to the number of parameters in the full model minus the number of parameters in the restricted model. The advantage of the LR test is that it is simple to calculate from the log-likelihoods of the two models. It requires that both models be estimated, however, which may not be entirely trivial. Both full and restricted models must be estimated on exactly the same cases, something that missing data may make less than easy to do in some software packages.

The Wald test provides an alternative to the LR test that requires the estimation of only the full model, not the restricted model. The logic of the Wald test is that if the restrictions are correct then the *unrestricted* parameter estimates should be close to the value hypothesized under the restricted model. For example, a restriction might be that coefficients on three independent variables are all hypothesized to be zero. If this is correct, then the estimated coefficients ought to all be close to zero as well.

The Wald test is based on the distribution of a quadratic form of the weighted sum of squared normal deviates, a form that is known to be distributed as a chi-square distribution. If:

$$x \sim N_J[\mu, \Sigma]$$

then

$$(x - \mu)' \Sigma^{-1} (x - \mu) \sim \chi^2 [J]$$

where N_J is a J -dimensional multivariate normal distribution with variance-covariance matrix Σ , and $\chi^2[J]$ has J degrees of freedom. If the hypothesis that $E(x) = \mu$ is correct, then the quadratic form is distributed χ^2 . If the hypothesis is false, then the quadratic form will on average be larger and we reject the null hypothesis.

For the Wald test, we write the hypothesis as a *constraint* on the parameters:

$$H_0: c(\theta) = q$$

If this is true, then:

$$c(\hat{\theta}) \approx q$$

but, if the constraint is false, then:

$$c(\hat{\theta}) - q$$

should be farther from zero than would be expected.

The test statistic for the Wald test is:

$$W = [c(\hat{\theta}) - q]' \text{Var}(c(\hat{\theta}) - q)^{-1} [c(\hat{\theta}) - q]$$

Under the null hypothesis this has a χ^2 distribution with degrees of freedom equal to the number of restrictions. Further:

$$\text{Var}(c(\hat{\theta}) - q) = \hat{C} \text{Var}(\hat{\theta}) \hat{C}'$$

and

$$\hat{C} = \left[\frac{\partial c(\hat{\theta})}{\partial \hat{\theta}'} \right]$$

where C is $J \times K$, where K is the number of parameters in the model and J is the number of restrictions.

For the special case of *linear* constraints, this takes on a simple form:

$$c(\theta) - q = R(\theta) - q = 0$$

so

$$\hat{C} = \left[\frac{\partial c(\hat{\theta})}{\partial \hat{\theta}'} \right] = R$$

Hence,

$$\text{Var}(c(\hat{\theta}) - q) = R \text{Var}(\hat{\theta}) R'$$

and

$$W = [R\hat{\theta} - q]' [R\text{Var}(\hat{\theta})R']^{-1} [R\hat{\theta} - q]$$

with degrees of freedom equal the number of rows in R .

For example, suppose we want to test the hypothesis that $\theta_2 = \theta_3$ when there are five parameters in the model. The restriction implies that $\theta_2 - \theta_3 = 0$. The R matrix is just:

$$R = \begin{bmatrix} 0 & 1 & -1 & 0 & 0 \end{bmatrix}$$

so that $R\theta = 0$ holds if the restriction $\theta_2 = \theta_3$ is true.

More than one restriction produces more than one row in R —one row for each restriction. If we add the restriction that $\theta_4 = -\theta_5$, then R becomes:

$$R = \begin{bmatrix} 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \end{bmatrix}$$

The p value that results from the Wald test provides a test of the joint hypothesis that all restrictions are simultaneously true.

Three Brief Examples

Here we consider three examples of applications of ML to common social science estimation problems.

Poisson Event Counts

If the data are observed counts of events that occur over time, the Poisson distribution provides a good starting point. The Poisson assumes that events occur

independently and at a fixed rate within time periods. If these assumptions are substantively sensible, we might model the number of coups d'état in the world, the number of wars initiated, the number of troops killed or the number of suicide bombings per year (or month) as Poisson processes.

The Poisson data generating process gives us the log-likelihood for the sample:

$$\begin{aligned} l(\lambda | y) &= \sum_{i=1}^N \left(\log \frac{e^{-\lambda} \lambda^{y_i}}{y_i!} \right) \\ &= \sum_{i=1}^N (-\lambda + y_i \log(\lambda) - \log(y_i!)) \\ &= -N\lambda + \log(\lambda) \sum y_i - \sum \log(y_i!) \end{aligned}$$

Because the last term does not involve λ , we can drop it from the log-likelihood without affecting the ML estimator.

If we thought that the dependent variable of interest had a constant rate of occurrence in all places and all times, then we could proceed to estimate the parameter as discussed earlier. However, in almost all interesting social science applications we have a variety of variables that we think affect the rate of occurrence. For example, the rate of coups d'état in a year may depend on world economic conditions in that year and might vary by region. The number of combat deaths may depend on the level and type of conflict. If we can measure these independent variables, then we want to incorporate them into the model as explanations of why the rate of events, measured by λ , varies across cases in the data.

To do this, we recognize that there is variation in λ across cases, and so we replace it with λ_i , where i is the unit of analysis. The log-likelihood then becomes:

$$l(\lambda_i | y) = - \sum \lambda_i + \sum \log(\lambda_i) y_i$$

ignoring the factorial term. If we leave the model in this form, there are as many parameters λ_i as there are cases. This model is identified only for the trivial case where $\lambda_i = y_i$. This says that each case is different but that we cannot say why it is different and we cannot estimate a variance for λ_i .

However, if we believe that our substantive explanatory variables can account for the variability in λ_i across cases, then we can reparameterize the model in terms of the smaller number of explanatory variables and a small number of parameters. In this case, we might choose the parameterization:

$$\lambda_i = e^{\mathbf{x}_i \beta}$$

We pick this form because λ_i must be nonnegative. This functional form takes values of $\mathbf{x}_i \beta$ between $-\infty$ and $+\infty$ and return estimates of λ_i that respect the nonnegativity required. We assume there are k columns

in \mathbf{x} , so there are also k elements in β . Because it will usually be the case that k is much smaller than n , we have dramatically reduced the number of parameters in the model while also providing a model that explains how the rate of events (λ_i) varies as each \mathbf{x} varies. The elements of β are the coefficients of this Poisson regression.

After we reparameterize in this way, the log-likelihood becomes

$$l(\beta | \mathbf{y}, \mathbf{x}) = - \sum e^{\mathbf{x}_i \beta} + \sum \mathbf{x}_i \beta y_i$$

Because this is nonlinear in β we will not be able to derive a closed-form solution for the parameters. Numerical methods can easily maximize this function, however, and can also return the estimated variance-covariance matrix for the parameters.

To test hypotheses in this model we might focus first on the individual parameters and use the z score for each to calculate a p value against the null hypothesis that the population parameter is zero, that is, that the x variable has no effect on the rate of event counts. Such a test has exactly the same logic as the t test for coefficients in a linear regression.

If we have a more complicated theory, then we might test that some set of variables are all irrelevant to the rate of events. For example, perhaps we want to test the hypothesis that international economic conditions do not affect the rate of coups d'état. We might use several indicators of economic conditions. The null hypothesis in this case is that all the coefficients on the economic variables are zero. We could use either a LR or a Wald test for this. If we fail to reject the null, then the data are not inconsistent with a lack of impact of economic conditions. If we reject the null, then we conclude that at least one of the economic variables affects the rate of coups.

This example illustrates the ability to reparameterize the log-likelihood function in order to incorporate substantive explanations and also to then test hypotheses about these possible explanations. This reparameterization is extremely flexible and can be used to capture a number of alternative specifications and hypotheses.

Heteroskedastic Regression

When a linear regression presents evidence of heteroskedasticity, the usual approach in least-squares is to use a generalized least-squares (GLS) estimator in place of the usual OLS. The virtue of GLS is that we do not need to know anything about *why* the data are heteroskedastic in order to estimate the model by GLS. The GLS estimator will provide consistent estimates of the regression slopes, but will also provide consistent estimates of the standard errors of those slopes, making correct hypothesis tests possible. If the slopes are all we care about, this is a sensible solution.

In many cases, however, we might wish to treat the heteroskedasticity as itself the subject of substantive interest. For example, the content of election campaigns may affect not only how candidates are perceived but also affect the *clarity* of those perceptions. The clarity can be modeled by assuming that the variance parameter, σ^2 , varies across individuals depending on both campaign and individual level variables such as the amount of advertising, the number of issues discussed, the individual's level of interest in politics and their amount of television exposure. In this case we wish to reparameterize the variance as $\sigma_i^2 = f(\mathbf{z}_i \gamma)$, where \mathbf{z} contains the variables that affect clarity of candidate perception and γ is the vector of coefficients measuring these effects. Because σ_i^2 must be nonnegative, we adopt the parameterization $\sigma_i^2 = e^{\mathbf{z}_i \gamma}$.

As with the heteroskedastic regression model, there are also variables that affect the mean of perceptions. For example, liberals may see Democrats as closer to them, whereas conservatives see them as further away. In the normal distribution, this requires another reparameterization. If the mean perception varies across individuals, then the parameterization becomes $\mu_i = \mathbf{x}_i \beta$.

If we assume our dependent variable, candidate perceptions, follows a normal data generating process, then the log-likelihood is:

$$l(\mu_i, \sigma_i^2 | \mathbf{y}) = \sum \left(-\frac{1}{2} \log(2\pi) - \frac{1}{2} \log \sigma_i^2 - \frac{1}{2} \frac{(y_i - \mu_i)^2}{\sigma_i^2} \right)$$

Replacing μ_i and σ_i^2 with their reparameterizations gives:

$$l(\beta, \gamma | \mathbf{y}, \mathbf{x}, \mathbf{z}) = \sum \left(-\frac{1}{2} \log(2\pi) - \frac{1}{2} \mathbf{z}_i \gamma - \frac{1}{2} \frac{(y_i - \mathbf{x}_i \beta)^2}{\exp(\mathbf{z}_i \gamma)} \right)$$

This parameterization now has, say, k parameters in β and j parameters in γ . This is a significant reduction from the $2N$ parameters we have in μ_i and σ_i^2 , which are also underidentified. This provides a parsimonious model of both perceptions and clarity and offers substantive insight, through the γ vector, into why some perceptions are more variable than are others.

Again, there are nonlinear functions of the parameters that preclude a closed-form solution to the log-likelihood equations, so numerical methods are used for estimation. Hypothesis testing is straightforward using z scores for individual parameters or the LR or Wald test for sets of parameters.

Logit Model for Binary Outcomes

Perhaps the single most widely used ML estimator is the logit model for binary outcomes. Many social outcomes are inherently dichotomous: a citizen votes or does not,

a person marries or does not, a person is employed or is not. For these models, we start with the simplest data generating process, the Bernoulli distribution:

$$\begin{array}{cc} y & P(y) \\ y_i \sim 1 & \pi \\ 0 & 1 - \pi \end{array}$$

where the event occurs with probability π and fails to occur with probability $1 - \pi$.

We reparameterize this model to allow the probability of success to vary across observations, so π becomes π_i . The likelihood is therefore:

$$L(\pi_i | \mathbf{y}) = \prod \pi_i^{y_i} (1 - \pi_i)^{1-y_i}$$

As with the Poisson example, there are N parameters in this form of the model, so some simplification is required.

To construct the logit model, we again reparameterize, this time replacing the probability of success for each case with the cumulative logistic distribution and introducing explanatory variables and parameters to account for the variation in probability. The cumulative standardized logistic distribution is:

$$P(y = 1) = \frac{1}{1 + e^{-\mathbf{x}\beta}}$$

where \mathbf{x} is the matrix of predictor variables, and β is a vector of coefficients. If we reparameterize π_i to equal this function, the log-likelihood becomes:

$$\begin{aligned} l(\beta | \mathbf{y}, \mathbf{x}) \\ = \sum_{i=1}^N y_i \log \frac{1}{1 + e^{x_i \beta}} + (1 - y_i) \log \left(1 - \frac{1}{1 + e^{x_i \beta}} \right) \end{aligned}$$

Numerical methods are used to maximize this, and hypothesis testing proceeds as before.

We can convert this to the probit model by simply choosing to parameterize in terms of the cumulative normal rather than the cumulative logistic. In that case, the log-likelihood becomes:

$$l(\beta | \mathbf{y}, \mathbf{x}) = \sum_{i=1}^N y_i \log \Phi(x_i \beta) + (1 - y_i) \log(1 - \Phi(x_i \beta))$$

where

$$\Phi(x_i \beta) = \int_{-\infty}^{x_i \beta} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{2}(x_i \beta)^2\right) dx$$

This is the integral of a standard normal variate. It has no closed form and so is usually abbreviated as simply $\Phi(x_i \beta)$.

Here we see that models of binary outcomes rest on a common assumption that the Bernoulli distribution with variable parameter π_i is a reasonable model for binary outcomes. The choice between logit or probit is simply a matter of whether we choose to reparameterize π_i as a cumulative logistic or a cumulative normal. Other binary

choice models result from choosing other distributions, such as the complementary log-log or the Cauchy distribution. This also illustrates the flexibility of ML in allowing us to incorporate a variety of alternative parameterizations within a common base likelihood.

Conclusion

ML provides a general and flexible approach to statistical estimation and inference. ML estimators are consistent, efficient, asymptotically normally distributed, and lead to identical inferences when reparameterized. These are powerful reasons for the success of the method. On the negative side of the ledger is the requirement for large samples in order to have confidence in the asymptotic approximations required.

Measurement Error, Issues and Solutions

Richard A. Zeller

Kent State University, Kent, Ohio, USA

Glossary

communality The sum of the squared factor loadings for an measure across all factors.

concept A specific idea concerning crucial aspects of a narrow variety of behaviors.

construct A general idea concerning crucial aspects of a wide variety of behaviors.

convergent validity The strong positive correlation among measures of a dimension.

correlation matrix An arrangement of correlation coefficients, each defined by its row and column.

Cronbach's alpha The average of all possible split-half reliabilities projected onto the number of measures in a scale.

dimension The physical specification of the location of a concept in space.

discriminant validity The correlation among measures of each dimension when they are more strongly correlated among themselves than they are with measures of other dimensions.

effect parameter The degree to which a presumed cause affects a presumed effect.

eigenvalue The sum of the squared factor loadings for a factor across all measures.

epistemic correlation The correlation between a concept and an observed variable designed to measure that concept.

epistemic path The strength of the causal effect of a concept on an observed variable designed to measure that concept.

factor analysis A statistical tool designed to reduce a large number of measures to a small number of dimensions.

factor loading The correlation of an measure with a factor.

measurement The link between theory and data.

measurement error The difference between a concept and the observations designed to measure that concept.

operational definition A formulation that specifies a protocol, the quantitative result of which is our attempt to assess the concept.

path coefficient The estimated strength of a causal effect.

random error The haphazard fluctuation of a variable that does not produce the same observation under identical theoretical and observational conditions.

reliability The degree to which an observation designed to measure a concept is free from random error.

scale A dimension created from multiple measures.

systematic error The patterned fluctuation of a variable that produces an observation that differs from the concept it was designed to measure.

validity The degree to which an observation designed to measure a concept is free from both systematic error and random error.

varimax A rotation algorithm that maximizes high and low factor loadings, minimizing mid-value factor loadings.

Measurement is the act of establishing a correspondence between observations and concepts. In a perfect world, we would have perfect measures of our concepts. But in the real world of research, we possess no such perfect measures; we have no “gold standard” against which to evaluate how good our measures are. In order to advance our disciplines, we need pretty good, but not perfect, measures for our concepts. We need measures that are highly, but not perfectly, reliable and valid. We ought not to use woefully inadequate measures. Instead, we should use measures that are, although not perfect, pretty good. This entry establishes how to create and evaluate pretty good measures.

Measurement

Measurement is the link between theory and data. Data are made up of observations of behavior. Theory is made up of constructs. A construct is a general idea concerning

crucial aspects of a wide variety of behaviors. Constructs are made up of concepts. A concept is a specific idea concerning crucial aspects of a narrow variety of behaviors. Measurement is the act of establishing a correspondence between observations and concepts. Social science concepts include aggression, pain, co-dependence, self-esteem, alienation, economic output, productivity, satisfaction, conflict, development, safety, communication, political participation, socioeconomic status, deviance, fertility, learning, health, physical fitness, and stress. In a perfect world, we would have perfect measures of our concepts. But in the real world of research, we possess no such perfect measures; we have no “gold standard” against which to evaluate how good our measures are.

Measurement error is the difference between a concept and the observations designed to measure that concept. Measurement error is made up of random error and systematic error. Random error is the haphazard fluctuation of a variable that does not produce the same observation under identical theoretical and observational conditions; systematic error is the patterned fluctuation of a variable that produces an observation that differs from the concept it was designed to measure. Reliability is the degree to which an observation designed to measure a concept is free from random error; validity is the degree to which an observation designed to measure a concept is free from both systematic error and random error.

In order to advance our disciplines, we need pretty good, but not perfect, measures for our concepts. We need measures that are highly, but not perfectly, reliable and valid. We ought not to use woefully inadequate measures; that is, we should not use measures possessing weak reliability and validity. Instead, we should use measures that are, although not perfect, pretty good. Let us illustrate.

Galileo wanted to measure the speed of a falling object. In order to measure speed, he had to measure time and distance. His measure of distance was highly reliable and valid. But what could he use to measure time? For his purposes, the hourglass was inadequate; the pulse was adequate—Galileo did not have (and did not need) a quartz watch! The clever Galileo used the relatively reliable and valid pulse of an assistant as his measure of time. For his purposes, pulse was highly, but not perfectly, reliable and valid.

How could Galileo have evaluated the reliability and validity of a pulse as a measure of the concept time? More generally, how can any scientist evaluate the reliability and validity of any measuring instrument? Answer: Galileo could have had multiple assistants measure a clear interval of time using their respective pulses. That is, he could have had 10 assistants check their pulses during the passage of the same interval of time.

Suppose that Galileo defined a clear interval of time (e.g., from when the object started falling to when it hit the ground). Suppose he asked 10 assistants to measure their pulses during this time interval. Suppose he summed each of the 10 measures for each instrument, creating a pulse scale (a scale is a dimension created from multiple measures). I illustrate in the following the procedures that Galileo could have used to evaluate the reliability and validity of his pulse (time measurement) scale.

Hauser argued in 1969 that the major challenge in social research is to find and evaluate the reliability and validity of the scales that we use to measure our concepts. He notes that “. . . inadequate measurement, more than inadequate concept or hypothesis, has plagued social researchers and prevented fuller explanations of the variances with which they are confounded.”

Given concepts and the hypothesized causal connections among those concepts, sociology researchers are faced with the “reality” test. Does our conceptual structure coincide with what we observe? This is the major challenge of science. In order to evaluate the causal relationships among concepts, we must find an adequate measure for each concept. I now turn to the task of finding adequate measures for concepts. This presentation focuses primarily on exploratory factor analysis. Other studies (e.g., the 1987 Hayduk study) focus primarily on confirmatory factor analysis.

The Criteria for Adequate, but Not Perfect, Measurement

The following are standard protocols of adequate, but not perfect, measurement.

- Multiple measures. There should be multiple measures designed to assess each dimension of the concept.
- Measure clarity. Each measure should be designed to measure one and only one dimension of a concept.
- Convergent and discriminant validity of measures of a concept. There should be a strong positive intercorrelation among measures designed to assess each dimension of the concept. Moreover, these intermeasure correlations should be stronger than the correlations of these measures with measures designed to assess other dimensions.
- Factor analysis. The dimensions in data should be identified.
- Scaling. Once the clarity, convergence, and discriminance of a set of measures have been established, scales should be constructed.

- Equivalence reliability. The equivalence reliability among the measures of each dimension of a concept should be strong.
- Correction for attenuation. Correlations between scales with imperfect reliability will be less than what the correlation would have been if the scales were perfectly reliable, and this underestimate of the correlation should be corrected.

Additional criteria for good measurement, the examination of which goes beyond the present discussion, include:

- Known groups validity. Once scales have been constructed, comparisons of scale scores between groups known to be high and low on the dimensions of the concept should be made.
- Construct validity. Scales should correlate as theoretically specified with measures of other concepts.

Let us discuss each of these target criteria in turn.

Multiple Measures

A dimension is the physical specification of the location of a concept in space. Each dimension is designed to represent its respective concept. A dimension is made up of a set of measures. When a set of concepts represents the general idea of a construct, the space is called multidimensional. For example, in 1966 Nisbet argued that the construct “Alienation” is one of the major unit-ideas of sociology. In 1959, Seeman argued that “Alienation” is an umbrella construct for the concepts “Social isolation,” “Powerlessness,” “Normlessness,” and “Meaninglessness.” In 1967, Neil and Rettig constructed multiple measures for each of these concepts. In 1980, Zeller, Neal, and Groat established the reliability and stability of these concepts, as assessed by scales constructed from their respective measures. I now turn to a discussion of the measurement issues raised by the attempt to assess the

concepts of “Alienation” and the protocol used by these authors.

Consider only the concepts “Social isolation” and “Powerlessness” under the umbrella construct “Alienation.” Zeller, Neal, and Groat conceptually defined “Social isolation” as “... the experience of a social cleavage between oneself and others.” They defined “Powerlessness” as “... low subjectively held probabilities for controlling events.” Multiple Likert items were developed as measures of these two concepts. For example, as measures of “Social isolation,” Zeller, Neal, and Groat used:

S_1 , “Real friends are easy to find as ever.”
(reverse scoring)

S_2 , “Sometimes I feel all alone in the world.”

As measures of “Powerlessness,” they used:

P_1 , “People like me can change the course of world events if we make ourselves heard.” (reverse scoring)

P_2 , “The world is run by the few people in power, and there is not much the little guy can do about it.”

Common response categories for Likert items are: 1 = “Strongly disagree”; 2 = “Disagree”; 3 = “Mildly disagree”; 4 = “Neutral”; 5 = “Mildly agree”; 6 = “Agree”; 7 = “Strongly agree.” Reverse-scored items assign a 7 (not a 1) to “Strongly disagree”; a 6 (not a 2) to “Disagree”; and so on.

Figure 1 presents a measurement path model of the construct “Alienation.” “Alienation” is conceptualized as the umbrella construct that causes the concepts “Social isolation,” and “Powerlessness.” The model specifies six measures of “Social isolation,” labeled s_1 , s_2 , s_3 , s_4 , s_5 , and s_6 , and six measures of “Powerlessness,” labeled p_1 , p_2 , p_3 , p_4 , p_5 , and p_6 .

In path models, causal effects are represented by arrows. In path analysis, these causal effects are estimated by path coefficients; a path coefficient is the estimated strength of a causal effect. The theoretical causal effect of

Figure 1 Two-factor measurement path model for “Alienation.”

“Alienation” on “Social isolation” is represented by P_s ; the theoretical causal effect of “Alienation” on “Powerlessness” is represented by P_p , where P stands for the theoretical path coefficient. Thus, P_s refers to the path from “Alienation” to “Social isolation,” and P_p refers to the path from “Alienation” to “Powerlessness.”

The epistemic causal effects of “Social isolation” on each of the measures of “Social isolation” (e.g., s_1 , s_2 , s_3 , s_4 , s_5 , and s_6) are represented by p_{s1} , p_{s2} , p_{s3} , p_{s4} , p_{s5} , and p_{s6} . The epistemic causal effects of “Powerlessness” on each of the measures of “Powerlessness” are represented by p_{p1} , p_{p2} , p_{p3} , p_{p4} , p_{p5} , and p_{p6} , where p stands for the causal, epistemic effect of each concept on its respective measures. The measurement model in Fig. 1 has 12 measures, six for each concept.

The only thing that the researcher observes is the answers provided by the respondent to the items on the questionnaire. The data obtained from the questionnaire are variables; each has a mean and a variance. These variables can be correlated with one another and with other variables relevant to the research questions.

In order to illustrate the principles of factor analysis just described, I present a dimensions of “Alienation” data set. I created this data set using transformations of random numbers. Therefore, the universe that underlies this data set has known parameters. But prior to the research, the researcher does not know what those parameters are. Indeed, if the researcher had foreknowledge of these parameters, there would be no reason to conduct the research. I first show how these parameters are estimated

using the standard protocols of factor analysis; I then compare the results of the factor analysis with the parameters.

Table I presents a correlation matrix of the 12 measures of alienation—a correlation matrix is an arrangement of correlation coefficients, each defined by their respective row and column. For example, the correlation between s_1 and s_2 is 0.506 ($r_{s1s2} = 0.506$). This can be seen by looking down column s_1 in Table I and across row s_2 . It can also be seen by looking down column s_2 in Table I and across row s_1 . Thus, the correlation matrix is a symmetric matrix. That is, $r_{s1s2} = r_{s2s1}$, $r_{s1s3} = r_{s3s1}$, and so on.

The correlation of an item with itself is equal to 1 ($r_{s1s1} = 1.000$). The set of correlations of each item with itself forms a diagonal across the correlation matrix. This diagonal is called the main diagonal. The symmetry of the correlation matrix is that each correlation in the upper right triangle (above and to the right of the main diagonal, as shown in Table I) is identical to its counterpart in the lower left triangle (below and to the left of the main diagonal).

Intercorrelations among measures also form groups. The triangle of correlations among measures of “Social isolation,” the triangle of correlations among measures of “Powerlessness,” and the rectangle of correlations between the “Social isolation” measures and the “Powerlessness” measures are presented in Table I. A visual inspection of the table shows that the intercorrelations among the measures of “Social isolation” hover around 0.5; the intercorrelations among the measures

Table I Correlation Matrix of 12 Measures of Alienation

		s_1	s_2	s_3	s_4	s_5	s_6	P_1	P_2	P_3	P_4	P_5	P_6		
C. Triangle of correlations among social isolation measures	s_1	1	0.506	0.487	0.517	0.495	0.502	0.200	0.257	0.228	0.212	0.258	0.219	Upper right triangle

	s_6	0.502	0.506	0.470	0.510	0.507	1	0.279	0.297	0.258	0.225	0.277	0.222		
E. Rectangle of correlations between s measures and p measures	p_1	0.200	0.269	0.233	0.213	0.229	0.279	1	0.500	0.511	0.492	0.510	0.487	D. Triangle of correlations among powerlessness measures	Main diagonal
	p_2	0.257	0.303	0.316	0.292	0.297	0.297	0.500	1	0.497	0.500	0.531	0.538		
	p_3	0.228	0.260	0.262	0.248	0.263	0.258	0.511	0.497	1	0.507	0.535	0.492		
	p_4	0.212	0.244	0.273	0.238	0.226	0.225	0.492	0.500	0.507	1	0.500	0.495		
	p_5	0.258	0.255	0.294	0.233	0.283	0.277	0.510	0.531	0.535	0.500	1	0.547		
	p_6	0.219	0.276	0.256	0.249	0.229	0.222	0.487	0.538	0.492	0.495	0.547	1		

of “Powerlessness” hover around 0.5; and the correlations between the “Social isolation” measures and the “Powerlessness” measures hover around 0.25.

Table I presents all the information we have. This information is nothing more than marks on a piece of paper. From these marks, we have created variables and a correlation matrix. By no stretch of the imagination does this data collection protocol constitute strong data. Instead, it is subject to all of the foibles known to researchers: social desirability, response set, lying, ignorance, apathy, fatigue, and so on.

Analysis and inference remain to be done. What can we do with the correlations in Table I that will allow us to evaluate the measurement model? In order to answer this question, we must create some principles of analysis and inference.

Let us begin at the beginning. We have a pool of items. We created this pool of items with the specific intent of measuring our concepts. Recall that we created the measurement model presented in Fig. 1 by sheer imagination—we made it up. By no stretch of the imagination does this measurement model constitute strong theory, so we have weak data and weak theory. But, as we shall see, this combination can lead to a rather strong inference about the measurement model. We now turn to the equipment we need to make that inference.

An epistemic correlation is the correlation between a concept and an observed variable designed to measure that concept. The term epistemic path refers to the strength of this causal effect. The epistemic path is the traditional answer to the question: “To what degree is this measure a valid measure of the dimension it is designed to measure?” In Fig. 1, the p_{ij} from either “Social isolation” or “Powerlessness” to their respective measures represent epistemic paths.

The epistemic correlation crosses the line between the theoretical and the observational. The theoretical concept is, in principle, unobservable; nobody has ever seen “Social isolation” or “Powerlessness.” We attempt to measure a concept using an operational definition. An operational definition specifies a protocol, the quantitative result of which is our attempt to assess the concept. In our “Alienation” example, each of the 12 items are operational definitions designed to measure their respective concepts. The protocol is that we will ask respondents to provide their opinions on a questionnaire, and we will use their responses on our preestablished quantitative ladder as the relative level of each respondent on each respective concept.

The epistemic correlation is the crux of measurement. It is, in measurement terminology, the validity coefficient. But an epistemic correlation can never be directly observed. We cannot make this observation directly because the concept is unobservable. Therefore, the epistemic correlation requires that the conceptual structure be inferred.

In Fig. 1, the epistemic path from “Social isolation” to measure s_1 is p_{s1} . This path spans the chasm between the theoretical and what is observed; p_{s1}, \dots, p_{s6} are the six epistemic paths from “Social isolation” to the measures of “Social isolation”; p_{p1}, \dots, p_{p6} are the six epistemic paths from “Powerlessness” to the measures of “Powerlessness.” But how can we evaluate whether the two-dimensional structure in Fig. 1 is the appropriate measurement model? After we have made this inference, how can we assess the strength of the epistemic paths of the inferred model? Finally, how can we assess the pattern of association among the concepts? Clearly, proper inference in measurement presents the scientist with a substantial challenge.

If a measure were perfectly reliable and valid, each epistemic path would be 1.00. When one measure assesses its target concept with perfect reliability and validity, that measure alone is sufficient to measure its respective concept. In this situation, multiple measures are unnecessary and superfluous. Even if the epistemic path from a dimension to a measure were near perfect (i.e., $p_{ij} = 0.95$), the use of more than one measure would add very little to measurement reliability and validity.

As the epistemic path is reduced in strength, the number of measures needed for acceptable measurement reliability increases. Much of the measurement challenge involves evaluating the veracity of the measurement model and finding credible estimates for the epistemic and conceptual paths.

Measure Clarity

Each item should be designed to assess one and only one dimension of a concept. There is no substitute for clear measures. There is no substitute for the depth and breadth of substantive knowledge of a concept and its dimensions. There is no substitute for a researcher’s clinical experience with those who exhibit the phenomenon in question. In addition, there is no substitute for diligence, persistence, cleverness, and creativity in the construction of measures. I may have underplayed the importance of item clarity by giving it only one short paragraph. I have seen numerous studies in which item weakness in terms of clarity, substantive knowledge, and construction has led to unsatisfactory measurement results. However, this is a paper on measurement, not on the construction of clear measures.

Convergent and Discriminant Validity of Dimensions within a Concept

When multiple measures are designed to assess a single dimension, the standard of the research industry has long been that these measures should be highly intercorrelated.

Convergent validity is the condition of strong positive correlation among measures of a dimension. The industry also requires that measures of one concept be differentiable from measures of another concept. Discriminant validity is the condition that measures of each dimension are more strongly correlated among themselves than they are with measures of other dimensions. In Fig. 1, correlations among s_i and correlations among p_i (in the triangles of correlations within groups of measures) are convergent correlations; correlations between the s_i and the p_i (in the rectangle of correlations between S measures and P measures) are discriminant correlations. There are two convergent clusters in Fig. 1.

Factor analysis is the major statistical technique designed to describe measure intercorrelations. The purpose of factor analysis is the identification of dimensions in the data. As such, factor analysis enables researchers to (1) describe the dimensions of a set of measures, (2) select those measures that best represent each of the identified dimensions, and (3) estimate the strength of the epistemic path from each dimension to its respective set of measures.

However, when evaluating the degree to which a large set of measures represent a small number of theoretical dimensions, the application of factor analytic techniques is as much an art as it is a science. This is because there are numerous conceptual and empirical ambiguities in the measurement setting. Conceptually, the researcher wants to find out: (1) how many dimensions of the concept are “real” and (2) to what degree each dimension of the concept is related to other dimensions of the same concept and to other concepts. Empirically, the researcher wants to assess the degree to which each measure represents (1) the dimension it is designed to represent, (2) dimensions other than the one it is designed to represent, (3) systematic method artifacts, and (4) random error.

At the same time, the researcher’s primary interest is in the substantive association between the dimensions of the concept and other concepts; the measurement effort itself is of secondary importance. Nevertheless, bad measurement most surely will torpedo the best of conceptual schemes and sentence them to the intellectual trash heap, whether they belong there or not. The end result of the factor analysis should be that the researcher has inferred how many dimensions are represented by the measures, which measures define which dimensions, and to what degree.

Factor Analysis

Factor analysis is a statistical tool designed to describe correlations economically. Specifically, factor analysis is designed to reduce a large number of measures to a small number of dimensions. In order to accomplish this objective, a series of mathematical calculations are performed on a correlation matrix. When a researcher has a strong

theory and strong data, the appropriate factor analytic tools are confirmatory. However, researchers usually lack such a strong theory and strong data. When a researcher lacks a strong theory and strong data, the appropriate factor analytic tools are exploratory.

Ordinarily, the researcher wants the number of factors to be as small as possible while still maintaining fidelity to the patterns of correlations. Exploratory factor analysis is appropriate in situations in which the researcher is less than highly confident *a priori* about how many factors are necessary and sufficient to describe the data, about which measures define which factors, and about the pattern of association among the factors.

Exploratory factor analysis focuses on the extraction and rotation of factors. Extraction is the process of removing and describing the desired number of factors from a correlation matrix. Rotation is the process of solving for a viewing location of those factors that makes the most theoretical sense. There are a variety of different mathematical approaches to the extraction and rotation of factors. I limit this discussion to principal components extraction and to varimax rotation.

Extraction

Principal components extraction applies a complex mathematical algorithm to a correlation matrix. Components, commonly called factors, are extracted from the correlation matrix sequentially. The first and strongest factor is extracted and then statistically removed from the matrix. Then the second factor is extracted and removed from the matrix. This process continues, extracting weaker and weaker factors, until there are as many factors as there are variables in the correlation matrix. But the analyst only wants to examine the strong systematic factors. Parsimony is achieved when the strong systematic factors are retained in the analysis while the weak random factors are discarded. I examine the criteria for making the decision concerning how many factors are systematic shortly. First, I must define factor loading.

A factor loading is the correlation of an measure with a factor. Like correlation coefficients, factor loadings vary from -1.0 to 1.0 . Each measure has a factor loading on each factor. If a measure has a strong positive factor loading (i.e., >0.5) on a factor, that measure is said to define that factor. If a measure has a strong negative factor loading (i.e., <-0.5) on a factor, that measure is said to define the opposite of that factor. As the strength of the factor loading decreases, the capacity of the factor loading to define the factor also decreases.

Two crucial tools in the interpretation of factor analyses are the communality and the eigenvalue. The communality (symbolized h^2) is equal to the sum of the squared factor loadings for a measure across all factors. For any measure, the communality reports the proportion of variance that measure shares with the factor structure.

The higher the communality, the more that measure shares variance with the other measures in the correlation matrix. When the number of factors is equal to the number of measures in the correlation matrix, all principal component communalities will equal 1.00. The sum of the communalities over all measures will equal the number of measures. But the purpose of factor analysis is to reduce a large number of measures to a small number of factors. When this reduction takes place, the communalities reveal how much variance an item shares with the systematic factors retained in the analysis.

The eigenvalue is equal to the sum of the squared factor loadings for a factor across all measures. For any factor, the eigenvalue divided by the number of measures reports the proportion of variance of the correlation matrix on that factor. The sum of the eigenvalues over all factors will equal the number of measures.

But, I reiterate, the analyst only wants to examine the systematic factors. When factors are extracted from a correlation matrix, the systematic factors are extracted first. But the mathematical algorithm does not know when systematic patterns have been exhausted. Instead, the analyst must specify the number of factors to be included in the factor analysis. How does the analyst decide how many factors to include? I now turn to the answer to that question.

How Many Factors? For many measurement questions, good theoretical arguments can be articulated for varying numbers of factors. Ordinarily, none of these arguments constitute strong theory and ordinarily, the researcher does not possess strong data. When faced with either of these liabilities, the factor analyst can provide two rules of thumb designed to assist in the decision about how many factors are sufficiently systematic to be included in subsequent analyses: the 1.0 eigenvalue cut-off and the scree test.

- The 1.0 eigenvalue cut-off rule of thumb is a decision rule for setting the number of factors to be retained in the analysis as equal to the number of factors with eigenvalues ≥ 1.0 . Factors with eigenvalues ≥ 1.0 should, according to this rule of thumb, be retained as systematic factors. Factors with eigenvalues < 1.0 should be discarded as random. Table II presents the eigenvalue, the percentage of variance explained, and the cumulative percentage of variance explained for each component. There are 12 factors in this analysis, one for each of the 12 measures. The 12 factors together account for 100% of the variance in the matrix. The eigenvalue for the first component is 5.080; this component accounts for 42.333% of the variance in the matrix (e.g., $5.080/12 = 0.42333$). The second factor has an eigenvalue of 2.025 and accounts for 16.875% of the variance in the matrix. Together, factors 1 and 2 account for 59.208% of the variance

Table II Total Variance Explained^a

Component	Eigenvalue total	Percentage of variance	Cumulative (%)
1	5.080	42.333	42.333
2	2.025 ^b	16.875	59.208
3	0.584	4.869	64.078
4	0.537	4.471	68.549
5	0.529	4.410	72.959
6	0.520	4.330	77.290
7	0.493	4.112	81.402
8	0.482	4.015	85.417
9	0.473	3.946	89.363
10	0.452	3.763	93.126
11	0.428	3.570	96.696
12	0.396	3.304	100.000 ^c

^a Extraction method: principal component analysis.

^b 1.0 eigenvalue cut-off.

^c Twelve components account for 100% of the variance.

(e.g., $42.333\% + 16.875\% = 59.208\%$). Factor 3 has an eigenvalue of only 0.584, and the remaining factors account for successively less variance. The 1.0 eigenvalue cut-off indicates that we should retain two factors in this analysis.

- The scree test rule of thumb is a decision rule for setting the number of factors to be retained by the identification of the point of disjuncture in the pattern of eigenvalues extracted on each subsequent factor. The scree test uses the fact that there are as many factors in a principal components analysis as there are measures. Factors with eigenvalues on the larger side of the disjuncture should be considered systematic; factors with eigenvalues on the smaller side of the disjuncture should be considered random. The scree test is carried out using a scree plot. A scree plot presents the size of the eigenvalue on the vertical axis and the component number on the horizontal axis. A scree plot is read by noting the number of factors for which the eigenvalue is greater than the trajectory of eigenvalues suggests. Figure 2 presents the scree plot for this factor analysis. In Fig. 2, the eigenvalues increase only slightly as we move back from factor 12 to factor 3; then there is a substantial increase in the scree plot line as we move back from 3 to 2. This substantial increase is the disjuncture in the scree plot line that leads the analyst to the inference that there are two systematic factors in the data.

Rotation of Factors

As I have noted, the factors as extracted do not usually present the optimal vantage point from which to examine the results. In addition to the 1.0 eigenvalue cut-off rule and the scree test, analysts can make educated guesses

about the number of factors by the number of measures that define each rotated factor. The rotation of factors improves the analysts educated guesses.

Varimax rotation uses a mathematical algorithm that maximizes high- and low-value factor loadings and minimizes mid-value factor loadings. The varimax rotated two-factor matrix is presented in Table III. All factor loadings are positive. The factor loadings on factor 1 are between 0.7 and 0.8 for the s_i , the measures of “Social isolation,” and between 0.1 and 0.3 for the p_i , the measures of “Powerlessness.” The reverse is true for the factor loadings on factor 2. On this factor, the factor loadings are between 0.1 and 0.3 for the s_i and between 0.7 and 0.8 for the p_i . Given this analysis, we call label factor 1 the social isolation factor and factor 2 the powerlessness factor.

Figure 2 Scree plot of two-factor structure.

Table III Rotated Two-Factor Matrix^a

	<i>Factors</i>	
	<i>1 (Social isolation)</i>	<i>2 (Powerlessness)</i>
s_1	0.752	0.128
s_2	0.761	0.186
s_3	0.733	0.203
s_4	0.767	0.150
s_5	0.755	0.168
s_6	0.732	0.182
p_1	0.144	0.746
p_2	0.236	0.735
p_3	0.168	0.749
p_4	0.143	0.744
p_5	0.184	0.765
p_6	0.149	0.759

^a Values in italics indicates high-value factor loadings.

The data warrant the inference that the 12 items measure two dimensions. These dimensions have been named social isolation and powerlessness to coincide with the content of the items created by Neal and Rettig. What would have happened if we had factor analyzed the six “Social isolation” items separately from the six “Powerlessness” items? Figure 3 shows that the scree plots would have indicated that there was a single factor in each of these six-item data sets. Table IV shows that all items designed to measure each of these factors separately have strong factor loadings.

Scaling

Once the number of factors and which measure defines which factors have been established, the researcher needs to create scales. One scale should be created to represent each dimension. If the measures defining each dimension have roughly equal variances,

Figure 3 Scree plots of two single-factor structures. (A) “Social isolation” measures. (B) “Powerlessness” measures.

Table IV Rotated Single-Factor Matrices

<i>Social isolation</i>		<i>Powerlessness</i>	
s_1	0.759	p_1	0.757
s_2	0.785	p_2	0.774
s_3	0.762	p_3	0.768
s_4	0.780	p_4	0.755
s_5	0.773	p_5	0.788
s_6	0.755	p_6	0.772

the simplest way to create a scale is to sum the measures defining each scale. In practice, researchers can tolerate moderate variation in the measure variances.

The standard deviations of the items in this analysis are roughly comparable, ranging from 1.38 to 1.46. Thus, scales were created by summing the items defining each dimension. Specifically:

$$\text{Social isolation scale} = s_1 + s_2 + s_3 + s_4 + s_5 + s_6$$

$$\text{Powerlessness scale} = p_1 + p_2 + p_3 + p_4 + p_5 + p_6$$

Given that we have scales for each dimension of “Alienation,” we can solve for the correlation as follows:

$$r = \frac{e}{\sqrt{a+2b}\sqrt{c+2d}} \quad (1)$$

where

- a is the number of items in scale 1.
- b is the sum of the off-diagonal correlations among the items in scale 1.
- c is the number of items in scale 2.
- d is the sum of the off-diagonal correlations among the items in scale 2.
- e is the sum of the intercorrelations between the items in scale 1 and the items in scale 2.

Let scale 1 be the six-item social isolation scale and scale 2 be the six-item powerlessness scale. From Table I, we get:

$$a = 6$$

$$b = 0.506 + 0.487 + 0.522 + 0.517 + \dots + 0.510 + 0.507 = 7.647$$

$$c = 6$$

$$d = 0.500 + 0.511 + 0.497 + 0.492 + \dots + 0.495 + 0.547 = 7.642$$

$$e = 0.200 + 0.257 + 0.228 + 0.212 + \dots + 0.277 + 0.222 = 9.144$$

Substituting these values into formula 1, we get:

$$r = \frac{e}{\sqrt{a+2b}\sqrt{c+2d}} = \frac{9.144}{\sqrt{6+2(7.647)}\sqrt{6+2(7.642)}} = \frac{9.144}{21.289} = 0.430$$

Equivalence Reliability

The equivalence reliability of each scale should be assessed. The standard of the research industry is to use Cronbach's alpha for this purpose. Cronbach's alpha is the average of all possible split-half reliabilities projected onto the number of measures in the scale. Standard statistical computer software packages can be used for this purpose. However, care must be taken in using these packages to ensure that all the measures and only the measures that define a specific scale are included in the calculations. As a rule of thumb for adequate measurement, Cronbach's alphas mirror instructional grades:

- A—0.9 or higher are considered excellent;
- B—0.8 to 0.9 are adequate;
- C—0.7 to 0.8 are marginal;
- D—0.6 to 0.7 are seriously suspect;
- F—less than 0.6 are totally unacceptable.

The formula for Cronbach's alpha using a correlation matrix is:

$$\alpha = \left(\frac{a}{a-1}\right)\left(1 - \frac{a}{a+2b}\right) \quad (2)$$

where a is the number of items, and b is the sum of the off-diagonal correlations.

Substituting the values for the social isolation scale into Eq. (2), we get:

$$\alpha = \left(\frac{a}{a-1}\right)\left(1 - \frac{a}{a+2b}\right) = \left(\frac{6}{6-1}\right)\left(1 - \frac{6}{6+2[7.647]}\right) = 0.862$$

Similarly, for the powerlessness scale, we get:

$$\alpha = \left(\frac{c}{c-1}\right)\left(1 - \frac{c}{c+2d}\right) = \left(\frac{6}{6-1}\right)\left(1 - \frac{6}{6+2[7.642]}\right) = 0.862$$

(See Table V.) By our standards, this reliability is adequate but not excellent.

Table V Sample-Size Analysis

N	Statistic				Difference from universe			
	<i>r</i>	α_s	α_p	ρ	<i>r</i>	α_s	α_p	ρ
∞ (universe)	0.429	0.857	0.857	0.500	—	—	—	—
1000	0.430	0.862	0.862	0.499	0.001	0.005	0.005	−0.001

Correction for Attenuation

The correlation between scales with imperfect reliability is less than what that correlation would have been if the scales were perfectly reliable. Alternatively stated, the correlation between the concepts “Social isolation” and “Powerlessness” is stronger than the correlation between the social isolation scale and the powerlessness scale. This difference, called attenuation, is caused by the less-than-perfect reliability of the scales as measures of their respective concepts. We can use the following formula to correct for attenuation:

$$\rho_{t1t2} = \frac{r_{12}}{\sqrt{(\alpha_1 \alpha_2)}} \quad (3)$$

where

ρ_{t1t2} is rho, the “true” correlation between concept 1 and concept 2, the correlation that has been corrected for attenuation due to unreliability;

r_{12} is the observed correlation between scale 1 and scale 2;

α_1 is the Cronbach’s alpha for scale 1;

α_2 is the Cronbach’s alpha for scale 2.

Correcting the observed correlation for attenuation using Eq. (3), we get:

$$\begin{aligned} \rho_{t1t2} &= \frac{r_{12}}{\sqrt{(\alpha_1 \alpha_2)}} = 0.430 / \sqrt{(0.862)(0.862)} \\ &= 0.430 / 0.862 = 0.499 \end{aligned}$$

From this analysis, the best estimate of the theoretical correlation between “Social isolation” and “Powerlessness” is 0.499.

An Assessment

Thus, the criteria for adequate, but not perfect, measurement have been achieved:

- Multiple measures. Each concept is represented by multiple items.
- Measure clarity. The items measuring each concept are clear.
- Convergent and discriminant validity of dimensions. There is a strong positive intercorrelation among measures designed to assess each dimension of the concept. Moreover, these intermeasure correlations are stronger than the correlations of these measures with measures designed to assess the other dimension.
- Scaling. Scales have been constructed.
- Equivalence reliability. Cronbach’s alphas for each scale are an adequate 0.862.
- Correction for attenuation. Unreliability has been removed from the observed correlation between “Social isolation” and “Powerlessness,” providing us with an estimate of the theoretical correlation of 0.499.

Earlier, I said that the data were created “... using transformations of random numbers. The universe that underlies this data set has known parameters.” Now I will reveal what those universe parameters were:

$$\begin{aligned} \alpha_{\text{social isolation}} &= \alpha_{\text{powerlessness}} = 0.857 \\ \rho_{t1t2} &= 0.500 \end{aligned}$$

Wow! The analysis did an incredibly good job of estimating what occurred in the universe! The reliabilities as estimated from the data analysis (0.862) are very close to the universe reliabilities from which the data were generated (0.857). Moreover, the correlation between the

concepts as estimated from the data analysis (0.499) was very close to the universe correlation between the concepts (0.500).

Using the presented statistical tools and having a weak theory and weak data, we have emerged with excellent estimates of crucial universe parameters. If the map is isomorphic with the terrain, use the map. These statistical tools are maps. We use them because there is a high degree of isomorphism between the tools and the universe from which the data were generated.

Measurement in the Real Research World

Interpretative clarity rarely is achieved as easily as in our example. Given a research setting in the real world, how should an analyst proceed? I now turn to a brief discussion of the application of these tools in the real research world.

Secrest and Zeller in a 2002 study wanted to develop a brief screening instrument that would reliably and validly measure the dimensions of adjustment by stroke patients following their suffering of a stroke. They created 45 items from the literature, their knowledge of poststroke patients, and their imaginations. They collected data on these 45 items from 55 poststroke patients. They conducted their analysis using the protocols presented in this entry. Specifically, in order to establish the number of factors and to identify which items defined which factors, they used (1) the 1.0 eigenvalue cut-off, (2) the scree test, (3) the minimum communality cut-off, and (4) the pattern of factor loadings criterion. The 1.0 eigenvalue cut-off and the scree test have already been described.

- The minimum communality cut-off. The analyst can also decide to exclude measures that are not useful in the interpretation. Specifically, analysts can make decisions about the inclusion or exclusion of measures based on communalities. Once measures with inadequate communalities have been eliminated from consideration, additional factor analyses are conducted to evaluate the clarity of the results. Communalities of 0.25, 0.275, and 0.30 are common minimum communalities used to eliminate measures in an analysis. Any such minimum communality is arbitrary, but an arbitrary minimum communality for the exclusion of weak measures is better than the default 0 minimum, which includes measures so weak as to be worthless. Secrest and Zeller used a 0.275 communality cut-off to eliminate some of the items.

- The pattern of factor loadings criterion. In general, a well-defined measure has a strong factor loading on its primary factor and relatively weak factor loadings on all other factors. The varimax rotation maximizes this pattern. However, some measures in Secrest and Zeller's study, despite varimax rotation, had strong factor loadings

(i.e., >0.5) on more than one factor and/or have roughly equal moderately strong factor loadings (i.e., <0.5 and >0.3) on more than one factor. These difficult-to-interpret patterns of factor loadings reduced the clarity of the definition of the factors. Consequently, for continued inclusion in subsequent principal components analyses, the measures in this rotated component matrix had to have a factor loading on their primary factor of ≥ 0.5 and a difference of ≥ 0.2 between the factor loading on their primary and their secondary factor.

Using a 0.275 communality cut-off and their pattern of factor loadings protocols, Secrest and Zeller reduced the number of items from 45 to 20. These 20 items factored into two clear, theoretically meaningful factors, with 10 items defining each factor. Scales created from these factors had Cronbach's alphas equaling 0.874 and 0.869. They started with vague theory and items of unknown characteristics; they ended with a reliable and valid brief screening instrument measuring the two important dimensions of adjustment by stroke patients following their suffering a stroke. They did this with only 55 observations.

Sample Size: How Many Observations Are Needed?

Did Secrest and Zeller have enough observations (e.g., $N=55$) to conduct these analyses? Tabachnick and Fidel (in a 1996 study) and Kerlinger (in a 1986 study) answered this question with a resounding "No!" In exploratory factor analytic designs, Tabachnick and Fidel recommended more than 100 respondents and, if possible, 300 subjects per item, and Kerlinger recommended "10 subjects per item."

In my experience, a researcher should have an adequate but not excessive number of respondents to evaluate the factor structure. At some point, additional respondents do not improve the evaluation of the measure and waste precious research resources. Somewhere between too few and too many responses is an optimum sample size. Sample-size deficiency indicates that the number of respondents is less than optimum; sample-size overkill indicates that the number of respondents exceeds the optimum. A body of literature has emerged making this argument. For example, in 1999, MacCallum *et al.* argued:

Our theoretical framework and results show clearly that common rules of thumb regarding sample size in factor analysis are not valid or useful. . . . Good recovery of population factors can be achieved with samples that would traditionally be considered too small for factor analytic studies, even when N is well below 100. . . . [I]t is better to have more indicators than fewer. . . .

Just as content validity may be harmed in introducing additional items that are not representative of the domain of interest, so recovery of population factors will be harmed by the addition of new indicators with low communalities.

Sapnas and Zeller, in 2002, argued that for exploratory factor analysis a sample size of 25 observations are inadequate but that 50 or more are adequate. In this tradition, we argue that attention to the optimization of the number of respondents will improve social measurement.

Summary

Measurement is the *sine qua non* of science. Without good measurement, all other scientific activities are futile. Factor analysis is a powerful statistical tool. It serves the goal of the measurement of social constructs best when it is allowed to flow through numerous options and iterations. It operates best on the assumption that the researcher has some insight, but not a strong theory, concerning the topic under investigation. It operates best when used as the statistical midwife assisting the substantive researcher-mother to give birth to the advancement of knowledge. The potential for statistical imagination in the use of exploratory factor analysis in service to the reduction of measurement error provides substantial value-added of substantively driven research efforts.

Measurement Theory

Joel Michell

University of Sydney, Sydney, Australia

Glossary

conjoint measurement The process of simultaneously acquiring evidence that three attributes are quantitative via observing how an increase or decrease on one attribute is affected by trade-offs between magnitudes of the other two.

derived measurement The process of acquiring evidence that an attribute is quantitative via the discovery of system-dependent constants in the relationship between two or more fundamentally measured attributes.

extensive attribute A quantitative attribute, the additive structure of which is directly observable to humans across some range of its magnitudes.

fundamental measurement The process of acquiring evidence that an attribute is quantitative by observing its additive structure directly across some range of its magnitudes employing an operation for concatenating objects.

intensive attribute A quantitative attribute, the additive structure of which is not directly observable to humans across any of its range.

magnitude A specific level of a quantitative attribute, for example, a specific length, such as the length of this page.

measurement The practice of attempting to identify the magnitude of a quantitative attribute by estimating the ratio between that magnitude and an appropriate unit.

quantitative attribute An attribute, the levels of which stand in additive relations to one another.

ratio A relationship between two magnitudes of a quantitative attribute whereby one of them is r times the other, where r is a positive real number.

From the time of Ancient Greece to the present, measurement has been recognized as a scientific method. Since the 17th century, its position has been central. From the 19th century it has been applied to psychological attributes, and from the 20th century, most

famously, to cognitive abilities, personality traits, and social attitudes. These applications proved controversial and the ensuing controversies stimulated a revival of interest in measurement theory. Scientists and philosophers had reflected upon measurement prior to this period. Indeed, the earliest work on measurement theory was Book V of Euclid's *Elements*, which has been decisive in guiding subsequent thinking. It was only more recently, however, that measurement theory became a topic treated in its own right, and over the past century, measurement theorists, building upon the contributions of the past, have attempted to advance our understanding of what measurement is and what conditions are necessary for its occurrence.

Central Issues of Measurement Theory

One of the distinguishing features of measurement, as a method of observation, is that it involves numerical terms. For example, a length is observed to be 2.5 meters, a weight, 5.37 grams, and so on. Of course, the involvement of numerical terms is not unique to measurement. Other observational procedures, such as counting, involve them as well. However, measurement is distinguished from counting by the fact that the latter deals with natural, integral, and rational numbers (in the consideration of frequencies, differences between frequencies, and relative frequencies), while measurement also involves real numbers (in the consideration of incommensurable magnitudes). The real numbers include the irrational numbers (such as $\sqrt{2}$, π , and e) and these are neither counted nor arrived at by taking differences or ratios between counts. Irrational numbers seem beyond observation

and, yet, they figure within the terms of an observational method, viz., measurement.

As will be shown, this perplexity was resolved early in the history of measurement theory and it focuses attention upon what, for psychologists, is an easily overlooked feature of measurement. If the width of a room measures 2.5 meters, the numerical term, 2.5, is, in fact, a *ratio*. What I mean by this is not the fact that $2.5 = 25/10$ (because the measure of a quantity does not equal a ratio of natural numbers in every case), but rather that 2.5 is the ratio between two non-numerical terms; that is, in this case, two lengths, viz., the room's width and the meter. As the concept of measurement has been traditionally understood, such ratios are the key to understanding measurement.

Traditionally, measurement is the practice of attempting to identify the magnitude of a quantitative attribute by estimating the ratio between that magnitude and an appropriate unit. Among other things, measurement theory attempts to answer the following questions. (1) What are ratios? (2) What is a quantitative attribute? (3) What is the relationship between ratios and numbers? (4) What kinds of evidence support the conclusion that an attribute is quantitative? This discussion gives some indication of ways in which these questions have been approached.

Ratios

Measure was narrowly defined in antiquity. The measure of something was the number of units it equalled, where *number* meant whole number (or *natural number*, as it is now called). Thus, the measure of a crowd in a stadium might be 1000 persons. Such a concept of measure works well for discrete quantities but not for continuous quantities. The length of the stadium might not equal some whole number of units. For example, it might be $100 \times \sqrt{2}$ meters. In Book V of his *Elements*, Euclid offered a generalization of the concept of measure capable of dealing with continuous quantities.

Like measures, Euclid's ratios are relations between specific levels of a quantitative attribute (call any such level x) and an appropriate unit (call it y). However, while ratios are not natural numbers, Euclid realized that they could be specified by reference to natural numbers. Consider the sequence of natural numbers: 1, 2, 3, . . . and so on. Let m and n be any two such numbers. Then for specific x and y , one and only one of the following three propositions will be true:

- (i) $mx > ny$
- (ii) $mx = ny$
- (iii) $mx < ny$.

If (i) is true, then $x/y > m/n$; if (ii) is true, then $x/y = m/n$; and if (iii) is true, then $x/y < m/n$. This means that any

ratio of natural numbers (m/n) is exceeded by, equals, or exceeds the ratio of x to y . Letting m and n each range across the set of all natural numbers, it follows that for any specific x and y , the following three exhaustive and disjoint sets of numerical ratios (i.e., ratios of natural numbers) are defined:

- 1. $R_{(x/y)}$ = the set of all numerical ratios less than x/y (i.e., $\{m/n \mid m/n < x/y\}$);
- 2. $S_{(x/y)}$ = the set of all numerical ratios equal to x/y (i.e., $\{m/n \mid m/n = x/y\}$); and
- 3. $T_{(x/y)}$ = the set of all numerical ratios exceeding x/y (i.e., $\{m/n \mid m/n > x/y\}$).

(Of course, (2) may be empty, in which case x is said to be *incommensurable with y*). Euclid implicitly defined the ratio between any x and y by declaring that for any levels of a quantitative attribute, w , x , y , and z ,

$$x/y = w/z \quad \text{if and only if} \quad R_{(x/y)} = R_{(w/z)}, \\ S_{(x/y)} = S_{(w/z)} \quad \text{and} \quad T_{(x/y)} = T_{(w/z)}.$$

This concept of ratio clarifies important issues in measurement theory. First, it specifies precisely what is estimated in measurement: for any x and y , measurement is the attempt to estimate the boundary or "cut" (as Dedekind was to call it later) between $R_{(x/y)}$ and $T_{(x/y)}$. Second, it implies that absolute precision in measurement is generally impossible: for any x and y , the best estimate of x/y will be an interval estimate. Third, the concept makes explicit how numbers get into measurement: both what is estimated and the estimation of it are numerical.

Quantitative Attributes

A measure is always the measure of a quantitative attribute. An attribute is always an attribute of something (i.e., of an object or a system). Furthermore, an attribute is always either a *property* of a thing (such as, for example, the density of a sample of gas) or a relation between things (such as the distance between two objects). Some attributes (for example, length) are quantitative and others (for example, the attribute of biological species) are not. Finding out which an attribute is, requires knowing the character of quantitative attributes.

Given the centrality of the concept of ratio to measurement theory, the concept of a quantitative attribute was defined in a way that ensured any two magnitudes of the same attribute stand in a ratio. Taking the natural numbers as a guide reveals how this can be done: any two natural numbers stand in a ratio because of the additive relation holding between them. For example, the ratios of $40/5$ and $80/10$ are the same because 40 is eight 5s added

together just as 80 is eight 10s. That is, ratios derive from additive structure, so characterizing the structure of quantitative attributes means characterizing additive structure. Measurable attributes (like length) are traditionally thought to differ from natural numbers in being continuous and in possessing no smallest magnitude and, so, characterizations of their structure typically accommodate these features as well.

At the beginning of the 20th century, Hölder characterized quantitative structure, and the following specification for length is based on, but is not identical to, his exposition. In the following characterization, the symbols, a , b , and c refer to specific lengths, that is, specific magnitudes of length independently of any measurements being made. Physical objects have length (i.e., spatial extension) measured or not, and the following conditions characterize all lengths, measured or not. The expression, $a + b = c$, does not refer to any human operations. Most lengths are either too big or too small for human operations and, more importantly, if for any lengths a , b , and c , $a + b = c$, then that is true regardless of human operations. The expression, $a + b = c$, denotes a relation: viz., that length c is entirely composed of discrete parts, a and b . The first four conditions state what it means for lengths to be additive. The remaining three ensure that no lengths are excluded (i.e., there is no greatest nor least length, nor gaps in the length series).

1. For every pair, a and b , one and only one of the following is true:

- (i) $a = b$;
- (ii) there exists a c , such that $a = b + c$;
- (iii) there exists a c , such that $b = a + c$.

2. For any a and b , $a + b > a$.

3. For any a and b , $a + b = b + a$.

4. For any a , b , and c , $a + (b + c) = (a + b) + c$.

5. For any a , there is a b , such that $b < a$.

6. For any a and b there is a c such that $c = a + b$.

7. For every nonempty class of lengths having an upper bound, there is a least upper bound.

Condition 7 may seem obscure. An upper bound of a class is anything not exceeded by any member of the class. A least upper bound is any upper bound not exceeding any other upper bound. The requirement that any class of lengths having an upper bound has a least upper bound ensures that there are no gaps in the sequence of lengths, as follows. Consider, for example, these two classes of lengths: any length, x , is a member of class A if and only if the square of x 's measure in meters is less than 2; and any length, y , is a member of B if and only if the square of y 's measure in meters exceeds 2. There is no greatest length in class A and, so, A does not contain any length that qualifies as its upper bound. However, any length belonging to class B will be an upper bound of A because no length in A exceeds any length in B . But

there is no least member of class B . Thus, if A and B exhausted the class of all lengths, class A would have an upper bound but possess no least upper bound and condition 7 would fail. For condition 7 to be true, there must be a length falling between these two classes (i.e., greater than every length in A and less than every length in B) and that must be the length, z , such that the square of z 's measure in meters is 2 (i.e., $z = \sqrt{2}$ meters). Condition 7 ensures that the gap between classes A and B is plugged and, similarly, all such gaps.

Condition 7 is not necessary for an attribute to be measurable. The minimum condition necessary for measurement, in the context of conditions 1–6 above, is the Archimedean condition, 8, below (first described by Euclid and Archimedes in ancient mathematics):

8. For every pair of magnitudes of length, a and b , there exists a natural number, n , such that $na \geq b$ (where $1a = a$ and $na = (n - 1)a + a$).

Given the above characterization of length as an unbounded, continuous quantitative attribute, it follows that the class of ratios of lengths is isomorphic to the class of positive real numbers. That is, for every pair of lengths, x and y , there is a positive real number, r , such that $x/y = r$; and given any positive real number, r , there is a pair of lengths, w and z , such that $w/z = r$. Part of what this means is that every length is measurable relative to any other length taken as the unit of measurement. That is, the above characterization guarantees the measurability of lengths.

Length is the quantitative attribute that we are most familiar with and it provides the model for understanding all other quantities. All other quantitative attributes measured in physics are likewise taken to be continuous, quantitative attributes and, so, are taken to satisfy an analogous set of conditions.

Numbers and Representations

For most of the 20th century, the majority view among measurement theorists was some version or other of the representational theory of measurement. According to this view, measurement involves a mapping between the magnitudes of an attribute and numbers in such a way that relations between the numbers represent relations between the magnitudes. Furthermore, according to the representational view, the existence of this mapping is thought to be the key feature upon which measurement depends.

According to the results outlined above, such an isomorphism exists. If there is an isomorphism between ratios of magnitudes of a quantitative attribute and the positive real numbers, then relative to each unit, there is a mapping between magnitudes of the attribute and the

real numbers. Furthermore, according to this mapping, not only are all magnitudes of the attribute represented numerically, additive relations between different magnitudes are represented as well.

Two philosophical considerations motivated the representational theory. The first was the view that numbers are abstract entities, rather than constituents of the empirical world. Especially important historically was the fact that the representational view is compatible with logical positivism, a philosophy that dominated the philosophy of science last century. One of the doctrines that the logical positivists were most famous for was that logic (including mathematics) consists only of conventional stipulations about the use of signs and, as a consequence, does not say anything about the world. If this is true, then the overwhelming effectiveness of mathematics in natural science seems, at first sight, quite unreasonable. The representational theory of measurement was used as a way of explaining this apparent unreasonableness away. According to this theory, mathematics is effective, not because it says anything about the world itself, but because it mirrors the form of real-world structures.

The second philosophical consideration motivating the representational view was the desire to understand measurement as far as possible in terms of directly observable operations upon objects. Most early representational measurement theorists, such as N. R. Campbell, Ernest Nagel, and S. S. Stevens, attempted to reformulate the conditions characterizing a quantitative attribute in terms of directly observable conditions applying to empirically identifiable objects. This program encountered considerable difficulty with conditions such as the continuity condition (see condition 7 above). As a result, this condition was abandoned; later, representational theorists replaced it with Archimedean conditions of one form or another, as in the first volume of *Foundations of Measurement*.

Hölder, in his epoch-making 1901 paper, had proved not only that a continuous quantitative attribute must satisfy the Archimedean condition but also that if the Archimedean condition is substituted for the continuity condition, then the resulting structure is isomorphic to a substructure of the positive real numbers. In the literature on the representational theory of measurement, this result is referred to as *Hölder's Theorem* and it was pivotal to the development of representational theory given by Luce, Suppes, Krantz, and Tversky in their *Foundations of Measurement*. However, Archimedean conditions are no more reducible to observational terms than is the continuity condition. Recent versions of the representational theory, such as Volume 3 of *Foundations of Measurement*, have used the continuity condition.

The representational view actually broadens the concept of measurement somewhat because the class of quantitative structures (as characterized by conditions

1–7 above) is a proper subset of the class of empirical structures possessing mappings into the real numbers. In particular, structures that involve no more than equivalence relations; no more than weak order relations; and no more than equivalence or order upon differences; may have mappings into subsystems of the real numbers, yielding what Stevens called *nominal*, *ordinal*, and *interval scales of measurement* in addition to so-called ratio scales (produced by conditions 1–7).

The mappings sustaining these different kinds of scales of measurement have different invariance properties and the validity or meaningfulness of numerical conclusions inferred from measurements are relative to these invariance properties. This fact was first recognized by Stevens and has subsequently been most thoroughly investigated by Louis Narens as part of the theory of meaningfulness.

The alternative to the representational view is the realist theory of measurement. It is based upon the thesis that the real numbers are ratios of magnitudes of continuous quantitative attributes, a view defended early in the 20th century by Frege in *Grundgesetze der Arithmetik* and by Whitehead in the third volume of his and Russell's *Principia Mathematica*, and then, again, toward the end of that century, by a number of realist philosophers, such as David Armstrong. The logic of this view is that if real-world structures (such as quantitative attributes) are isomorphic to mathematical structures, then the world already contains mathematical structure. This is because two systems are isomorphic only if they share the same structure. According to this view, the numbers are not abstract entities but are relations (i.e., ratios) between real things, and mathematics is the study of real (and imagined) structures considered abstractly.

Evidence for Quantity

If there is no logical necessity that attributes studied in any science be quantitative, then the issue of the structure of attributes is always an empirical one. Hence, a part of measurement theory is the investigation of the general forms that evidence for quantitative structure may take.

Historically, the quantitative attributes recognized first were time, weight, and the geometric attributes of length, area, volume, and plane angle. In each case, with such attributes, its additive structure is directly evident to human observers under certain fairly simple conditions. For example, the additive structure of lengths can be seen in extending lengths by concatenating rigid, straight rods. That is, the structure of the attribute (length) is directly reflected in the structure of objects (rods) possessing the attribute. Such attributes are called *extensive*. Ancient philosophers sometimes wrote of other attributes as quantitative (such as temperature, density, and even psychological attributes like pleasure and pain) and, indeed,

the Pythagoreans and Platonists thought that the fundamental structure of reality must be quantitative. However, ancient philosophers do not appear to have distinguished the structure of attributes from the structure of the objects manifesting those attributes.

This distinction was explicitly drawn during the Medieval period when a number of philosophers began to analyze intensive quantities. In their work, the hypothesized additive structure of intensive attributes, such as temperature, was modeled upon the structure of extensive attributes, but, at the same time, this modeling went along with the recognition that the additive structure of such attributes was not reflected in the concatenation of relevant objects. Thus, Duns Scotus noted that when volumes of liquid at different temperatures are combined, the volumes add together while the temperatures do not. Nonetheless, he thought that increase or decrease in temperature involved the addition or subtraction of homogeneous parts. However, these were not parts of the objects involved (the liquids), they were parts of temperature. Thinking in these terms involves making a distinction between the structure of the object and the structure of the attribute.

This distinction having been made, the scientists of the 17th century, such as Galileo and Newton, were able to contemplate hitherto unmeasured, intensive attributes, to explore indirect ways of measuring them, and to propose theories relating intensive attributes to extensive attributes. Despite the flowering of quantitative physics, it was not until late in the 19th century that the issue of evidence for quantitative structure was first raised by Helmholtz.

The first to treat this issue in a systematic fashion was the British measurement theorist, N. R. Campbell. Campbell distinguished two forms of evidence: fundamental measurement and derived measurement. Fundamental measurement occurs in the case of extensive attributes, where an operation of concatenation applied to relevant objects directly reflects the additive structure of the attribute. Derived measurement, according to Campbell, depends upon the existence of a system-dependent constant, which occurs as a function of fundamentally measurable attributes. For example, density is a function of mass and volume, the latter two attributes being fundamentally measurable (mass via weight and volume via length) and density is a different constant for each system (or kind of substance). Campbell did not bring out the logic of derived measurement, but it seems sound. If for each different kind of stuff it is observed that the ratio of mass to volume is a constant (for example, one constant for gold, another for silver), then it is sound scientific reasoning to argue that each different kind of stuff possesses a property (its density) that the observed constant reflects. Because the effect (the constant) is quantitative, it is scientifically sound to argue that its cause (the stuff's density) must likewise be quantitative.

The soundness of this reasoning was later confirmed by the development of the theory of conjoint measurement. While the general idea behind conjoint measurement had been variously anticipated, by Hölder among others, it was the series of papers beginning with Luce and Tukey in 1964 and culminating in the three volumes of the *Foundations of Measurement* that thoroughly developed the theory. This work emerged under the auspices of the representational theory of measurement and it was motivated by a desire to identify more or less directly observable, psychological structures that could be given the sort of numerical representation characteristic of measurement (i.e., what Stevens had earlier called interval or ratio scale representations).

The idea behind conjoint measurement is somewhat counterintuitive. Suppose that in some system, under certain conditions, two independent, quantitative attributes combine to produce a third, dependent attribute. Furthermore, suppose that this third attribute is not extensive and that all we are able to observe with respect to it are increases or decreases in order. The theory shows that providing we can identify distinct levels of the two independent attributes (measuring them is not required) and providing the combination of these two attributes to produce the third involves no interactions, then the additive structure of all three attributes is displayed in various order relations between levels of the third attribute. The counterintuitive feature of the theory is that purely ordinal relations are diagnostic of additive structure. This feature means that the theory is potentially useful in sciences like psychology where it is widely believed that attributes are quantitative and, yet, we seem to be restricted to observations of order, not quantity.

For example, it is widely believed by psychometricians that quantitative features of both the task and the person determine a person's performance on an intellectual task. Despite a preference for such quantitative hypotheses, all that can be observed is that one person does better on a task than another. It is in contexts such as this that the theory of conjoint measurement can be applied. If the probability of solving the task correctly is thought to be a noninteractive function of the person's ability and the task's difficulty (increasing with the first and decreasing with the second), then ordinal relations between the probabilities (as estimated via relative frequencies) can be used to assess the evidence for the quantitative hypothesis as opposed to nonquantitative alternatives. A large class of so-called item response models in psychometrics are of this general form.

Item response models are just one class of probabilistic measurement models. During the 20th century, under the influence of positivist philosophy of science, the view became accepted in psychology that scientific theories, including theories of measurement, should account for all relevant observational data. Since data are always fallible

and in psychology always include the effects of uncontrolled and, often, unknown factors, characterizations of quantitative structure, such as conditions 1–7 above, do not provide an adequate guide to the form that relevant observational data may take. The preferred alternative is to use probabilistic measurement models, which it is hoped capture the form data takes when evidence for underlying quantitative structures is obscured by the effects of extraneous factors. In recent years, simpler probabilistic models, such as the kind of item response models mentioned above, have been supplemented by more complex models, as represented by, e.g., Regenwetter and Marley.

It should be stressed that fundamental, derived, and conjoint measurement are not the only forms of evidence pertinent to the hypothesis that attributes are quantitative. Other forms are discussed in the three volumes of the *Foundations of Measurement* and, no doubt, others are yet to be recognized. This remains an open-ended area of measurement theory. However, the existence of this area makes it clear that it may well be equally fruitful in psychology and social science to develop nonquantitative theories and methods. Measurement theory undermines Pythagorean pretensions regarding the place of measurement in science. To strive for measurement is appropriate where attributes are quantitative, and inappropriate where they are not; we have no way of knowing which they are other than by considering the evidence.

Meta-Analysis

Jamie DeCoster

Free University Amsterdam, Amsterdam, The Netherlands

Glossary

effect A research finding examined in a meta-analysis.

effect size A statistical estimate of the strength of an effect.

heterogeneity The variability observed in a sample of effect sizes.

meta-analytic summary Using meta-analysis to answer a specific research question.

moderator A study characteristic that influences the effect size.

primary research Directly conducted research, in contrast to meta-analytic research, which uses the results of other studies.

quantitative literature review Using meta-analysis to review the behavior of an effect as it is reported in the research literature.

Meta-analysis, also known as quantitative synthesis, refers to a set of statistical procedures that combine the results of multiple studies in a single analysis. Traditionally, when reviewers wanted to make inferences about the results of a set of studies, they had to use vaguely defined, qualitative methods. To introduce the same scientific rigor to the review process that is typically required in primary research, meta-analysis provides statistically valid rules for aggregating and discriminating the results found within a literature. Its procedures allow researchers to estimate the average strength of a finding observed across several studies, to determine whether the finding is consistent or varies from study to study, and to test whether variability in the finding relates to study characteristics.

Introduction

Since its introduction less than 30 years ago, meta-analysis has strongly influenced research in many areas of the social sciences. It has become the accepted standard

for summarizing research in many fields because of its emphasis on objective observation and its openness to critical evaluation. Meta-analysis has also provided the means to investigate new types of research questions, such as how the strength of an effect relates to the setting in which it was investigated. Its growing popularity has even impacted those who perform only primary research, in that the guidelines for writing journal articles in many fields have changed to facilitate meta-analysis. It has therefore become important for all social scientists, even those who never actually plan to perform a meta-analysis, to have at least a basic understanding of these procedures. Knowing the ideas behind meta-analysis is necessary to be able to read and critically evaluate meta-analyses performed by others. It is also important to understand how to best present research so that it can easily be included by meta-analysts in their reviews. Without this knowledge, researchers risk isolation from important sources of information and opportunities for their own ideas to guide future theorizing.

By far the most common use of meta-analysis has been in quantitative literature reviews. These are review articles in which the authors select an effect that has been investigated in primary research under a large number of different circumstances. They then use meta-analysis to describe the overall strength of the effect, as well as the circumstances that affect its magnitude and direction. As knowledge of meta-analytic techniques has become widespread, it is more common to see researchers using simple meta-analytic summaries within primary research papers. In this case, meta-analysis is used to provide support for a specific theoretical statement, usually about the overall strength or consistency of a relationship within the studies being conducted. As might be expected, calculating a meta-analytic summary is typically a much simpler procedure than is performing a quantitative literature review.

Steps to Conduct a Meta-Analysis

There are five basic steps to a meta-analysis. First, the research question that will be addressed by the analysis is defined. Second, a population of primary research studies that can be examined to answer the question is located. Third, an effect size from each study is calculated and its characteristics are coded into “moderating variables.” Fourth, the database of effect sizes is statistically analyzed. Finally, the results of the analyses are presented and interpreted. The following discussions provide a basic overview of how to conduct a meta-analysis, focusing on these five steps. Also considered are any differences between the procedures for quantitative literature reviews and those for meta-analytic summaries.

Define the Meta-Analytic Research Question

Forming a clear meta-analytic research question requires three decisions: choosing an effect to examine, defining the population in which to examine the effect, and deciding what information the analysis should provide about the behavior of the effect.

An effect can almost always be thought of as a relationship between a pair of variables, so defining the effect primarily involves choosing appropriate definitions for these variables. An effect size metric must also be chosen to be the basis for the analysis. This is a specific statistic that will be calculated from the results of each study, so that they may all be compared and aggregated. Effect size statistics must provide a measure of the strength of the relationship that is independent of the sample size. Note that the most commonly used statistics (such as t , F , and p -values) are dependent on sample size, and so cannot be used as effect sizes. Descriptions and formulas for a number of acceptable metrics can be found in the literature. Although the choice of effect size metric will not influence the validity or significance of any of the meta-analytic tests, a given effect size is easier to calculate from certain research designs than from others. The effect size metrics most commonly used in the social sciences are the standardized mean difference (g) and the correlation coefficient (r). The standardized mean difference is typically used when most of the studies in the analysis reported t or F statistics, whereas the correlation coefficient is typically used when most of the studies reported correlation or regression coefficients.

To define the population, a decision must be made about the characteristic studies must have to be included in the analysis. The more broadly defined the population of the analysis, the more generally applicable the conclusions drawn from the results. However, it is always important to make sure that the definition is restrictive

enough so that the included studies all concern the same phenomenon. For meta-analytic summaries, it is appropriate to limit the consideration to the studies performed in a specific paper or set of papers. Although this limits drawing conclusions to a very small population, this is usually appropriate for the purpose of the analysis. Quantitative literature reviews, on the other hand, require broader definitions that encompass the different ways researchers have examined the effect of interest.

Meta-analysis can provide three levels of information about effect size, with each level requiring somewhat more work to obtain than the last. First, it can provide an estimate of the average strength of an effect. Second, it can reveal whether a set of effect sizes comes from a single distribution, or if there appear to be systematic differences. Third, it can test whether the values of the effect sizes are related to other measured study characteristics. When performing a quantitative literature review, it is generally desirable to examine all of these questions. For a meta-analytic summary, it is best to choose the lowest level of analysis that provides the required information.

Locate the Relevant Literature

Once the boundaries of the meta-analysis have been defined, the next step is to find every study within that area that provides an estimate of the effect of interest. Typically, it is known ahead of time exactly what studies will be included when performing a meta-analytic summary. This is not the case for a quantitative review, which usually requires a comprehensive literature search to locate the relevant articles. Most literature searches start with queries into one or more computerized indices. Indices are available for most topic areas, allowing specific word and phrase searches within the titles and abstracts of relevant articles. One important index that should be examined in almost any search is *Dissertation Abstracts*. This index contains a reference to every doctoral dissertation completed in North America, making it an excellent way to locate research that might not have made it into a published form.

Although computerized indices are fairly easy to use, some care must be taken when selecting search terms to obtain complete results. Theoretical constructs that define the area of analysis should be identified first. Next, to identify each of the constructs, lists should be created of the different words or phrases that have been used in the literatures being searched. If the index being used assigns key words to its entries, the lists must contain any of these words that are related to the relevant constructs. “Wildcards” should be used if they are supported by the index. These are special characters (such as “*” or “?”) that can be added to the search terms to indicate that matching entries might have additional characters before or after

the specified characters. This helps prevent missing studies that happen to use the desired term in a grammatical form different from what was specified. Once the lists are completed, query the index for studies that include at least one term related to each construct. The best way to do this is to first perform a conjunctive (“or”) search for each construct, finding studies related to each list, then perform a disjunctive (“and”) search on these results, to locate studies that are related to all of the constructs.

Although computerized indices can quickly provide a large list of studies related to a topic, a thorough literature search does not rely on these alone. After obtaining an initial set of studies, an “ancestor search” can be performed by checking the references within the studies to locate older articles that might be related to the topic. If there is a seminal study that was of theoretical or methodological importance to the field, a “descendent search” can be performed by using the *Social Science Citation Index* or the *Science Citation Index* to locate later articles that list the seminal study in their references. Sometimes external organizations will establish “research registers” for a field that has significant societal impact; these are actively maintained lists of ongoing research projects. If there are any existing reviews of a topic (whether meta-analytic or not), the articles that they have already identified as relevant should be examined. Consider also a hand-search of any journals that commonly publish research on the phenomenon of interest. Finally, contacting active researchers in the field can yield information about recent projects that are not indexed in the usual sources. One good way to locate active researchers is through the use of Internet listservers and newsgroups.

Once these different methods have been used to perform a comprehensive search, their results must be combined into a master list lacking redundancies. A review of each study on this list will determine whether it actually fits the area of the meta-analysis. Sometimes it can be determined whether a study fits simply by reading the abstract; at other times the study’s method and results will need to be closely examined. This process can be made easier by developing a set of specific criteria that studies must satisfy to be included in the analysis. When deciding to exclude a study from the analysis, the criterion on which this decision is based should be noted. It is not uncommon for researchers to change aspects of the research question as their knowledge of the topic becomes more complete through the course of performing the review. Should the decision be made to redefine the population (and consequently the inclusion criteria), knowing why each study was excluded limits the number of studies that need to be reexamined.

For a quantitative review to draw accurate conclusions, its literature search must be as complete as possible.

Researchers wishing to limit the number of studies in their meta-analyses should do so by using more restrictive inclusion criteria instead of by performing a less comprehensive search. This will not be possible when the goal is to review a very general area. In this case, the researcher should first use a comprehensive search to locate the population of studies that examined the effect of interest. From this population, the desired number of studies to analyze can then be randomly sampled.

Calculate Effect Sizes and Code Moderating Variables

Once a set of relevant studies has been obtained, they are used to create a quantitative data set for analysis. The first thing to do is calculate an effect size from each study. Every effect size metric has a computational formula that will allow it to be calculated from raw data. However, meta-analysts will often not have access to this information, especially when conducting a quantitative review. Analysts calculating an effect size from someone else’s research must typically rely on whatever statistics are provided in the report (although the authors may sometimes be directly contacted for additional information). It is almost always possible to calculate an estimate of the effect size from a study, although it may be very imprecise for statistically impoverished reports. If there is wide variability in the precision of their estimates, meta-analysts will sometimes perform separate analyses, including only the most precise estimates, to see if the inclusion of imprecise estimates affects the results.

To determine if a study characteristic influences an effect, it must first be coded as a moderating variable. Meta-analysts commonly consider moderators related to the study setting, sample, design, and methodology. For each moderating variable, it is best to write down an explicit coding scheme detailing how to translate study characteristics into values of the moderator. If a moderator has continuous scale, its unit of measurement must be specified. For categorical moderators, the meta-analyst must specify the different groups that compose the variable, as well as what study characteristics are associated with each group. It is typically a good idea to pilot the coding scheme to make sure that it is well understood by the coders, and that it provides reliable data.

The final meta-analytic data set should contain variables for the effect size, the sample size, and any moderators to be examined. For a meta-analysis to produce valid results, it is essential that these values are accurate, so it is standard practice to have at least two different people calculate and code each effect size. This provides an additional check on the accuracy of the calculations and allows the reliability of the moderator codes to be reported.

Analyze the Meta-Analytic Database

As with data from primary research, the basic distribution of effect sizes should always be examined before performing the analyses. It is especially important to determine if the distribution has multiple modes or outliers. A multimodal distribution can indicate that the studies are coming from several different subpopulations. In this case, an attempt should be made to identify a moderating variable that can explain the different groups of effects. If the modes are highly distinct, an analyst might consider analyzing each of the groups separately. Studies that produce outlying effect sizes should be examined closely to make sure that they truly fit within the boundaries of the analysis. Consider excluding any outlier that is particularly extreme, whether its characteristics fit the defined population or not, because it will have an inappropriately large influence on the results.

Descriptive analyses can be used to obtain information about the central tendency and consistency of the effect sizes. The most commonly used estimate of central tendency is the weighted mean effect size, whereby each effect size is weighted by the inverse of its variance. Some other measures that have been used are the mean effect size weighted by the sample size, the unweighted mean effect size, and the median effect size. Estimates of the mean effect size combined with its standard error are often used to calculate confidence intervals around the population effect size.

After estimating the central tendency, how well this single value describes the full pattern of effect sizes can be determined by computing its heterogeneity (Q). The heterogeneity statistic reveals the likelihood of observing the amount of variability present in the sample if the effect sizes were all drawn from a single distribution. A significant amount of heterogeneity indicates that the effect sizes are likely not all from the same distribution. In this case, it is often desirable to explain the variability through moderator analyses. Moderator analyses are used to determine if the effect sizes are related to study characteristics. Before testing any moderators, it is necessary to decide whether to treat the individual studies as fixed or random factors in the statistical models (although this question may be circumvented by using Bayesian analysis). This decision has implications for the formulas used to analyze the data, as well as for the inferences drawn from the results. Fixed-effects models are limited to drawing conclusions about the specific studies and conditions present in the analyses, whereas random-effects models allow drawing conclusions about a wider theoretical population of which the studies in the analysis are considered to be a random sample. Fixed models are used much more often than random models are, although this is more due to the fact that fixed-effects analyses are simpler and typically more powerful, rather than because they are more appropriate.

The method for testing of a moderator depends on how the moderator was coded. A categorical moderator can be examined by using heterogeneity statistics to estimate the between-group and within-group variability. The amount of between-group heterogeneity (Qb) can be used to test whether the moderator can account for a significant amount of the variability in the effect sizes, whereas the amount of within-group heterogeneity (Qw) can be used to test whether there is a significant amount of variability that cannot be accounted for by the moderator. It is possible for both of these statistics to be significant. This would indicate that the moderator has a significant influence on the effect size but that there are other important sources of variability.

A continuous moderator can be tested by using a weighted regression analysis to estimate the strength of the linear relationship between the moderator and the effect size. The weight for a given study is usually set to be the inverse of the effect size variance, although sometimes meta-analysts choose to use the sample size instead. Parameter estimates for the weighted regression can be obtained using any standard statistical program, although the standard errors of the estimates will need to be corrected for the unique characteristics of meta-analytic data.

It is also possible to build more complicated models to predict effect sizes. Models containing multiple predictors, including interaction and higher order polynomial models can be tested using a weighted multiple regression analysis. Categorical predictors may be included in these models, but they must be coded by a set of indicator variables. The parameters from a multiple predictor model can be estimated using a standard statistical program, but it is necessary to correct the standard errors of the estimates as when testing a continuous moderator. When interpreting the results of a multiple predictor model, keep in mind that the precision of the estimates will be reduced if there are correlations among the predictor variables. The significance of the parameters in the model will be determined by the independent ability of each moderator to account for variability in the effect sizes. Moderators that are significant when tested individually may be nonsignificant in the multiple predictor model if they are collinear with other included variables.

Report and Interpret the Results

There are many similarities between performing a meta-analysis and conducting a standard research study. In both cases, the process is to pose a research question, collect data, analyze the results, and draw conclusions about the findings. The presentation of a meta-analysis consequently parallels the presentation of primary research. A quantitative literature review is written using the standard sections found in empirical articles. In the introduction, the theoretical

motivation for conducting the analysis is explained and the definitions of the effect and the populations are provided. The method section explains how the studies were selected for inclusion, how the effect sizes were calculated, and how any moderating variables were coded. The reliability of the moderator codes should also be explained in the method section. In the results section, the analyses are described and the findings are reported. Finally, the discussion section should present the theoretical implications of the results and suggest new directions for research.

It is necessary to provide this same information when reporting a meta-analytic summary, though in a compressed format. If the summary includes moderator analyses, these should be presented as a separate study in the paper, using the guidelines for quantitative reviews. If the primary interest is presenting descriptive analyses, however, it will likely be simple to incorporate it directly into the introduction or discussion. In this case, the purpose and method of the meta-analysis should be described in one paragraph, with the results and discussion in a second.

The presentation of the meta-analysis should provide enough detail so that another researcher could replicate the analyses. Even though there are standard guidelines for how to perform a meta-analysis, there are also a number of subjective decisions that are up to the discretion of the analyst. For example, the moderator analyses can be strongly influenced by the author's personal beliefs. Different researchers might have different opinions on what moderators should be examined and how they should be defined. It is therefore important to clearly describe and justify each subjective decision so that others can evaluate the choices.

Although performing a meta-analysis necessarily requires a large number of calculations, it is important not to allow statistics to dominate the presentation. Always embed the analyses in a theoretical framework that provides them with meaning. The report should describe how the theoretical perspectives in the field influenced the way the constructs were defined and how the analysis was conducted. Also be sure to describe any implications that the findings may have for existing models of the phenomenon of interest. Specific effort should go into helping the audience understand the meaning of any effect sizes reported. The easiest way to do this is to compare them to the strengths of other effects that would already be known by the intended audience. Alternatively, other tools to help readers understand the practical significance of your effect sizes can be found in texts on power analysis.

Critically Evaluating a Meta-Analysis

The main purpose of meta-analysis is to provide a scientifically rigorous method for summarizing research,

but not every meta-analysis meets this goal. Just as there is variability in the quality of primary research, there can be great differences in the quality of meta-analyses. When judging a meta-analysis, consider whether it uses appropriate methods of data collection and analysis (its internal validity), properly represents the phenomenon of interest (its external validity), and makes a distinct theoretical contribution (its scientific importance).

The first thing to consider when evaluating the internal validity of a meta-analysis is the validity of the studies in its sample. A meta-analysis can be no more valid than the primary research that it aggregates. If there are methodological problems with the studies in the sample, then the validity of the meta-analysis must also be called into question. The meta-analysis should include enough studies so that it has sufficient power to test the proposed research question. If a meta-analysis examines moderating variables, then consider both the reliability of the moderator codes and how the studies are distributed across the levels of each moderator. Unreliable codes and unbalanced designs will reduce the power of moderator analyses. Finally, consider whether confounding variables could provide alternative explanations for any significant moderators.

Possibly the most important factor affecting the external validity of a meta-analysis is the extent that the sample represents the theoretical population of interest. To draw firm conclusions about a given population, the sample should be an unbiased representation of every study that has been conducted within that population. Meta-analytic summaries are typically applied to very specific populations, making external validity less of an issue. The search procedures used for quantitative literature reviews, however, should be closely examined to determine whether any relevant subpopulations were overlooked. For example, some quantitative reviews exclude unpublished or foreign studies because they are difficult to obtain. If there is reason to suspect that these studies might be different than the ones included in the analysis, then valid conclusions cannot be drawn about the literature as a whole. Finally, consider the way the author defined the target population. If it includes highly divergent studies, then the analysis may in fact be combining different phenomena. In this case, the results may have little meaning.

If it is determined that the conclusions drawn from a meta-analysis are valid, the next step is to evaluate the importance of its findings. Sometimes a meta-analysis will simply provide an estimate of an effect size within a set of studies. Although this may be valuable, it does not make as great a scientific contribution as an analysis that additionally uses moderator analyses to determine the conditions under which the effect is stronger, weaker, or even reversed. Finally, consider the extent to which the results of the analysis have theoretical implications. The more implications a meta-analysis has for existing

theories, the more likely it will influence future research. The best meta-analyses provide statistically valid information about an internally consistent population, which is then used to provide novel insights about the phenomenon under study.

Missing Data, Problems and Solutions

Andrew Pickles

University of Manchester, Manchester, UK

Glossary

censoring and coarsening Forms of imperfect observation of a variable whereby only boundaries can be placed on its value.

imputation Assigning a value to a missing value.

item nonresponse Missing the value of one variable.

missing at random (MAR) Noninformative or ignorable missing data, in reference to a missing-data mechanism in which the probability of missingness depends only on other observed data.

missing completely at random (MCAR) A missing-data mechanism in which the probability of missingness is a constant.

missing not at random (MNAR) Informative or nonignorable (NIGN), in reference to a missing-data mechanism in which the probability of missingness depends on the value of variables that may also be missing.

selection model An equation that relates predictors to the probability of observing some variable.

unit nonresponse The complete absence of data for a sample unit.

Unless proper account is taken, statistical analyses of samples that include units with incomplete data records can result in biased estimates of means, rates, and measures of association (such as regression coefficients) that are intended to represent corresponding values in an entire population. These biases can be avoided, reduced, or at least explored using a number of statistical strategies.

Introduction and Problem

The term missing data is used to refer to circumstances in which the available data on a set of individuals are less than what is intended, planned, or desired for a particular

analysis. The last two words are important here, in that how missing data are described and the methods that may be employed to deal with them depend as much on what is desirable to investigate as on the extent and arrangement of missing values in the data file. The problem of missing data is ubiquitous. Though the emphasis here is on the occurrence of this problem within large social surveys, the problem is also common in small experimental studies. A sample unit (a survey participant, for example) may not be located or may refuse to respond (unit nonresponse). Variables may be completely missing (item nonresponse) through an error in questionnaire design or may be missing from just some respondents. In multistage sampling, nonresponse may occur at any of the levels; for example, student record data may be missing if a student's school refuses participation or because a particular student individually refuses. In addition, circumstances arise whereby although some sort of response is obtained, the information content of that response is incomplete. For example, it may be known that an event has occurred in some interval of time, without knowing when (so-called interval censoring), or that the event has not yet occurred (so-called right censoring). Sometimes, the precision of the recorded data is distrusted—for example, when study participants exhibit “digit preference,” or rounding their responses to, say, units of 10 years. This loss of information is sometimes referred to as data coarsening.

The problem of missing data does not appear to be solvable by improvements in fieldwork practice alone. As research questions become more complex, so do the necessary data required to answer them, and this increases the burden on respondent participation. Although a good case can be made that one of the responsibilities of social membership is participation in research that is likely to contribute to the common good, participation only by informed consent invariably remains a legitimate individual right, and in attempting to coerce

participation and response completion, it is easy to cross the boundary of what is ethically acceptable. It is inevitable that some data will be missing. Rather than making blind attempts to minimize missing data at any cost, there is a good case to be made that this problem should be actively managed. Data that are deliberately allowed to be missing, or data “missing-by-design,” present a comparatively tractable analytical problem compared to data that are missing by happenstance. For example, when it is considered that a set of questionnaires or experimental test packs A, B, C, and D are jointly too burdensome, it is appropriate to consider designs in which subjects are randomly assigned to receive packs ABC, ABD, or ACB (pack A being considered a core pack).

Collecting data from a large initial sample with a low participation rate is almost always cheaper than collecting the same amount of data from a small sample, all of whom have been persuaded to participate. Persuading the less willing to provide data is a costly and time-consuming process. Although the presence of missing data implies having less data than intended, it is often not the consequent reduction in available sample size for an analysis that is the critical problem. Instead, the reason to strive for a high participation rate is because those less willing to participate are different from those more willing, and they can be different in all sorts of ways that are unknown. How to be sure that conclusions reached from an analysis of the willing will apply to the less willing? And how is it possible to be sure that results from analyzing the willing subjects describe the whole population and are not biased? There are ways in which the likely bias can be reduced. Sometimes, however, a lack of knowledge about the causes of “missingness” leads to an inability to justify any one adjustment. In such circumstances, a sensitivity analysis exploring the impact of different assumptions should be undertaken.

Types of Missing Data

The choice of how to deal with missing data should be based on how the missing data are generated. A very useful classification is as follows: Let Y_{obs} represent the observed part of the data, Y_{mis} represent the missing values, and R be an indicator for whether an observation is missing. The three principal types of mechanisms using these variables for the missingness are shown in the Fig. 1. If everyone in the population has an equal probability of being missing, then the missing data mechanism is said to be missing completely at random (MCAR). In this case, listwise deletion, or the dropping of any individual with an incomplete set of measures, does not lead to bias and can be understood as being equivalent to simply having a lower sampling fraction and thus smaller sample size. Thus, even when it is applicable (and it often is not),

Figure 1 The three principal types of mechanisms using the variables Y_{obs} , Y_{mis} , and R for the missingness.

listwise deletion reduces efficiency, sometimes resulting in a dramatic reduction in sample size. When the probability of missing is not constant, but differences in probability depend solely on data that are not missing, then the missing data are said to be missing at random (MAR). A particularly simple case of MAR is covariate dependent missing data, where the probability of missingness depends only on the value of an explanatory covariate or independent variable. This would include, for example, sex differences in response rate, provided that we knew the sex of all sample members, responders and non-responders alike. MAR also includes circumstances in which the rate of attrition from a particular wave of a longitudinal study varies with the value of the response from the previous (and thus observed) wave. When the probability of missingness varies in ways that depend on things other than covariates or observed values of the response variable, then the missingness mechanism is described as being informative, or nonignorable. Nonignorable missing data are substantially more difficult to deal with. In the case in which missing data are either MAR or nonignorable, simple listwise deletion is not only inefficient but will lead to bias.

Popular Methods Based on Misconceptions

A number of frequently used methods have some misconceived intuitive logic, lack a proper formal basis, and can be quite misleading.

Single Imputation: Mean Values

In this approach, missing values are replaced by the mean values of those with nonmissing values. This is based on the thinking that no bias is introduced because the estimated mean remains unchanged, or that any bias that might be introduced is conservative because no association between variables is being introduced. Both views are incorrect. Unless the missingness mechanism is MCAR, then it is not justifiable to assume that the mean for the unobserved individuals should be the same as that of the observed individuals. As for measures of association,

because variances are systematically reduced by repeated insertion of mean values, correlations can be inflated. In the multiple regression context, covariation of the y variable with the x variable with mean-imputed missing values will be downwardly biased, and as a result the y variable variation that ought to be accounted for by that x variable can be wrongly attributed to other independent variables with which it is correlated. Thus incorrect treatment of missingness in one x variable can result in biased estimates of the effects of all x variables, including those with complete data.

An extension of this approach replaces missing values by mean values but also constructs a dummy variable indicating the records in which this has been done. It is thought that inclusion of this dummy variable as an additional independent variable in subsequent analysis will account for differences between observed and imputed records. In general, it does not.

Single Imputation: Regression Estimates

In this approach, missing values are replaced by the predicted values from a regression (or similar) model. This is based on the thinking that this will mirror the pattern of association in the observed data. This ignores the possibility that the pattern of association among those with missing data may be different from that among the complete-data cases, risking bias. Moreover, because the predicted values include no error variance, the imputed values have less variance than do the observed values. Adding back in simulated “residuals” to reflect the missing error variance can improve this correspondence, but subsequent analyses in which imputed values are treated indistinguishably from properly observed values does not fully take account of the fact that these imputed values are not known, but remain guessed values. Standard errors, confidence intervals, and p -values reported from such analyses thus tend to be smaller than they should be.

In spite of their limitations, almost all studies make some use of these simple methods; for example, they are used to fill in occasional missing items in a many-item rating scale. A range of well-founded methods are now considered.

Covariate Adjustment

Suppose we have covariate dependent missing data, then the probability of missing a response Y or a predictor variable X is dependent on the value of some third variable Z . Except under special circumstances, this missingness will bias naive estimates of the regression relationship between X and Y . However, in the estimation of the regression relationship between X

and Y given Z (i.e., where both X and Z are used as predictors of Y), then this missingness, while reducing the precision of the estimate, does not bias the parameters being estimated.

A common response to this is to argue that in the usual circumstance in which it is suspected that missingness might be dependent on a whole set of covariates, all of these variables should then be included as additional covariates in the regression. This can be a perfectly satisfactory approach. However, it can also be entirely misleading. The issue hangs on whether the regression of X on Y , given these additional covariates Z_1, Z_2, \dots, Z_n , is the parameter of interest. For example, suppose the relationship between educational attainment and parental interest is being investigated. It might be decided that the child's truancy rate is a good predictor of nonresponse on the attainment test. Does the regression coefficient for the effect of parental interest on attainment, given the level of truancy, estimate the effect of interest? The answer is “probably not,” not if one of the ways in which parental interest exerts its effect is through ensuring school attendance. This regression may seriously underestimate the effect of parental interest. Thus covariate adjustment is only sometimes an effective strategy.

Weighting for Missing Data

An alternative to using variables associated with non-response as additional covariates is to use them as covariates in the calculation of nonresponse weights. The clearest example of this approach is for the analysis of studies involving a two-phase design. Under this design, individuals are stratified based on some preliminary measures (e.g., questionnaire report of child abuse), and individuals are selected for a detailed interview with a sampling fraction that depends on their stratum (e.g., oversampling those who experienced child abuse). Clearly those not interviewed will be missing the interview data, but this missingness is by design—the factors related to the probability of missingness are known. The sample is then analyzed using pseudo-likelihood or other design-based or marginal modeling methods that allow for the inclusion of probability weights. The probability weights are the inverse of the stratum-specific sampling fractions. It is important to distinguish probability weights from frequency weights. In probability weighting, whereas one sampled individual is being used to represent, say, 10 other individuals in the population, the variability in their response is nonetheless expected to be that of a single individual. In frequency weighting, the analysis is assuming that there were in fact 10 sampled individuals with identical responses. For many analyses, the estimates of regression-type coefficients are the same whether software is used that properly treats these

weights as probability weights or improperly treats them as frequency weights (a risk within programs such as Statistical Packages for the Social Sciences, or SPSS). However, to obtain properly corrected standard errors, confidence intervals, and p -values, software that properly recognizes the weights as probability weights is required. These typically use so-called linearization or sandwich estimators of the parameter covariance matrix, but jackknife or bootstrap methods could be implemented instead.

In order to apply this approach to data missing by happenstance rather than by design, then an exploratory stage is usually required in which predictors of complete response are sought. Once identified, either strata are formed and stratum-specific response rates are calculated (e.g., for men and women), or a binary regression model is estimated (e.g., logit) and the predicted probabilities from this are used as estimated individual specific sampling fractions. In either case, the weight is the inverse of the estimated sampling fraction. Caution is required both to avoid an excessively wide range of estimated sampling fractions and to include the full range of covariates and their possible interactions. As used by survey statisticians, this sometimes seems as much an art as an exact science. The quality of the weighting can be checked by comparing the simple population distribution for variables measured on the whole sample (e.g., all those measured in the phase-1 screen) with that obtained for the same variables but based on the weighted complete-data cases only (the phase-2 sample).

The great advantage of these weighting methods over covariate adjustment is that they leave the user free to estimate all of the effects of interest to them, without the need to involve other covariates that they do not want in their model. Indeed, users of secondary survey data remain largely unaware that weights provided as part of the survey typically adjust for both sampling design and missing data due to unit nonresponse. Their principal disadvantage is that they can be inefficient, though more efficient variations are anticipated. In addition, for those wedded to model-based inference (for example, those wishing to estimate multilevel and latent variable models), available statistical theory to justify their estimation in the presence of probability weights is largely limited to circumstances in which the weights vary only at the highest level. Even in the marginal modeling framework, unless an independence-working model is being assumed, current standard generalized estimating equation (GEE) implementations require the same restriction.

Multiple Imputation

The principal unsolved problem in the use of single imputation of values obtained by some form of regression

model was that the proper variability and uncertainty of the imputed records were not being communicated to the analysis stage. This can be achieved by the use of multiple imputation. This is a comparatively new and still developing field. It cannot yet be considered entirely general. However, because the difficult imputation part can be separated from the analysis part, specialist staff and software can be used to generate imputed data sets that can then be analyzed by relatively unsophisticated users equipped with standard software. This can be very effective, particularly for small to moderate levels of missingness, where the missing data mechanism is structured, and for data sets that are to be placed in the public domain.

Successful multiple imputation requires three conditions. First, all associations among variables must be properly reflected in the imputations. Unless the missingness follows a clear pattern of comparatively small sequential blocks of variables, such that primarily it is possible to predict imputed values using variables that are either known or have already been imputed, then the imputation task becomes complex. Second, each imputed value should reflect both the full range of associations with other variables and the full extent of the uncertainty. Technically, the model used for imputation should be at least as “large” (i.e., nonparsimonious) as the model to be used in the analysis. This may require numerous predictors to be included, but Bayesian considerations would suggest that the individual coefficients should be shrunk, requiring the use of specialist methods. Third, to communicate the uncertainty in our imputed values to the analysis stage, several data sets are generated. In each data set, the observed values remain the same but the imputed values may change as a result of using different imputations. These different imputations should reflect the full uncertainty in the estimated models used for imputation (e.g., should draw parameter values from their sampling distribution and not just reuse the same point estimates of the coefficients from the imputation regression) and not just add different “residuals.” The foregoing has been described in the context of model-based imputation, but similar considerations apply when the imputation is based on some kind of matching and substitution of incomplete data records by complete data records—so-called hot-deck methods.

Instead of a single file with incomplete records, the end result is several files, but each one is complete. With modest amounts of missing data, five imputation replicates are often sufficient. As the proportion and uncertainty of the missing data increase, so more replicates are required. Each of the, say, m files is then analyzed using naive methods that know nothing about any missing data, and the desired statistic, be that a mean, a difference, or a model coefficient, is estimated as if the data were truly all complete. The results from each of the m analyses are

then combined. The average of the estimated statistics is reported as the point estimate. The standard error of this estimate is calculated from combining the simple variance of the point estimates over the m replicates (the between-imputation variance B) and the average of the estimated variances (standard errors squared) as reported by the m naive analyses (the within-variance W), these being combined using what has become known as Rubin's formula, i.e., overall standard error = $\sqrt{\{(1-1/m)B + W\}}$.

Maximum-Likelihood Model-Based Inference

Likelihood inference is based directly on the joint probability density function for the variables and the observation scheme, which, using the notation at the beginning of this article, can be written as $f(y^{(\text{obs})}, y^{(\text{mis})}, r)$. This can be factored into one part describing the probability of the data and the second part describing the probability of observation or missingness:

$$f(y^{(\text{obs})}, y^{(\text{mis})}, r) = f(y^{(\text{obs})}, y^{(\text{mis})}) f(r | y^{(\text{obs})}, y^{(\text{mis})})$$

However, we observe only $f(y^{(\text{obs})}, r)$, and this can be expressed in terms of the above factorization by

$$f(y^{(\text{obs})}, r) = \int f(y^{(\text{obs})}, y^{(\text{mis})}) f(r | y^{(\text{obs})}, y^{(\text{mis})}) dy^{(\text{mis})}.$$

Integration over $y^{(\text{mis})}$ is a mathematical way of saying that to obtain the probability density for the observed parts of the data, it is necessary to average over all possible values of the missing data, weighting each by their probability of occurrence. That is essentially what is done when multiple imputation is used—this is integration by sampling. However, if the missing data mechanism is random or completely at random, then $f(r | y^{(\text{obs})}, y^{(\text{mis})})$ does not depend on $y^{(\text{mis})}$ and, as a consequence,

$$\begin{aligned} f(y^{(\text{obs})}, r) &= f(r | y^{(\text{obs})}) \int f(y^{(\text{obs})}, y^{(\text{mis})}) dy^{(\text{mis})} \\ &= f(r | y^{(\text{obs})}) f(y^{(\text{obs})}). \end{aligned}$$

This gives a log-likelihood of the following form:

$$L = \log f(r | y^{(\text{obs})}) + \log f(y^{(\text{obs})}).$$

The first term contains no information about $f(y^{(\text{obs})})$ and so it can be “ignored” within a likelihood-based analysis. Even though the missingness may be highly selective, as long as the probability of missing depends only on observed data and that, conditional on the observed data, it does not depend on the missing data, then it can be ignored if the data are analyzed using full maximum likelihood.

This is an extremely powerful conclusion. It provides one of the major justifications for preferring repeated-measures analyses undertaken in multilevel or random-effects programs, rather than the “same” analysis undertaken in multivariate analysis of variance (MANOVA) procedures, because the standard algorithms for the latter require complete data and use listwise deletion, whereas the former will include those with both complete and incomplete sets of repeated measures. Latent variable and latent class models often lend themselves rather easily to treatments of missing indicator variables under an assumption of missing at random, and the same theory justifies the fitting of a common model across groups identified by different patterns of missing data, an approach that has been used in the structural-equation modeling field. Sometimes, particular implementations of maximum-likelihood methods do not lend themselves easily to MAR analyses. However, these implementations can sometimes be imbedded as the maximization step in an E–M algorithm that iterates between estimating quantities for records with missing data (the E, or expectation, step) and then maximizing the complete data likelihood (the M step).

That maximum likelihood will automatically cater for missing data that are missing at random does not remove from the analyst the onus of checking that the missing data assumptions are met. It also increases the importance of correctly specifying the model. This last arises because results generally become more sensitive to model misspecification biases as the proportion of missing data increases.

Nonignorable Nonresponse and Selection Models

A more direct approach to the problem of missing data is to estimate a joint model of (1) the probability of observing the response of interest and (2) the value of the response if observed. Often associated with the work of James J. Heckman, in economics, model (1) is usually estimated as a probit model and is referred to as the selection equation. With predictors of observing the response, z , with regression-type coefficients γ , the response of subject i is observed only if $z_i\gamma + u_{1i} > 0$ [where $u_1 \sim N(0, 1)$]. If it is observed, then the substantive regression equation for the value of the response (model 2) is a normal linear regression (if the response is continuous or a probit regression if the response is binary/ordinal), i.e., $y_i = x_i\beta + u_{2i}$ [where $u_2 \sim N(0, \sigma)$]. The two error terms, u_1 and u_2 , are expected to be correlated if the substantive equation does not contain all the predictors of nonresponse that also predict the substantive response. If the errors are correlated, then the model allows for

the possibility that nonresponse depends on unobserved values of the response variable—that is, the missingness is nonignorable. An essentially similar model occurs in the statistical literature in which the probit model is replaced by a logit model.

It is usual to include in the selection equation all the variables in the substantive regression equation, but it is helpful to add other instrumental variables that the analyst assumes are not related to the value of the response. A classic example occurs in the analysis of wages. Wages are missing for those without a job; the number of dependent children can be expected to influence willingness to work, but not the wages offered for a given job. In the absence of such instrumental variables, results from these models can sometimes be unstable, with erratic variation in coefficients and significance for rather modest changes in the set of included covariates and distributional assumptions. It should be noted that covariates are required for all observations, those with and those without the response variable of interest. Elaborations of this basic model for more complex multilevel settings are possible.

Implications for Study Design

A recurring theme has been the value of having at least some data on all subjects, particularly if those data are expected to be related to nonresponse. These data can be used as additional covariates, for calculating weighting strata, for imputing missing values, or as covariates in a selection equation. Thus an important part of any study design is to identify what variables can be collected, even about nonparticipants. Sometimes relevant data can be extracted from other sources; examples include using postal codes to link to small area census data, or calculating weights to match known population proportions. Use of such data allows methods that assume a MAR mechanism (rather than the naive MCAR mechanism)

in order to take account of an increasing range of selection effects, and allows postponing or avoiding having to use the much less robust methods that allow for nonignorable missingness. In a similar way, patterns of missingness that have been deliberately created (missing data by design), and are thus amenable to missing-at-random methods, may be preferred over rather more complete data when the reasons for missingness are not known.

Misspecification in Linear Spatial Regression Models

Raymond J. G. M. Florax

Free University Amsterdam, Amsterdam, The Netherlands

Peter Nijkamp

Free University Amsterdam, Amsterdam, The Netherlands

Glossary

misspecification test A statistical test, typically used in a regression context, directed toward identifying violations of the standard assumptions of ordinary least squares (heteroscedasticity, autocorrelation, nonnormality) or the functional form and the inclusion of explanatory variables.

spatial autocorrelation Similarity in attribute values, measured either at a nominal, ordinal, or interval scale, over geographical locations; also referred to as spatial dependence or spatial clustering.

spatial effects Catchall term referring to spatial autocorrelation or dependence (spatial clustering), and spatial heterogeneity.

spatial heterogeneity The occurrence of dissimilar attribute values over spatial locations.

spatial process models Spatial regression models, typically with a linear additive specification, in which the relationship among areal units is specified exogenously using a weight matrix that mimics the spatial structure and the spatial interaction pattern.

specification strategy A prespecified series of misspecification tests for regression models aimed at detecting the correct underlying data-generating process.

Spatial effects are endemic in models based on spatially referenced data. An increased awareness of the relevance of spatial interactions, spatial externalities, and networking effects among researchers has led to studies in the area of spatial econometrics. Spatial econometrics focuses on the specification and estimation of regression models explicitly incorporating such spatial effects. The

multidimensionality of spatial effects calls for misspecification tests and estimators that are notably different from techniques designed for analysis of time series. With that in mind, the focus here centers on spatial effects, referring to both heterogeneity and interdependence of phenomena occurring in two-dimensional space. Spatial autocorrelation or dependence can be detected by means of cross-correlation statistics in univariate and multivariate data settings. There are tools for exploratory spatial data analysis and misspecification tests for spatial effects in linear regression models. Discussions of specification strategies and an overview of available software for spatial regression analysis, including their main functionalities, aim to give practitioners of spatial data analysis a head start.

Spatial Effects

The awareness of and incorporation of space are fundamental to geography. In 1979, the geographer Waldo Tobler formulated the first law of geography, stating “everything is related to everything else, but near things are more related than distant things.” The relevance of spatial effects extends, however, beyond geography, and the effects are ubiquitous in many of the social sciences. Relevant to this, a seminal 1991 book by Andrew D. Cliff and J. Keith Ord about models and applications of spatial processes begins with an example from epidemiology. The spatial mortality pattern from cholera in London, from 1848 to 1849, is analyzed and the high incidence of the disease in the London metropolis is attributed to the high organic content of the Chelsea, Southwark, and

Vauxhall waters. Similarly, spatial analysis techniques are used to analyze diffusion—adoption patterns of innovations by farmers, to prescribe spatially differentiated fertilizer doses in precision agriculture, to explain network effects among individuals, and to investigate human—environment interactions in processes of environmental degradation.

Economists have traditionally been more reluctant to consider space as a relevant factor. In 1890, the economist Alfred Marshall acknowledged the role of space, maintaining that the working of the market depends “chiefly on variations in the area of space, and the period of time over which the market in question extends; the influence of time being more fundamental than that of space.” It took until the 1950s, however, before Walter Isard opposed this, calling it “Anglo-Saxon bias” that repudiates the factor of space, compresses everything within the economy to a point so that all spatial resistance disappears, and thus confines economic theory to “a wonderland of no spatial dimensions.” An ongoing debate has since revolved around whether space is merely a geographical facilitator or medium for movement, or whether space has an intrinsic explanatory function. The monopolistic competition model of Avinash Dixit and Joseph Stiglitz in 1977 inspired a revolution in economic theory that increased awareness of imperfect competition and increasing returns to scale; this model subsequently became apparent in the “new economic geography” of Paul Krugman, Masahisa Fujita, and others. Nowadays, spatial dimensions are taken into account in the study of economic growth, high-tech innovations, urban economics, public sector productivity, fiscal policy interdependence, and international trade.

Spatial Dependence and Spatial Heterogeneity

Spatial effects include spatial heterogeneity and spatial dependence. Spatial heterogeneity refers to structural relations that vary over space, either in a discrete or categorical fashion (for instance, urban vs. rural, or according to an urban hierarchy), or in a continuous manner (such as on a trend surface). Spatial dependence points to systematic spatial variation that results in observable clusters or a systematic spatial pattern. These descriptions already show that in an observational sense, spatial dependence and spatial heterogeneity are not always easily discernible. The clustering of high values in, for instance, urban areas and urban fringes can be interpreted as spatial clustering of high values pertaining to urban areas and to low values to rural areas, but it may as well be viewed as spatial heterogeneity, distinguishing metropolitan areas from their hinterland.

The typical feature of spatial dependence or spatial autocorrelation is that it is two-dimensional and

multidirectional. An observation of an attribute at one location can be correlated with the value of the same attribute at a different location, and vice versa, and the causation pattern can occur in different directions. Figure 1 shows two identical (7×10) regular grid systems with distinct spatial distributions of the same values. The absolute location of the nonzero values is the same in both grids, but graph A shows a clustering of relatively low values on the left-hand side and high values to the right. Graph B shows a much more random spatial allocation of values. In terms of spatial effects, note that the distribution in graph A exhibits spatial dependence and spatial heterogeneity, whereas graph B does not.

The occurrence of spatial heterogeneity does not necessarily have severe implications for the information that can be obtained from a spatial data series. Spatial autocorrelation does, however, because an observation is partly predictable from neighboring observations. A series of spatially dependent observations therefore contains less information. This is similar to the situation in time series analysis, wherein a forecast with respect to the future can be partly inferred from what happened in the past. The two-dimensional and multidirectional nature of spatial autocorrelation ensures that the spatial case is more complex.

Spatial Econometrics

The history of analysis of the spatial autocorrelation problem goes back to the work of statisticians such as Thomas Moran, Geary, and Whittle in the late 1940s and early 1950s. The development of the subsequent literature was rather slow until Cliff and Ord published their seminal book about spatial autocorrelation in 1973. Their book focused on the statistical analysis of spatial data series, although not exclusively from a spatial statistical point of view because there was also some attention given to modeling. The modeling context is, however, much more pronounced in the efforts of the Dutch—Belgian economist Jean Paelinck, who coined the term spatial econometrics in the early 1970s. Paelinck and Leo Klaassen jointly wrote the first monograph on spatial econometrics in 1979, stressing the need to model spatial relations explicitly, epitomizing the asymmetry in spatial interrelations and the role of spatial interdependence. The edges of the field in those days were pushed ahead mainly by Dutch regional economists (Bartels, Brandsma, Hordijk, Ketellapper, and Nijkamp). Later, the center of activity shifted to the United States, where both economists and geographers concentrated on introducing new statistical tests (particularly, tests developed in a maximum-likelihood framework) and the specification and estimation of spatial regression models. During the late 1990s, these methodological developments were gradually being picked up in applied spatial research, which, among

other things, was facilitated by the availability of spatial econometric software.

The most comprehensive book of modern developments is Luc Anselin's 1988 book on methods and models of spatial econometrics, in which he defined spatial econometrics as "the collection of techniques that deal with the peculiarities caused by space in the statistical analysis of regional science models." The modeling perspective, already pondered by Paelinck, distinguished spatial econometrics from the broader field of spatial statistics, as discussed by Cressie in 1993. Theoretical overviews of spatial econometrics are available in further work by Anselin and Bera in 1998, and Anselin in 2001. The tutorial of the SpaceStat software, available online at <http://www.terraseer.com>, provides a good introduction to spatial econometrics, and LeSage's contribution to the Web book of regional science, available at <http://www.rri.wvu.edu>, gives a more applied, hands-on introduction.

Testing for Spatial Autocorrelation

Definition Spatial Autocorrelation

Two publications of the work of Cliff and Ord, in 1973 and 1981, induced extensive focus on the statistical properties of spatial data, in particular for spatial autocorrelation or dependence. Statistical tests for spatial association or dependence are always based on the null hypothesis of spatial independence. The general notion of independence is easily formalized as follows:

$$\Pr(X_1 < x_1, \dots, X_n < x_n) = \prod_{i=1}^n \Pr(X_i < x_i), \quad (1)$$

with $i = 1, \dots, n$. Consequently,

$$\Pr(X_i = a, X_j = b) = \Pr(X_i = a) \cdot \Pr(X_j = b). \quad (2)$$

For independent events, such as tossing an unbiased coin, the probability of the occurrence of a series of events (e.g., throwing 6 and subsequently 5) is determined multiplicatively by the chance of the occurrence of the individual events (i.e., throwing 6 and throwing 5). In the case of dependence, this implication does not hold, because the chance of the second event occurring is somehow conditional on the occurrence of the first event.

The notion of spatial dependence is similar, but is more specific in the sense that the dependence among events is mediated through space—for instance, either through distance or adjacency. Spatial dependence is referred to using informal terms, such as spatial clustering of similar values, an organized pattern, or systematic spatial variation. Strictly speaking, spatial dependence

Figure 1 Hypothetical example of a spatial distribution of values on a 7×10 regular grid. Adapted from Upton and Fingleton (1985).

is a characteristic of the joint probability density function. As such, it is verifiable only under simplifying conditions, such as normality. Spatial autocorrelation is simply a moment of that joint distribution. In this article, however, the common practice is followed, and spatial autocorrelation and spatial dependence are used interchangeably.

Spatial autocorrelation is easily observed in Fig. 1. In graph B, observations are randomly distributed over space, so the chances of observing a specific value are independently distributed. Graph A exhibits spatial autocorrelation or dependence, because the probability of a specific value occurring in a specific location depends on the value of neighboring locations.

Statistical Tests for Spatial Autocorrelation

The common element in all tests for spatial autocorrelation is that they relate a vector of attribute values for various locations to all other locations through a matrix representing the structure of the spatial system. Most test statistics are special cases of the general cross-product statistic, developed in various publications by Hubert, Golledge, Costanza, and Gale, given by Eq. (3):

$$\Gamma = \sum_{i=1}^n \sum_{j=1}^n w_{ij} y_{ij}, \quad (3)$$

where i and j ($= 1, \dots, n$) index the locations, w_{ij} are the elements of a matrix of the spatial topology of the system, and y_{ij} are the association between the values of a specific attribute at different locations. It is common to assume no self-association, which is easily incorporated in Eq. (3) by defining $w_{ij} = 0, \forall i = j$. Various metrics can

be used to measure the association among attribute values y_{ij} , such as the product of the attribute values $x_i \times x_j$, or the squared difference $(x_i - x_j)^2$. In 1991, Getis provided an overview of spatial association statistics as well as a comparison to spatial interaction models.

Most statistics for spatial association are special cases of the cross-product statistic. For spatial data measured on a nominal level (for example, unity for a location displaying the attribute, and zero otherwise, usually colored black and white on a map), so-called join-count statistics have been developed. They compute the observed frequency of black-black, black-white, and white-white joins. The comparison to what is expected by chance constitutes a formal test for spatial autocorrelation. The test statistics are asymptotically normally distributed and the moments, under free and nonfree sampling, were derived in the 1981 book by Cliff and Ord, in addition to extensions to categorical data organized in multicolored maps.

The most well-known spatial association statistics for ordinal and interval data are Geary's c and Moran's I . These statistics are also special cases of the general cross-product statistic. The univariate Moran's I statistic is given by Eq. (4):

$$I = \left(\frac{n}{S_0} \right) \times \left[\frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{\sum_{i=1}^n (x_i - \bar{x})^2} \right], \quad (4)$$

or, in matrix terms,

$$I = \left(\frac{n}{S_0} \right) \times \left(\frac{\mathbf{x}' \mathbf{W} \mathbf{x}}{\mathbf{x}' \mathbf{x}} \right), \quad (5)$$

where \mathbf{x} is an $n \times 1$ vector of observations x_i measured in deviations from the mean \bar{x} , \mathbf{W} is a spatial weight matrix with $n \times n$ elements w_{ij} representing the topology of the spatial system, and S_0 is the sum of the elements of the spatial weights matrix. The weight matrix is typically exogenously determined and can be defined using contiguity, distance, or more complicated specifications such as those based on the distance and length of the common border, referred to as generalized weights by Cliff and Ord in 1981. As for all autocorrelation statistics, a slight rearrangement of the statistic shows that it is based on a comparison of the covariance of spatially connected observations to the variance of all observations.

Statistical inference can be based on the standardized or z -value of Moran's I , as follows:

$$z_I = [I - E(I)] / SD(I), \quad (6)$$

but an assumption about the distribution of the x -variates is needed. The moments of I can be derived analytically assuming that the x follow a normal distribution, or that the distribution is unknown but can be approximated in a nonparametric framework using

a randomization approach. Alternatively, an estimated distribution function for Moran's I can be empirically generated following a permutation approach, as shown by Cliff and Ord in 1981.

It is common practice to interpret Moran's I as a correlation coefficient, although its value is, strictly speaking, not restricted to the $[-1, +1]$ interval. High positive values signal the occurrence of similar attribute values over space (either high or low values), and hence spatial clustering. Negative values indicate the joint occurrence of high and low attribute values in nearby locations. A value close to the expected value of Moran's I in the absence of spatial correlation [which equals $-1/(n-1)$ and therefore approaches zero with increasing sample size] can be taken as evidence of a random allocation of attribute values over space.

Concurrent results for Geary's c are developed in a similar fashion. The statistic is based on a different metric, and reads as follows:

$$I = \frac{(n-1)}{2S_0} \times \left[\frac{\sum_{i=1}^n \sum_{j=1}^n w_{ij} (x_i - x_j)^2}{\sum_{i=1}^n (x_i - \bar{x})^2} \right]. \quad (7)$$

In 1981, Cliff and Ord also derived the moments for the Geary statistic, under different assumptions. The expected value of Geary's c is one under the null hypothesis of no spatial autocorrelation, and the variance again depends on the stochastic assumption (normality or randomization). Statistical inference is straightforwardly based on the corresponding z -value of the statistic. Somewhat counterintuitive, a negative (positive) of Geary's c indicates positive (negative) spatial autocorrelation. Cliff and Ord also showed in 1981 that the asymptotic relative efficiency is generally better for the I test than for the c test, and it is therefore common practice to use Moran's I , especially in a regression context. The variance of Geary's c is also more sensitive to the distribution of the sample data. Note that these statistics and their asymptotic properties refer to "raw data." The moments for regression residuals are different, because residuals are, by definition, correlated, even if the errors are independent. The asymptotic properties of Moran's I for regression residuals have been derived, whereas those for Geary's c are not available.

These autocorrelation statistics have a series of important limitations, which were discussed by Cliff and Ord in 1981 and Anselin in 1988. First, for most straightforward specifications of the weight matrix, the statistics are topologically invariant, implying that changes in the size, shape, and relative strength of the link between the areal units are ignored. Second, in the connection or weights matrix, all links are given equal weight, which does not necessarily conform to an appropriate perception of space. Third, the level of aggregation of the data and the spatial arrangement is usually rather arbitrary, but it affects the magnitude of the statistics. In order to

ensure identification, the weights have to be defined *a priori* and exogenously, but this implies that for irregularly spaced areal units, no analytical mathematical properties can be derived. Finally, the specification of the weight matrix is such that out-of-sample observations are simply ignored. This leads to edge effects that are difficult to assess and it is cumbersome, or even impossible, to alleviate their disturbing influence.

Local Statistics and the Moran Scatterplot

During the 1990s, two extensions of the overall or “global” statistics were developed to further intensify exploratory spatial data analysis (ESDA). One extension centers on disaggregating the overall pattern of spatial variation in local spatial patterns, and is caught in so-called local indicators of spatial association (LISA). Exploratory spatial data analysis focuses on identifying spatial dependence patterns and spatial heterogeneity, either as an independent analytical tool or as a tool that assists in identifying the specification of a spatial regression model. The cross-product statistics discussed previously are global in nature in that they identify clusters of spatial association pertaining to the entire spatial system. However, spatial processes may be instable or nonstationary. Within an overall autocorrelated sample, local pockets of randomness may exist. Alternatively, localized clusters of spatial association, sometimes referred to as “hot spots,” may be observed within an overall randomly distributed sample of observations. The generalized cross-product statistic and variants such as Moran’s I can be disaggregated into local statistics. For instance, for a standardized weights matrix (i.e., the row sums are scaled to unity), the local Moran is given by Eq. (8):

$$I_i = \frac{(x_i - \bar{x}) \sum_{j=1}^n w_{ij} (x_j - \bar{x})}{\sum_{j=1}^n (x_i - \bar{x})^2 / n}, \quad (8)$$

which clearly shows that the local Moran is proportional to the global Moran’s I up to a scaling constant. Anselin showed in 1995 that the null distribution of the local statistic should not be approximated by the normal, but instead a randomization approach should be used for statistical inference.

The proportionality property distinguishes LISA from other local statistics, notably the Getis–Ord statistics. The latter compare the sum of values in neighboring locations within a certain distance band to the sum over all locations, and have a slightly different interpretation, explained by Getis and Ord in 1992. The LISA and the Getis–Ord statistics can both be used to identify local pockets of nonstationarity or to evaluate the contribution of individual areal units to the global spatial pattern. A second extension of the overall or global statistics builds on the general property

that any statistic taking the form of a ratio of a quadratic form and its sum of squares can be interpreted as a bivariate regression coefficient. Equations (4) and (5) show that Moran’s I has this form, and it is thus equivalent to the estimated parameter of a regression of $\mathbf{W}\mathbf{x}$ on \mathbf{x} . Rearranging gives Eq. (9):

$$I = \mathbf{x}'(\mathbf{x}'\mathbf{x})^{-1}\mathbf{W}\mathbf{x}, \quad (9)$$

omitting the standardization term that is unity for a standardized weights matrix. This result can be visualized in a Moran scatterplot that can be used visually to identify spatial clusters, outliers, and local nonstationarity, shown by Anselin in 1995 and 1996. As reported by Cressie in 1991, the Moran scatterplot is similar to the spatial lag scatterplot in exploratory geostatistics. When the x -variable is standardized (i.e., expressed in deviations from the sample mean, and divided by the standard deviation), and the value of x is plotted on the horizontal axis and the weighted average value of x for the neighbors is plotted on the vertical axis, the scatterplot contains four quadrants (see Fig. 2A, for an example). The quadrants in Fig. 2A possibly show clusters of high–high values (top right quadrant), low–low values (bottom left), and low–high and high–low values (top left and bottom right, respectively). Because the x -variable is standardized, exploratory tools such as the 2σ rule for outliers can be easily assessed. The Moran scatterplot can be used for any variable, including residuals of a regression model.

Illustration of Exploratory Spatial Data Analysis

A simple illustration from neoclassical economic growth theory can also be used for modeling purposes. In their pathbreaking 1992 article in the *Quarterly Journal of Economics*, Gregory Mankiw, David Romer, and David Weil analyzed the economic growth performance of 98 non-oil-producing countries, over the period 1960–1985. The data and the model presented here are identical to those used by the Mankiw–Romer–Weil (MRW) model, except that the spatial effects are considered explicitly here (the data can be found online at <http://post.economics.harvard.edu>). The weight matrix has been compiled using the centroid function in ArcView (see www.esri.com), and using SpaceStat to compute spherical distances between the countries’ centroids.

Figure 3 shows the spatial distribution of per capita income in 1960 and 1985 and the growth rate of per capita gross domestic product (GDP) over the period 1960–1985. The maps reveal that the spatial distribution of the level of GDP per capita is highly persistent over time. The richest countries are clustered in North America and Western Europe, and Australia and New Zealand have high GDP per capita levels as well, both in 1960 and

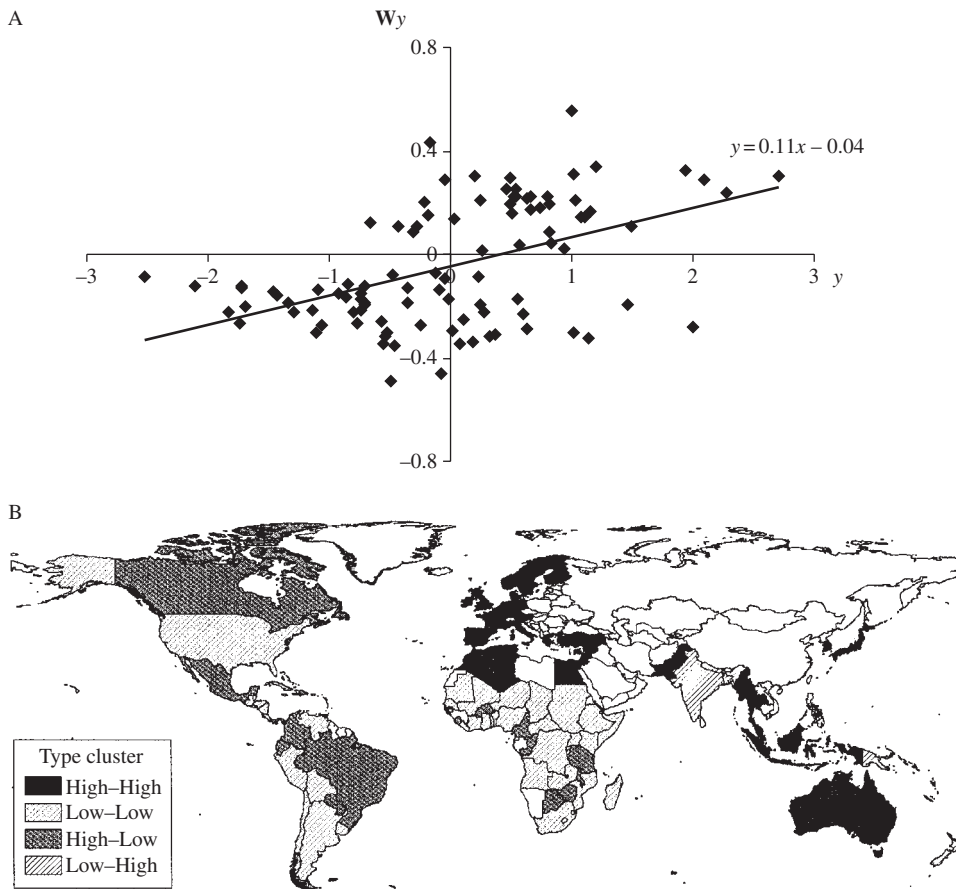

Figure 2 Moran scatterplot of economic growth (A), and a map differentiating between four types of countries based on the quadrants in the Moran scatterplot (B).

in 1985. The spatial distribution of economic growth seems much more random, although, in accordance with the theoretical prediction of neoclassical growth theory, the fast-growing economies are typically located outside the previously mentioned area with high-GDP-level countries. This pattern of spatial clustering is corroborated in the statistical analysis. The elements of the spatial weights matrix are specified as $1/d_{ij}$, where d_{ij} is the spherical distance of the geographical midpoints of the various countries, putting zeros on the diagonal. The weights matrix is standardized, implying that all elements are scaled such that each row sum equals one, in order to avoid scale effects. Table I shows that GDP per capita levels change from approximately \$3000 in 1960 to \$5300 in 1985 (in 1985 prices, U.S. dollars), and the growth rate of per capita GDP is approximately 2%. The normality test is rejected for the levels, but not for the growth rate, so the normality assumption is used for Moran's I in the latter case and the randomization approach is applied for the levels. The Moran I tests show that there is significant spatial clustering of similar values for GDP per capita levels. The same is true for GDP per capita growth rates, although at a considerably lower level.

Looking again at the Moran scatterplot of economic growth in Fig. 2, a mapping of the four types of countries identified in the Moran scatterplot is shown in Fig 2B. The scatterplot reveals the equivalence of Moran's I to the estimated regression coefficient of the linear trend line. The map shows that low-growth countries tend to cluster together (especially in Africa), but high-growth countries are either surrounded by other high-growth countries (in Europe) or by countries that exhibit considerably lower growth rates (in North and South America, and in Africa). This is a primary visual indication that spatial heterogeneity may be relevant for the regression model, either by varying the coefficients over different types of regions and/or allowing for groupwise heteroskedasticity.

Spatial Regression Models

The specification of spatial dependence in (linear) regression models is usually distinguished according to two types of representation. One is to model the dependence directly, for instance, by means of a distance deterrence function. If a sufficient number of data points are

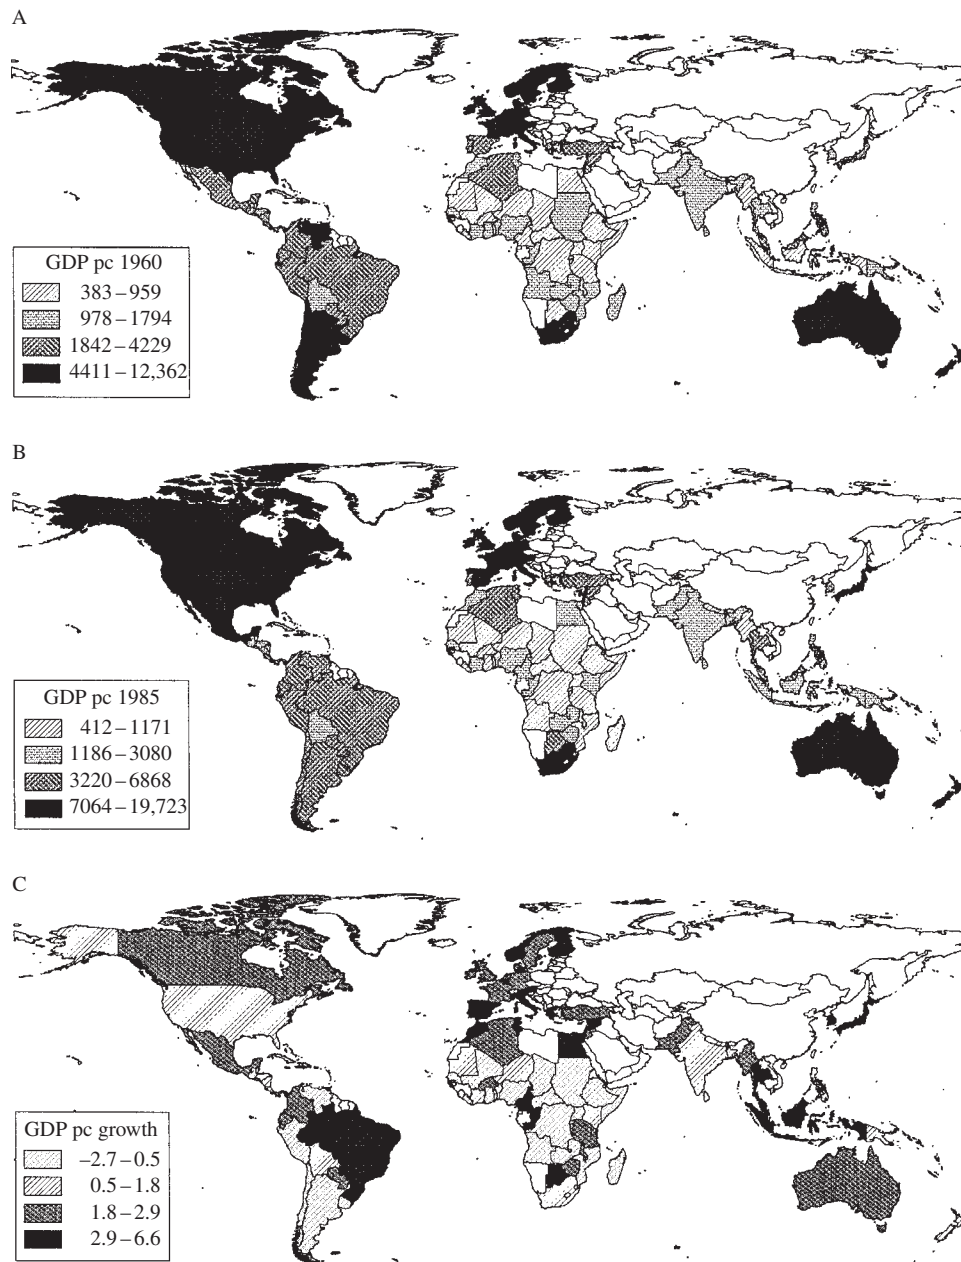

Figure 3 Maps of gross domestic product per capita (GDP pc) for the Mankiw–Romer–Weil sample of 98 non-oil-producing countries in (A) 1960 and (B) 1985. (C) Map of annual GDP growth over the period 1960–1985 for the Mankiw–Romer–Weil sample of 98 non-oil-producing countries.

available, the influence of spatial impediments can be estimated directly. Another approach is to provide exogenous structure by specifying the spatial topology and interaction structure in a spatial weights matrix, in order to avoid the incidental parameter problem that would arise when the influence of neighboring locations is estimated for each region separately. We restrict the discussion to the latter category of so-called spatial process models. There is a third type of model, the so-called conditional autoregressive

models, but for these types of models, it is rather cumbersome to attain appropriate estimates.

Spatial Process Models

A general specification for a spatial regression model is the specification combining a spatially autoregressive dependent variable among the set of explanatory variables and spatially autoregressive disturbances. For higher order

Table I Exploratory Statistics for Gross Domestic Product per Capita Levels^a

Statistic	Average	Wald test for normality ^b	Moran's I^b

^c Using the randomization approach.

^d Using the normality assumption.

processes, this autoregressive–autoregressive (ARAR) paradigm, the ARAR(i, j) model, is given by Eq. (10):

$$\mathbf{y} = (\rho_1 \mathbf{W}_1 + \cdots + \rho_i \mathbf{W}_i) \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (10)$$

$$\boldsymbol{\varepsilon} = (\lambda_1 \mathbf{W}_1 + \cdots + \lambda_j \mathbf{W}_j) \boldsymbol{\varepsilon} + \boldsymbol{\mu}.$$

For a first-order process, this reduces to the ARAR(1, 1) model:

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad (11)$$

$$\boldsymbol{\varepsilon} = \lambda \mathbf{W}_1 \boldsymbol{\varepsilon} + \boldsymbol{\mu},$$

where \mathbf{y} is the $n \times 1$ vector with observations on the dependent variable, \mathbf{X} is the $n \times k$ design matrix containing the explanatory variables, $\boldsymbol{\beta}$ is the $k \times 1$ vector with parameters, ρ is the scalar spatially autoregressive parameter, λ is the scalar spatial autoregressive disturbance parameter, and $\boldsymbol{\mu}$ is an $n \times 1$ independently and identically distributed vector of error terms. The spatial interaction pattern can be restricted to first-order neighbors (i.e., neighbors that have a common border) as in Eq. (11), or extended to higher order neighbors (i.e., neighbors of the neighbors, etc.) as in Eq. (10). Alternatively, the weight matrix can be specified using inverse distances, eventually with a cutoff point. In the latter case, an interpretation similar to the higher order interpretation is feasible, using distance bands. The weights matrices for the spatially lagged dependent variable and in the error term do not necessarily have to be identical, but they are assumed to be the same here for reasons of simplicity. Spatial stationarity is assured by constraining the spatial autoregressive parameters to lie in the interval $1/\omega_{\min}$ and $1/\omega_{\max}$, where ω_{\min} and ω_{\max} are, respectively, the smallest and the largest eigenvalues (on the real line) of the spatial weights matrix. For a row-standardized spatial weights matrix (i.e., the row sums are scaled to unity), the largest eigenvalue is always +1. The model contains a spatially homogeneous set of coefficients but can trivially be extended to allow for spatially varying coefficients and/or heteroskedasticity. A related model is the autoregressive moving-average (ARMA) variant, ARMA(1, 1), which, for the first-order case, reads as $\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + (\mathbf{I} + \lambda \mathbf{W}_1) \boldsymbol{\mu}$.

The most frequently used models are two special cases of the ARAR(1, 1) model, the spatial autoregressive error model, or AR(1) model, obtained for $\rho = 0$, and the spatial lag model when $\lambda = 0$. For ease of notation, one weight matrix is used from here on, and the subscript is omitted. Extensions to higher order cases are trivial. The spatial (autoregressive) error model reads as follows:

$$\mathbf{y} = \mathbf{X} \boldsymbol{\beta} + (\mathbf{I} - \lambda \mathbf{W})^{-1} \boldsymbol{\mu}, \quad (12)$$

The error covariance matrix is given by $\sigma^2[(\mathbf{I} - \lambda \mathbf{W})'(\mathbf{I} - \lambda \mathbf{W})]^{-1}$, showing that heteroscedasticity is present even if the error term is homoscedastic. This applies likewise to the spatial lag model,

$$\mathbf{y} = \rho \mathbf{W} \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \boldsymbol{\mu}, \quad (13)$$

for which the error covariance is the same as in the AR(1) model, assuming otherwise homoscedastic errors.

As a special case of the spatial ARMA model, the spatial moving average model can be easily derived as $\mathbf{y} = \mathbf{X} \boldsymbol{\beta} + (\mathbf{I} + \lambda \mathbf{W}) \boldsymbol{\mu}$, with error covariance matrix $\sigma^2(\mathbf{I} + \lambda \mathbf{W})(\mathbf{I} + \lambda \mathbf{W})'$. Although the AR and MA specifications appear to be similar, the difference in the error covariance shows that the spatial dependence in the MA model is restricted to first- and second-order neighbors, whereas in the AR model the dependence extends throughout the spatial system.

Interpretation of Spatial Effects

The standard spatial process models previously introduced illustrate two quite different interpretations of spatial dependence. As shown by Anselin and Rey in 1991, dependence can be modeled either as a substantive process or as a nuisance. In the spatial lag model, a substantive theoretical interpretation can be given to the spatial interaction. In the spatial error model, spatial dependence is caused either by (erroneously) omitted spatially correlated variables or by boundaries of regions that do not coincide with actual behavioral units. The different specifications of spatial dependence have divergent implications for estimation and statistical inference. The spatial error model is an example of the more general class of models with a nonspherical variance–covariance

matrix, although due to the multidirectional nature of spatial dependence, the estimation is more difficult than for time series (in particular, estimated generalized least-squares estimators are inconsistent). The spatial lag model exhibits endogeneity that can be taken into account by instrumental variable or general methods of moments techniques, but should preferably be solved using an appropriate maximum-likelihood estimator; see Anselin's 1988 paper for details. In contrast to the time series case, whereby ordinary least squares (OLS) remains consistent if the errors are not serially correlated and its use is therefore asymptotically warranted, OLS estimators for the spatial lag model are biased and inconsistent, irrespective of the properties of the error term. Nuisance dependence in the error term is less serious because OLS remains unbiased, but it is inefficient.

Rearranging Eq. (12) shows that the spatial error model is equivalent to an extended spatial lag model comprising both the spatially lagged dependent and the spatially lagged exogenous variables:

$$\mathbf{y} = \lambda \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} - \mathbf{W}\tilde{\mathbf{X}}\boldsymbol{\gamma} + \boldsymbol{\mu}, \quad (14)$$

where $\tilde{\mathbf{X}}$ is the original design matrix \mathbf{X} , except for the constant. The formal equivalence only holds if $k-1$ nonlinear constraints are satisfied, specifically $\lambda\boldsymbol{\beta} = -\boldsymbol{\gamma}$. This model is generally referred to as the "spatial Durbin" or "common factor" model. The similarity between the spatial error and the common factor model, discussed by Anselin in 2001, shows that tests with either the spatial error or the spatial lag model as the alternative hypothesis is likely to have power against the other alternative as well.

Testing for Spatial Effects in Spatial Process Models

Apart from focused tests with an informative alternative hypothesis that points to, for instance, the spatial lag or the spatial error model, various diffuse tests merely reflecting whether the residuals are spatially correlated have been developed. The oldest and best known is Moran's I for regression residuals, given by Eq. (15):

$$I = \left(\frac{n}{S_0} \right) \times \left(\frac{\mathbf{u}'\mathbf{W}\mathbf{u}}{\mathbf{u}'\mathbf{u}} \right), \quad (15)$$

where \mathbf{u} is the $n \times 1$ vector of OLS residuals. As with Moran's I for raw data given in Eq. (5), statistical inference can be based on the assumption of asymptotic normality, but an exact approach depending on the matrix \mathbf{X} is available too, although rather cumbersome to apply. Moran's I for regression residuals is a locally best-invariant test; moments and estimation details were given by Cliff and Ord in 1981 and Anselin in 1988. An

alternative large-sample test derived under less restrictive assumptions was derived by Kelejian and Robinson in 1992.

Unidirectional and Multidirectional Tests for Spatial Dependence

Focused tests have a clear alternative hypothesis and are developed in a maximum likelihood framework. They either refer to a unidirectional alternative hypothesis dealing with one specific misspecification or a multidirectional alternative comprising various misspecifications, or they are robust in the sense that the test allows for the potential presence of a second type of misspecification. The Lagrange multiplier tests, LM_λ and LM_ρ , are unidirectional tests with the spatial error and the spatial lag model as their respective alternative hypotheses. The LM error test is identical to a scaled Moran coefficient (for row-standardized weights), and reads as follows:

$$LM_\lambda = \left(\frac{1}{T} \right) \left(\frac{\mathbf{u}'\mathbf{W}\mathbf{u}}{s^2} \right)^2, \quad (16)$$

where s^2 is the maximum likelihood variance $\mathbf{u}'\mathbf{u}/n$; T is a scalar computed as the trace of a quadratic expression in the weight matrix, $T = \text{tr}(\mathbf{W}'\mathbf{W} + \mathbf{W}^2)$; and the test asymptotically follows a χ^2 distribution with one degree of freedom.

The LM lag test has the same asymptotic distribution, and looks similar:

$$LM_\rho = \left(\frac{1}{nJ_{\rho\beta}} \right) \left(\frac{\mathbf{u}'\mathbf{W}\mathbf{y}}{s^2} \right)^2, \quad (17)$$

where $J_{\rho\beta} = [(\mathbf{W}\mathbf{X}\mathbf{b})'\mathbf{M}(\mathbf{W}\mathbf{X}\mathbf{b}) + Ts^2]/ns^2$ is a part of the estimated information matrix, \mathbf{b} is the OLS estimated parameter vector, and \mathbf{M} is the projection matrix $\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$.

Unfortunately, the LM error test cannot be used to distinguish between the spatial autoregressive and the moving-average processes. The same holds for multidirectional tests, such as the test against the ARAR and the ARMA models, a test that is similar but not equal to the sum of the error and the lag tests:

$$LM_{\rho\lambda} = \frac{(\mathbf{u}'\mathbf{W}\mathbf{y}/s^2 - \mathbf{u}'\mathbf{W}\mathbf{u}/s^2)^2}{RJ_{\rho\beta} - T} + \frac{(\mathbf{u}'\mathbf{W}\mathbf{u}/s^2)}{T}, \quad (18)$$

and follows a $\chi^2_{(2)}$ distribution.

Finally, a multidirectional test against spatial error dependence and heteroskedasticity does equal the sum of the LM error test and the familiar LM test for heteroskedasticity due to Breusch and Pagan (i.e., the BP test):

$$BP = \frac{1}{2} \mathbf{f}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{f}, \quad (19)$$

where the elements of \mathbf{f} are defined as $f_i = (u_i/s)^2 - 1$, and \mathbf{Z} is an $n \times k$ matrix containing the variables causing the heteroskedasticity. The BP test is asymptotically distributed as χ^2 with k degrees of freedom, and hence this joint test follows a $\chi^2_{(k+1)}$ distribution.

Rather than simple spatial heteroskedasticity, increasingly complex forms of spatial heterogeneity are possible as well. They occur in the case of discrete or continuous spatial variation, and they can be restricted to the means of homogeneous subgroups (spatial analysis of variance or a trend surface) or can extend to all coefficients (spatial regimes, and error component or spatial expansion models). Anselin provided details and appropriate test statistics in 1988.

Robust Tests for Spatial Dependence

The derivation of specification tests with locally misspecified alternatives makes it possible to distinguish more clearly between spatial error and spatial lag dependence. As explained by Anselin *et al.* in 1996, these tests are labeled robust because the test statistics account for the potential presence of a spatial lag or spatially correlated errors when testing for the presence of spatially correlated errors or a spatial lag, respectively. The test for a spatial error process robust to the local presence of a spatial lag is as follows:

$$LM^*_\kappa = \frac{1}{T - T^2(nJ_{\rho \cdot \beta})^{-1}} \left[\frac{\mathbf{u}'\mathbf{W}\mathbf{u}}{s^2} - T(nJ_{\rho \cdot \beta})^{-1} \frac{\mathbf{u}'\mathbf{W}\mathbf{y}}{s^2} \right]^2. \quad (20)$$

This clearly shows the subtraction of a correction factor that accounts for the local misspecification of a spatial lag process. The test for a spatial lag process robust to the local presence of a spatial error is given by Eq. (21):

$$LM^*_\rho = \frac{1}{nJ_{\rho \cdot \beta} - T} \left(\frac{\mathbf{u}'\mathbf{W}\mathbf{y}}{s^2} - \frac{\mathbf{u}'\mathbf{W}\mathbf{u}}{s^2} \right)^2. \quad (21)$$

Both tests asymptotically follow a $\chi^2_{(1)}$ distribution.

It would be fruitful if it was also possible to test for a spatial error or a spatial lag model assuming local misspecification in the form of heteroskedasticity. This approach, however, leads to a highly nonlinear problem, discussed in 1988 by Anselin.

Small Samples, Specification Strategies, and Software

In the spatial econometrics literature, the design of misspecification tests has predominantly focused on continuous regression models (although some recent results, e.g., those of Kelejian and Prucha in 2001, are also concerned

with categorical models) and on the use of Lagrange multiplier tests. Although LM tests are asymptotically equivalent to Wald and likelihood ratio tests, LM tests are computationally convenient because they are based on parameter estimates under the null hypothesis. Although the increasing availability of large data samples alleviates the problem of the small sample distribution of the tests being markedly different from their asymptotic distribution, substantial efforts have been put into simulating the performance of the tests in small sample situations.

Small Sample Performance and Specification Strategies

The finite sample performance of spatial dependence tests across various “true” models is actually quite well documented; see Florax and De Graaff’s 2004 comprehensive overview. For diffuse misspecification tests, it has been shown that the power of Moran’s I is greater than the Kelejian–Robinson test. The latter is also more sensitive to departures of the normality of the error distribution, although, on the positive side, it has power against spatial dependence as well as heteroskedasticity. As would be expected, the power of focused LM tests against their correct alternative is very high. In general, the power of the tests in small samples is very satisfactory. Asymptotic results are approached for moderately sized samples of approximately 100 observations.

The power of the Lagrange multiplier spatial error (lag) test against a spatial lag (error) model seriously complicates the work of the practitioner of spatial modeling techniques. If both tests are significant, which underlying model is then correct? This issue is addressed in research on so-called specification strategies. Some researchers (for instance, Haining, Getis, Griffith, and Tiefelsdorf) advocate avoiding the search for the proper model specification altogether. They propose to “prewhiten” or “filter” the variables in such a way that the variables are free of spatial dependence and it is subsequently possible to resort to simple OLS for estimation purposes. As an alternative, it is possible to follow either a “classical” approach (start with simple OLS, perform LM tests, and select the model corresponding to the test with the highest value) or an approach inspired by David F. Hendry’s work (start with a very general model including spatial effects, and reduce the model on the basis of significance tests). Florax *et al.* showed, by means of Monte Carlo simulation, that the classical approach outperforms the Hendry approach, but a comparison to the filtering approaches is not yet available. The latter, as well as a specification strategy centering on how to deal with the joint occurrence of heteroskedasticity (or spatial heterogeneity) and spatial dependence, would be extremely relevant for practitioners of spatial econometric modeling.

Apart from further research on the small-sample performance and specification strategies, several other unresolved questions or points deserve further attention. For instance, mainstream econometrics is reluctant to accept the *a priori* imposition of the elements of the weights matrix, which can be avoided by using so-called direct representation models. Moreover, further advances in the treatment of spatial effects in a panel data setting are required (see Baltagi *et al.*'s 2003 discussion), and computational problems when dealing with large data sets need to be further explored.

Software for Spatial Exploratory and Explanatory Analysis

In recent years, there has been an upsurge in the development and availability of software for spatial statistics and spatial econometrics. The two most complete software packages are SpaceStat and James LeSage's extensive spatial econometrics toolkit of routines for the estimation of spatial econometric models developed in MATLAB (see www.spatial-econometrics.com). Anselin's SpaceStat package combines both exploratory tools and an extensive array of classical misspecification tests and estimators for spatial models. The package can be complemented with a free downloadable tool for mapping and exploratory spatial data analysis called GeoDa (see <http://sal.agecon.uiuc.edu>). This tool also facilitates the building of weighting matrices, and the output can be easily transferred to SpaceStat. LeSage's toolkit is slightly more oriented toward modeling, and contains an array of Bayesian routines in addition to the classical tests and estimators. Several other online software sources are available. In the context of spatial econometric modeling, the following tools are the most relevant:

- Kelly Pace's spatial statistics toolbox (see <http://spatial-statistics.com>) contains routines for MATLAB and programs to estimate spatial models for large samples.
- Roger Bivand's SPDEP Spatial Analysis Tools website (see <http://cran.r-project.org>) gives programs for spatial autocorrelation and regression analysis written in R.
- S+ SpatialStats (see <http://www.insightful.com>) is a complementary tool to the S-Plus statistical package that contains some spatial regression routines.
- Winbugs—Geobugs (see <http://www.mrc-bsu.cam.ac.uk>) has routines for spatial models based on the Gibbs sampler and Markov chain Monte Carlo (MCMC) estimation.

Two developments are particularly noteworthy and promising. One is the ongoing development of software and the boost to this development that can be expected to result from so-called open-source projects, which are typically Web based and essentially constitute a platform

and a common language for anybody who can credibly contribute to the development of software tools. The other development relates to the available information, the integration, and the accessibility of knowledge regarding spatial analysis. The U.S. National Science Foundation has recently funded a large-scale project to establish a Center for Spatially Integrated Social Science (CSISS; see www.csiss.org), which is intended to develop a successful clearinghouse for the tools, case studies, educational opportunities, and other resources needed by a spatially integrated social science approach. On the CSISS website, Luc Anselin has developed a spatial tools search engine that indexes a list of World Wide Web addresses (uniform resource locators, or URLs) and software archives of over 700 individual software titles. A spatial tool listing of links to portals (i.e., collections of links) is available as well.

Illustration of the Spatial Modeling Approach

The workings of the spatial econometric modeling approach can be illustrated by continuing with the economic growth example discussed previously. Table II presents the results for the Mankiw—Romer—Weil analysis in the first column. Economic growth over the period 1960–1985 is regressed on the GDP level in 1960, and three variables (investment share, population growth, and human capital) account for differences across countries. The implication of the estimation findings is that the 98 non-oil-producing countries are converging toward each other (or actually their so-called steady state) at a rate of 1.4% per year. The misspecification tests in column 1(OLS) show that the estimated standard errors are not accurate because of heteroskedasticity, and, more importantly, the estimates are biased because of the erroneously omitted spatially lagged dependent variable. The spatial lag model is therefore estimated, with results being reported in column 2 (Lag). The misspecification tests for this model indicate that there is no remaining spatial error correlation, but the model still suffers from heteroskedasticity. Then the error variance is allowed to differ between slow- and fast-growing economies; these results are presented in column 3 (Lag–Het). Relaxing the homoscedasticity restriction is, however, a rather mechanical solution to the potential relevance of spatial heterogeneity. It does not have a substantive interpretation. Therefore, the possibility of two spatial regimes is introduced, allowing the coefficients and the variances to differ between slow- and fast-growing economies. Columns 4a and 4b (Lag–Reg) show that this is an appropriate model. There is no heteroskedasticity when the regression parameters are allowed to vary between two different “clubs” of countries; the Chow test indicates

Table II Mankiw–Romer–Weil Specification with Diagnostics for Spatial Effects, and Spatial Process Models Allowing for Spatial Dependence and Heterogeneity

Variable	Lag–Reg				
	OLS (1)	Lag (2)	Lag–Het (3)	Slow (4a)	Fast (4b)
Constant	3.02 (3.65)	3.03 (3.95)	3.81 (5.65)	1.16 (1.17)	3.88 (5.39)
GDP Level, 1960	−0.29 (−4.68)	−0.28 (−4.86)	−0.31 (−5.70)	−0.08 (−1.30)	−0.26 (−3.92)
Investment share	0.52 (6.03)	0.52 (6.44)	0.56 (6.87)	0.21 (2.64)	0.41 (3.62)
Population growth	−0.51 (−1.75)	−0.29 (−1.09)	−0.17 (−0.73)	0.02 (0.07)	0.07 (0.27)
Human capital	0.23 (3.89)	0.19 (3.41)	0.20 (3.73)	0.06 (1.08)	0.17 (2.50)
Spatial lag GDP growth		0.74 (4.73)	0.74 (4.99)	0.60 (3.16)	
Convergence rate ^a	1.4	1.3	1.5	0.3	1.2
R ² adjusted	0.46	0.50	0.56	0.75	
Maximized log likelihood	−26.95	−23.07	−20.18	9.50	
Breusch–Pagan	10.26 ^{**}	10.93 ^b	5.78 ^c	0.83 ^c	
Chow–Wald	—	—	—	86.85 ^d	
I	3.12	—			
Lagrange multiplier error	2.24	0.06 ^e			
Robust Lagrange multiplier error	5.08	—			
Lagrange multiplier lag	10.34	7.76 ^f			
Robust Lagrange multiplier lag	13.18	—			

^a In percents per year. The convergence rate is equal to $100[\ln(\beta + 1)]/T$.

^b Test on random coefficients. The Breusch–Pagan test for two regimes, groupings of slow- and fast-growing economies, is 1.97 (with probability 0.16) for the spatial lag model.

^c Likelihood ratio test on groupwise heteroskedasticity (using slow- and fast-growing economies as groups).

^d For the tests on equality of individual coefficients for the different groups, only the constant and the GDP level are significant (4.09 with probability 0.03, and 4.17 with probability 0.04, respectively).

^e Lagrange multiplier test on remaining spatial error correlation.

^f Likelihood ratio test on spatial lag.

that overall the estimated regression parameters for the two types of countries are not identical; and the spatially lagged dependent variable is highly significant and is large in magnitude. From the “reduced” form of the spatial lag model, $\mathbf{y} = (\mathbf{I} - \rho\mathbf{W})^{-1}(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon})$, it is easily seen that the significance of the spatial lag variable can be caused by the omission of spatially correlated exogenous variables, and/or by spatially correlated factors within each country that are not considered in the specification. The modeling results reveal that instead of the 1.4% MRW convergence rate, a differentiation among slow-growing economies converging at a 0.3% rate, and fast-growing economies converging at a 1.2% rate, is more in accordance with reality. The ultimate model specification allows for spatial heterogeneity and accounts for the intrinsic spatial inter-relatedness of countries’ economies.

Conclusion

The use of appropriate spatial statistical and spatial econometric techniques is imperative. This applies to all analyses in the social sciences that are based, or should be based, on spatially referenced data. Such analyses are not necessarily restricted to cases in which data for a specific spatial area (cities, counties, states, or countries) are

employed. For any analysis that is intrinsically spatial, whether it is operationalized using individual data, institutional data (firms, hospitals, and the like), or spatially demarcated data, the use of spatial analysis techniques is a *conditio sine qua non*. The growing availability of easy-to-use software for spatial analysis makes it tempting to simply “try” all kinds of different spatial models and techniques, but it is highly desirable that this blends in with a careful consideration of the inherent subtleties underlying different spatial modeling techniques, and theoretical considerations with respect to the topic at hand.

Modeling Diffusion Processes

Andrew Cliff

University of Cambridge, Cambridge, UK

Peter Haggett

University of Bristol, Bristol, UK

Glossary

adoption curves Rates at which an innovation is adopted by a population through which a diffusion wave is passing. In the Hägerstrand model, the rates show distinctive changes over time.

barrier effects A variant of the Hägerstrand diffusion model developed by Yuill to show the spatial effects on spread of different categories of barrier.

Bartlett model An epidemic model developed by the British statistician M. S. Bartlett to show the relationships between the size of a community measured by population and the spacing of epidemic waves.

Bayesian entropy forecasting An approach to forecasting based on Bayes's theorem, which forecasts future events in a "least prejudiced" manner given any prior information.

contagious diffusion A type of diffusion process in which spatial contact is consistently maintained. It is also called neighborhood diffusion.

diffusion The process of spreading out or scattering over an area of the Earth's surface. It should not be confused with the physicist's use of the term to describe the slow mixing of gases or liquids with one another by molecular interpenetration.

Hägerstrand models A series of spatial diffusion models developed by the Swedish geographer Torsten Hägerstrand based on empirical studies of innovations in farm communities in southern Sweden. The models, first developed in the 1950s, were innovative in their pioneering of simulation using Monte Carlo methods.

hierarchy diffusion A type of diffusion wave that moves through the urban hierarchy in a cascading manner. Unlike contagious diffusion, its geographical pattern of spread may be discontinuous in space.

mean information field (MIF) A weighted matrix used in the Hägerstrand model to provide a probability surface for

simulating the spread of a process of interest. Originally used for the spread of information, it has since been widened to include such processes as the spread of disease through a population. Values within the matrix may be symmetric or asymmetric.

Monte Carlo methods Methods for finding solutions to mathematical and statistical problems by simulation. Used when the analytical solution to the problem is either intractable or unacceptably time consuming.

relocation diffusion A type of spatial diffusion in which the center from which the object being spread also changes its location.

serial interval The average time between the observation of symptoms in one case and the observation of symptoms in a second case directly infected from the first.

simulation model The artificial generation of processes (usually by means of pseudo-random numbers on computers) to imitate the behavior of models that reproduce complex, real-world situations. Simulation is a useful heuristic device and can be of considerable help in the development of explanation. Literally, simulation is the art or science of pretending.

In the social sciences, the modeling of diffusion processes involves the study of the mechanisms by which phenomena of interest disperse or are dispersed from a center, to spread widely or disseminate within a region or a population. The areas of disciplinary application are very wide, from economics and sociology to social psychology and history. Here models from the geographical and epidemiological literature are used to illustrate the broad principles involved in model building.

The Nature of Diffusion Processes

Types of Diffusion Process

Expansion and Relocation Diffusion

In the geographical literature, the term diffusion has two distinct usages. Expansion diffusion is the process whereby a phenomenon of interest (this may be information, a material, or a disease) spreads from one place to another. In this expansion process, the item being diffused remains, and often intensifies, in the originating region, but new areas are also occupied by the item in subsequent time periods (Fig. 1A). Relocation diffusion is also a spatial spread process, but the items being diffused leave the areas where they originated as they move to new areas (as in population migration) (Fig. 1B). The two processes of expansion and relocation may be combined (Fig. 1C).

This combination is shown in Figure 1D, which traces the spread of one of the world's great cholera pandemics—the El Tor strain—between 1960 and 1971. In 1961, it began to spread with devastating speed from the Celebes. By 1964, it had reached India, replacing the normal cholera strain that had been endemic in the Ganges delta for centuries, and by the early 1970s, it was pushing south into central Africa and west into Russia and Europe.

Expansion diffusion occurs in two ways. Contagious spread depends on direct contact. It is in this way that many infectious diseases pass through a population, from

person to person. This process is strongly influenced by distance, because nearby individuals or regions have a much higher probability of contact than remote individuals or regions. Therefore, contagious spread tends to occur in a centrifugal manner from the source region outward.

Expansion diffusion may, however, occur in a very different fashion, namely, by hierarchical spread. This describes transmission through an ordered sequence of classes or places. The process is typified by the diffusion of innovations from large metropolitan centers to remote villages. Within socially structured populations, innovations may be adopted first on the upper level of the social hierarchy and then trickle down to the lower levels. Cascade diffusion is a term reserved for processes that are always assumed to be downward from larger to smaller centers. When specifying a movement that may be either up or down the hierarchy, the preferred term is hierarchical diffusion.

Types of Diffusion Models

Alternative models of a spatial diffusion process are illustrated schematically in Fig. 2. Given the diffusion process being studied, there are three relevant questions an investigator may wish to ask:

1. From an accurate mapping of a sequence of stages it may be possible to identify the change mechanism and

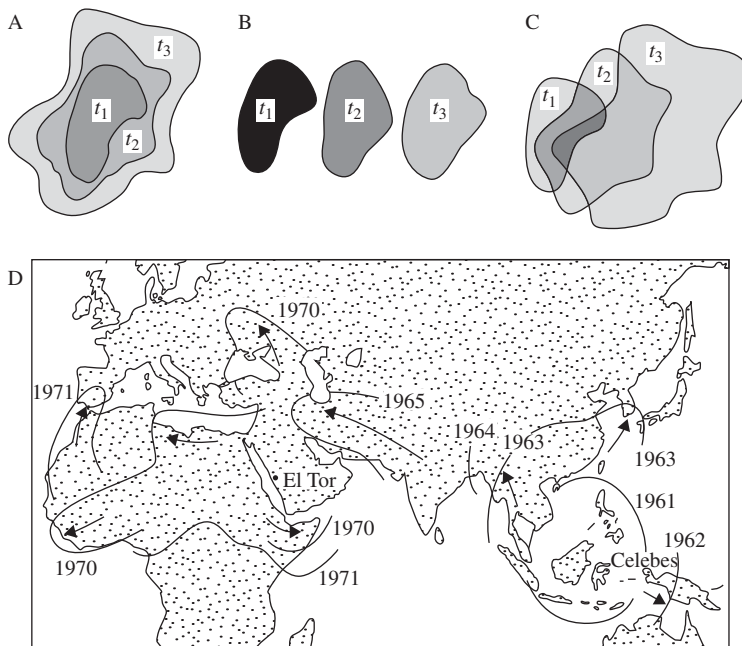

Figure 1 Types of spatial diffusion. (A) Expansion diffusion. (B) Relocation diffusion. (C) Combined expansion and relocation processes. The term t_i denotes the time period. (D) Example of a combined diffusion wave: the spread of the El Tor cholera pandemic, 1960–1971. Reproduced from Haggett (2000, Fig. 1.1, p. 2) by permission of Oxford University Press.

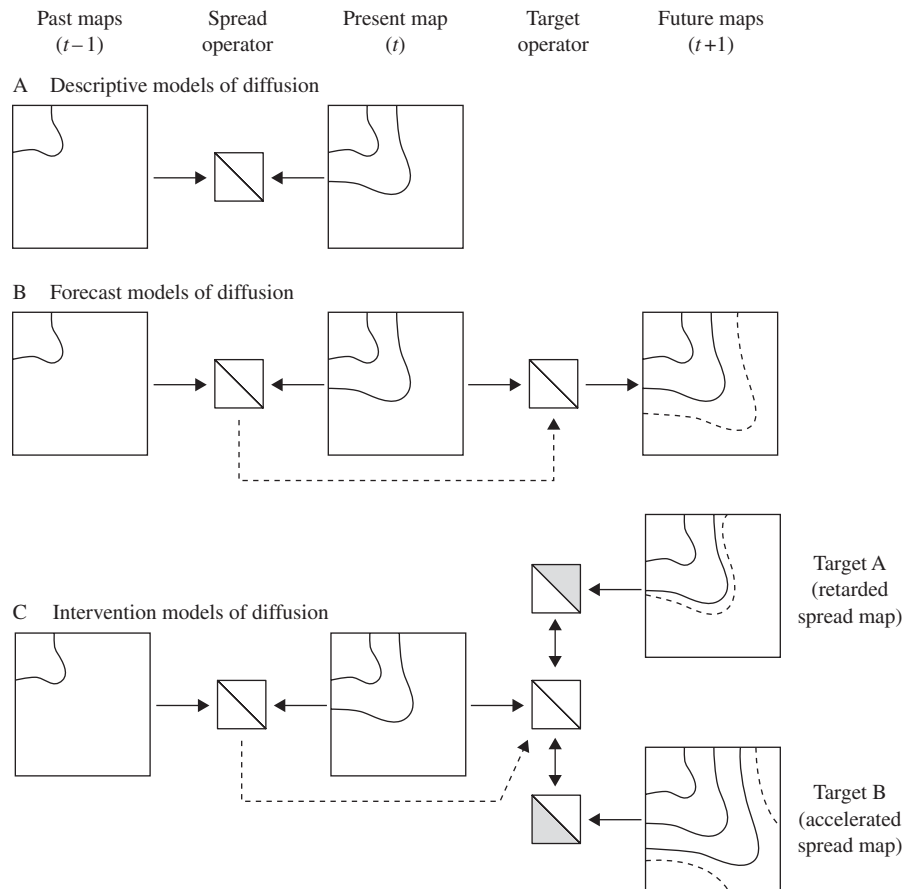

Figure 2 Map sequences as a predictive device. Descriptive, predictive, and interdictive models of a spatial diffusion process. The creation of operators (e.g., mean information fields) from a map sequence allows the forward progression of the map to a future time period. Reproduced from Haggett (2000, Fig. 1.12, p. 30) by permission of Oxford University Press.

summarize the findings in terms of a descriptive model. The key questions here are what is happening, and why?

2. If a model can simulate the sequence of past conditions reasonably accurately, then we may be able to go on to say something about future conditions. This move from the known to the unknown is characteristic of a predictive model: the basic idea is summarized in Fig. 2B. One must search for the target operator that appears—in terms of this model—to convert early maps of the past into later maps of the present and future. If such an operator can be found, and if some continuity can be assumed in this process (the heroic assumption that lies behind so much forecasting), then a future map can be sketched in. The error bands associated with each “contour” will be given by the width of the lines on the map; the further forward in time, the wider those bands are likely to be.

3. But planners and decision makers may want to alter the future, say, to accelerate or stop a diffusion wave. So the third question is what will happen in the

future, if there is some specific intervention? Models that try to accommodate this third order of complexity are termed interdictive models. These are shown in Fig. 2C.

Different Disciplinary Approaches to Diffusion Study

Spatial diffusion studies have not been the province of any single discipline. As the surveys by Brown and Rogers showed, approaches have varied with the background and traditions of the researchers involved. In the United States, the Berkeley School of Cultural Geography, led by Carl O. Sauer, played a central role. Sauer and his students were interested in how diffusion processes might help to account for the dispersal of cultural traits from given origins or cultural hearths. Sauer himself considered the cultural diffusion idea at the world scale in his 1952 Bowman lectures, “Agricultural Origins and Dispersals.” It was also in the United States that the

historian Frederick Jackson Turner developed his great theme of the “frontier” in U.S. history, which has proved to be one of the key ideas of cultural diffusion studies. Turner’s work was taken up by Webb in his classic regional study of the central grasslands in the United States, *The Great Plains*.

Purely economic phenomena have similarly been studied within a diffusion framework. An example appears in Fig. 3, taken from work by Lösch on price changes in space. This figure redraws from his data the spread of the business depression of 1929–1931 in the United States through the state of Iowa. Note the steady east-to-west movement of the depression.

Two further lines of approach to diffusion study have come from the fields of sociology and epidemiology. In sociology, the concern has focused on the spread of concepts through a society, the role of leaders in starting innovations, and the problem of resistance to change. Rogers reviewed hundreds of such studies, largely concerned with the innovation of new techniques in farming communities of the United States. Work in this field has concentrated on the factors that influence the propensity to adopt innovations and the speed of take-up.

In epidemiology, the analysis of disease transmission as a spatial spread process has been a major interest since the work of Hamer at the turn of the 20th century; it continues to be an important concern.

Diffusion as a Wave Process

Innovation Profiles

Much of the geographical interest in diffusion studies stems from the work of the Swedish geographer Torsten Hägerstrand. His *Innovation Diffusion as a Spatial Process* (1968) was concerned with the acceptance by farmers of several agricultural innovations, such as the control of bovine tuberculosis by vaccination and subsidies for the improvement of grazing, in an area of central Sweden. In one of his early studies, Hägerstrand described a four-stage model for the passage of what he termed innovation waves (innovations *förloppet*), but which are more generally called diffusion waves.

From maps of the diffusion of various innovations in Sweden, ranging from bus routes to agricultural methods,

Figure 3 Economic impulses as diffusion waves. Spread of the business depression of 1929–1931 through the state of Iowa in the central United States. Graphs show indices of business activity with their running means for 10 counties. Time contours show time of arrival of the depression “front.” Redrawn from Lösch, in Haggett (2000, Fig. 1.2, p. 4) by permission of Oxford University Press.

Hägerstrand drew a series of cross-sections to show the profile of the wave form at different points in time. He suggested that diffusion profiles can be broken into four types, each of which describes a distinct stage in the passage of an innovation through an area. Consider Fig. 4A, which shows the relationship between the proportion of adopters of an innovation against distance from the original center of innovation.

The primary stage marks the beginning of the diffusion process. A center of adoption is established at the origin. There is a strong contrast in the level of adoption between this center and remote areas that is reflected in the steep decline of the level of adoption curve beyond the origin. The diffusion stage signals the start of the actual spread process; there is a powerful centrifugal effect, resulting in the rapid growth of acceptance in areas distant from the origin and by a reduction in the strong regional contrasts typical of the primary stage. This results in a flattening of the slope of the proportion of adopters curve. In the condensing stage, the relative increase in the numbers

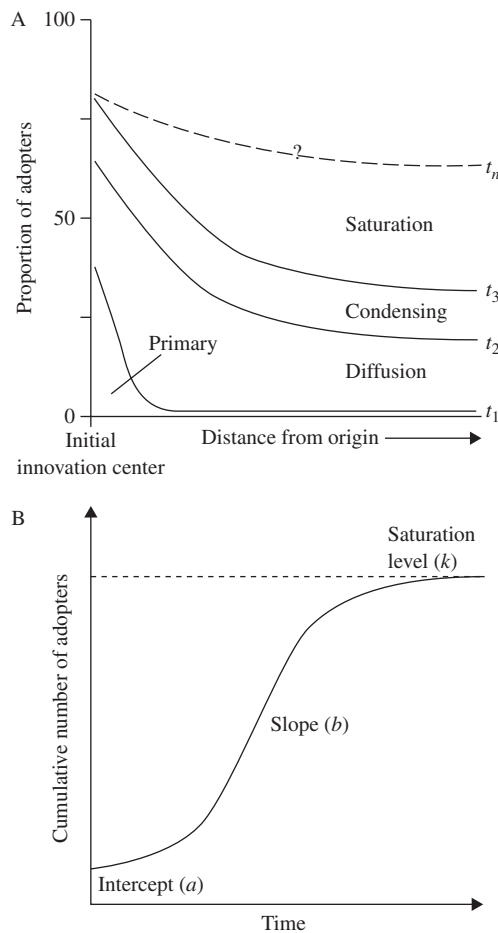

Figure 4 (A) Hägerstrand hypothetical profiles for diffusion waves. (B) Logistic curve. Reproduced from Cliff *et al.* (1981, Figs. 2.9, 2.10, pp. 17–18) with the permission of Cambridge University Press.

accepting an item is equal in all locations, regardless of their distance from the original innovation center; the acceptance curve moves in a parallel fashion. The final, saturation stage is marked by a slowing and eventual cessation of the diffusion process, which produces a further flattening of the acceptance curve. In this final stage, the item being diffused has been adopted throughout the country, so that there is very little regional variation.

Logistic Models

The shape of the profile in time and space has been formally modeled. First the temporal build-up in the number of adopters of an innovation is considered. If the total susceptible population at the start ($t = 0$) of the process is known, then the cumulative number of that total who will have become adopters at $t = 1, 2, \dots$ commonly follows an S-shaped curve when plotted against t (see Fig. 4B). y_t is used to denote the cumulative number of adopters in the total population at risk. Acceptance of an innovation is rather slow at first, but is followed by a rapid build-up as the innovation “takes off.” Ultimately, there is a leveling off as saturation of the susceptible population is approached. The model most commonly fitted to profiles of the form of Fig. 4B is the logistic model.

The logistic model is given by

$$p_t = (1 + e^{a-bt})^{-1} \quad (1)$$

or

$$y_t = k(1 + e^{a-bt})^{-1}, \quad (2)$$

where p_t is the proportion of adopters in the population at t , y_t is as defined above, and a , b , and k are parameters. The model is readily fitted by ordinary least squares since both Eqs. (1) and (2) reduce to simple regressions upon taking the appropriate transformation. The parameter k is usually interpreted as the maximum possible number of adopters (saturation level), a is the intercept, and b is the slope coefficient.

The structure of Eq. (2) is made clearer by looking at the first derivative, or the rate of change r_t in p_t with respect to time, where

$$r_t = \frac{dp_t}{dt} = bp_t(1 - p_t). \quad (3)$$

Since p_t is the proportion of the susceptible population that has actually adopted by time t , $(1 - p_t)$ is the proportion still at risk. The quantity $p_t(1 - p_t)$, then, represents the probability that a random meeting between two individuals is between an adopter and a potential adopter, while the parameter b represents the rate at which meetings take place (the rate of mixing). Note that b is the same whatever the distance between the adopter and the potential adopter, that is,

Eq. (1) implies spatially homogenous mixing between adopters and potential adopters. This assumption is in conflict with the contagious diffusion idea discussed earlier. Cliff and Ord in 1975 suggested the following extension of the logistic model that allows homogeneous mixing within n regions ($i = 1, 2, \dots, n$) but less mixing between regions (compare Rapoport's distance-biased net or island model):

$$r_{it} = (1 - p_{it})(b_i p_{it} + \sum_{j \neq i} c_{ij} p_{jt}). \quad (4)$$

Here c_{ij} is the rate of mixing between the i th and the j th regions. Extensions of the logistic model to handle inhomogeneous mixing as a function of the distance between adopters and potential adopters may be applied provided that a diffusion pole (that is, the original center from which the diffusion process started) can be specified.

Hägerstrand's Monte Carlo Model

The first major attempt within geography to formulate a model of the process of spatial diffusion was that of Hägerstrand. In developing the model in the context of innovation diffusion, Hägerstrand assumed that the decision of a potential adopter to accept an innovation was based solely upon information received orally at face-to-face meetings between the potential adopter and adopters. He further assumed that the contact probabilities between tellers and receivers conformed to the neighborhood effect.

Rules of the Basic Model

Hägerstrand's model was stochastic and was based upon the following rules:

1. The input numbers and spatial locations of adopters in the model were the actual configurations at the start of the diffusion process. The study area was divided up by a lattice of $5 \text{ km} \times 5 \text{ km}$.
2. A potential adopter was assumed to accept the innovation as soon as he or she was told by an adopter.
3. In each iteration, every adopter was allowed to contact one other person, adopter or non-adopter. The probability, p_i , that a carrier would contact an individual located in the i th cell of the study lattice is shown in Fig. 5. Each cell in this floating grid, which Hägerstrand called a mean information field (MIF), is $5 \text{ km} \times 5 \text{ km}$, and outside the grid, $p_i = 0$. These probabilities were estimated from an analysis of migration and telephone traffic data. The floating grid was placed over each existing adopter in turn, so that the adopter was located in the central cell of the MIF. What Fig. 5 tells us is that an

adopter located in the center of the central cell of the MIF has approximately a 44% chance of contacting someone within $\sim 0-2.5 \text{ km}$ of him- or herself, and that this contact probability decays over space to less than 1% at a distance of about 14 km (along diagonals) from the adopter and to 0 beyond $14-18 \text{ km}$. Since the probability is taken as 0 beyond 18 km , the MIF is exponentially bounded.

The location of each carrier's contact was determined in two steps. First, a random number r , $0 \leq r \leq 1$, from a rectangular distribution located the cell i according to the rule

$$\sum_{m=1}^{i-1} Q_m < r \leq \sum_{m=1}^i Q_m, \quad (5)$$

where Q_m , the probability of a contact in cell m with population n_m , is

$$Q_m = \frac{P_m n_m}{\sum_{m=1}^{25} P_m n_m}. \quad (6)$$

A second random number from a rectangular distribution on $[1, n_m]$ was drawn to locate the receiver in the cell. If the receiver was a potential adopter, he or she immediately became an adopter by rule (2); if the receiver was an existing adopter, the message was lost; if the receiver was identical with the carrier, a new address was sampled.

To take into account the reduction in interpersonal communication likely to be caused by physical features such as rivers and forests, two simplified types of barrier were introduced into the model plane, namely zero- and half-contact barriers. When an address crossed a half-contact barrier, the telling was cancelled with probability 0.5. However, two half-contact barriers in combination were considered equal to one zero-contact barrier. Using this model, Hägerstrand performed a series of computer runs to simulate the spatial pattern of acceptance of a subsidy for the improvement of pasture on small farms in the Asby district of central Sweden (see Fig. 6).

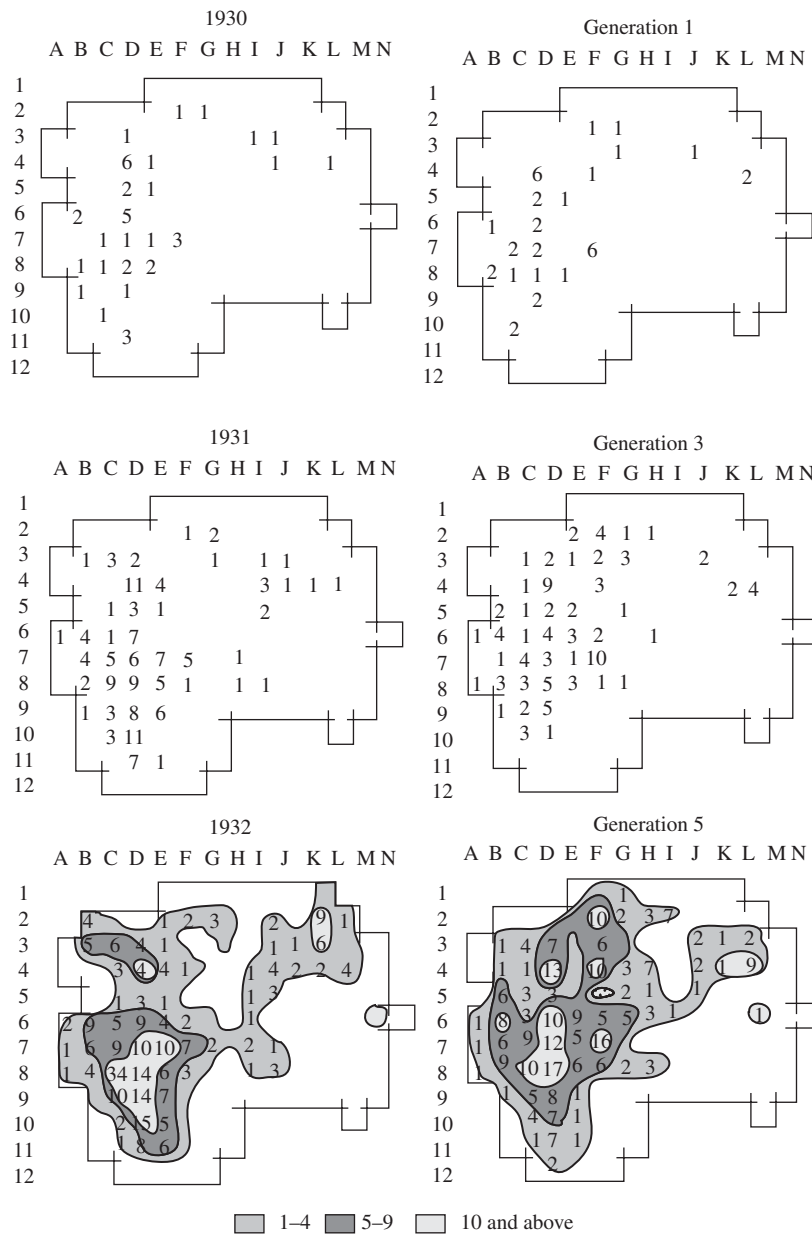

Figure 6 Real and simulated diffusion patterns. Simulation of the spatial pattern of the number of adopters of an improved pasture subsidy in central Sweden. From the initial distribution of adopting farmers in 1929 (generation 0), the next 3 years are shown; the actual distribution on the left (1930, 1931, 1932) and the simulated distribution on the right (generations 1, 3, and 5). Each square cell on the map is 5 km \times 5 km on the ground, and numbers give the number of adopters in each cell. Redrawn from Hägerstrand, in Haggett (2000, Fig. 1.3, p. 8) by permission of Oxford University Press.

Modification of the Hägerstrand Model

Barriers

Although in rule (4) of the model, a very simplified system of resistance to communication was proposed by Hägerstrand, barriers to diffusion waves are likely to be

much more complex in reality. The effect of barriers has been looked at by Yuill. His study used a 30×18 regular lattice of cells, and his MIF used a 3×3 grid rather than the 5×5 grid used by Hägerstrand. Fig. 7A gives the MIF, and it is assumed that two initial adopters (the solid

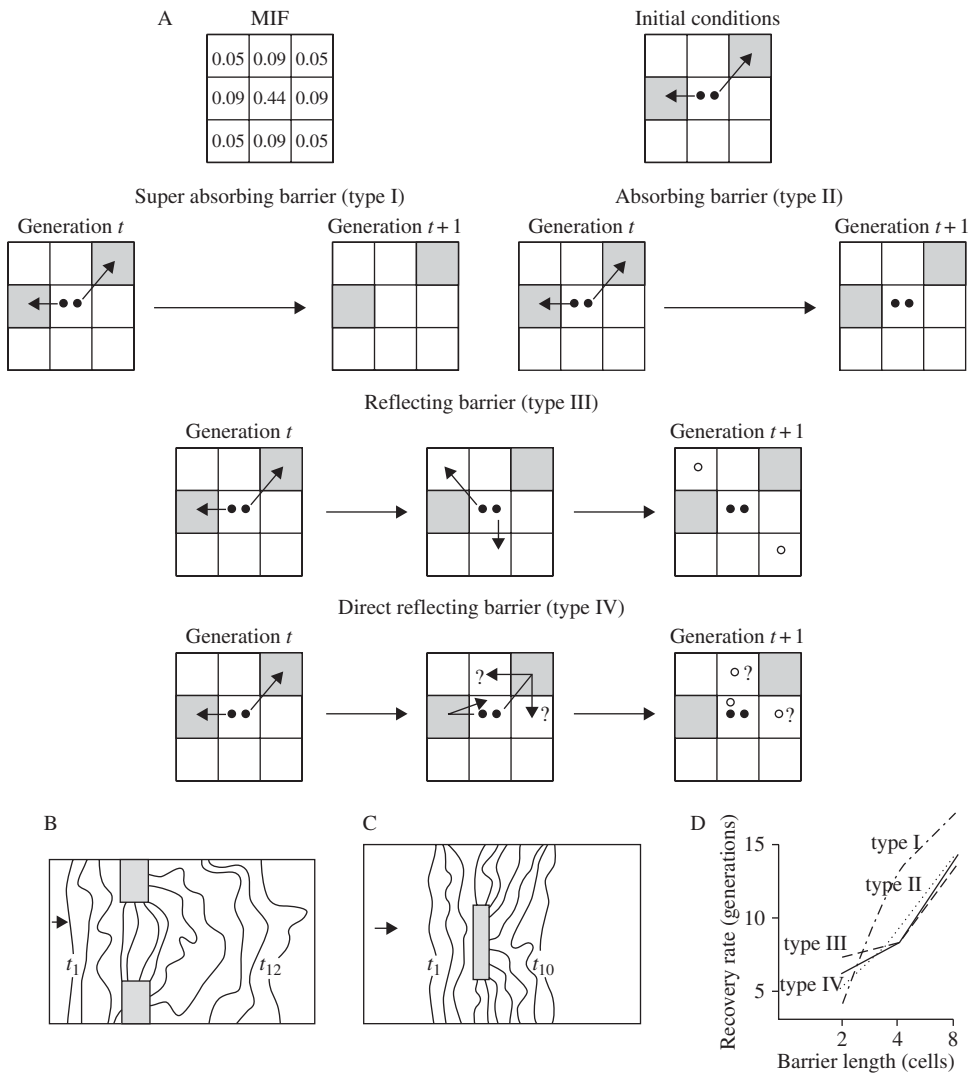

Figure 7 Barrier effects on diffusion waves. (A) Mean information field and the four types of barriers used by Yuill. (B) Diffusion wave passing through opening in an absorbing barrier. circles) have been located in the central cell. Imagine further that centering the grid over those two adopters has caused two cells of the MIF to be occupied by barriers (the stippled cells). The location of each carrier's contact in the next generation of the model (compare Hägerstrand's Monte Carlo experiment) is shown by the arrows.

Yuill envisaged four types of barrier cell in decreasing order of blocking effectiveness: type I, the super-absorbing barrier, which absorbed the new contacts and destroyed the transmitters; type II, the absorbing barrier, which absorbed the new contacts but did not affect the transmitters; type III, the reflecting barrier, which absorbed the new contracts, but the transmitters were

allowed to make a new contact in the same generation (the open circles); and type IV, the direct reflecting barrier, which did not absorb the contacts but instead reflected them randomly to the nearest available cell. Each situation was separately programmed and its results plotted. Figure 7B shows the advance of a linear diffusion wave ($t = 1$) through an opening in an absorbing bar barrier. The wave front becomes distorted in its passage through the opening because of the loss of contacts at the barrier edge (a frictional drag effect), but it reforms by about the 12th generation. Yuill referred to the number of generations required for the wave to return to its original form after first encountering the barrier as the recovery rate. An alternative version of the bar barrier

is shown in Fig. 7C, where the diffusion wave passes around a bar and reforms after about nine generations. Here the recovery rate is directly related both to the barrier length and to the kind of barrier, with the curve for the type I (super-absorbing) barrier showing strong contrasts to those of the other three types (Fig. 7D).

Corridors

The obverse of a barrier is a corridor of movement, and the identification of such corridors was the theme of a 1973 study by Levison *et al.* They constructed a Monte Carlo model to simulate the pattern of settlement of Polynesia by raft voyagers. The drift tracks of the rafts, from a variety

of starting points, were determined by sampling from ancillary probability distributions describing factors such as wind frequency, direction and force, ocean currents, and survival rates. Voyages were terminated by either (1) contact with another island or (2) expiry of the voyage as determined by survival rate probabilities. Mapping the distribution of voyage termination points in Polynesia permitted estimates to be made of the probability of reaching various Polynesian islands from the different starting points.

For certain kinds of innovations, a strong hierarchical effect might be expected in the adoption regime rather than a simple neighborhood effect. Figure 8A shows a

Figure 8 Patterns of diffusion through a system of settlements. hypothetical landscape. Center A is the biggest settlement (e.g., a city) and, for shopping and other social and economic services, influences the largest tract of surrounding countryside. This sphere of influence is demarcated by the solid boundary line in Figure 8. Centers of type D are the smallest settlements (e.g., villages), and influence the smallest amount of surrounding countryside (shown by the broken lines in Fig. 8B). An innovation is introduced in center A and is allowed to diffuse to other places by purely hierarchical spread, purely contagious spread, and by mixed process. The mixed process produces the fastest spread, the purely contagious spread the slowest.

Epidemiological Models

Epidemic Modeling: A Historical Note

Interest in the geographical distribution and spread of diseases around the globe is of some antiquity. Hirsch's *Handbuch der Geographische-Historische Pathologie* was first published nearly a century and a half ago; the history of mathematical modeling of epidemic processes goes back still further. Among the first applications of mathematics to the study of infectious disease was that of Bernoulli in 1760 when he used a mathematical method to evaluate the effectiveness of the techniques of variolation against smallpox. As disease statistics accumulated during the early 19th century, Farr in 1840 was able to fit a normal curve to smoothed quarterly data on deaths from smallpox in England and Wales over the period 1837–1839. This empirical curve-fitting approach was further developed by Brownlee, who considered in detail the geometry of epidemic curves.

The origin of modern mathematical epidemiology owes much to the work of En'ko, Hamer, Ross, Soper, Reed, Frost, Kermack, and McKendrick, who, using different approaches, began to translate specific theories about the transmission of infectious disease into simple, but precise, mathematical statements and to investigate the properties of the resulting models.

The Hamer-Soper Mass Action Model

The simplest form of an epidemic model, the Hamer-Soper model, is shown in Fig. 9A. It was originally developed by Hamer in 1906 to describe the recurring sequences of measles waves affecting large English cities in the late Victorian period. It has been greatly modified over the last half century to incorporate probabilistic, spatial, and public health features.

The basic wave-generating mechanism is a simple one. At any time t , assume that the total population in a region can be divided into three classes: the population at risk or susceptible population of size S_t , the infected population

of size I_t , and the removed population of size R_t . The removed population is taken to be composed of people who have had the disease, but who can no longer pass it on to others because of recovery, isolation on the appearance of overt symptoms of the disease, or death. The infected element in a population is augmented by the homogeneous mixing of susceptibles with infectives ($S \times I$) at a rate determined by a diffusion coefficient (β) appropriate to the disease. The infected element is depleted by recovery of individuals after a time period at a rate controlled by the recovery coefficient (γ). As Fig. 9A shows, the addition of further parameters to the model, such as the birth rate, μ , allows more complex models to be generated.

The formal articulation of Fig. 9A into a mathematical model handles three types of transition (Table 1):

1. A susceptible being infected by contact with an infective.
2. An infective being removed. It is assumed that infection confers lifelong immunity to further attack after recovery, which is reasonable for many infectious diseases such as measles and whooping cough.
3. A susceptible birth. This can come about through a child growing up into the critical age range (that is, reaching about 6 months of age).

As formulated, this model is aspatial. However, as has already been seen, by their very nature diffusion processes imply geographical spread between areas. Such spread may be result from a variety of social factors

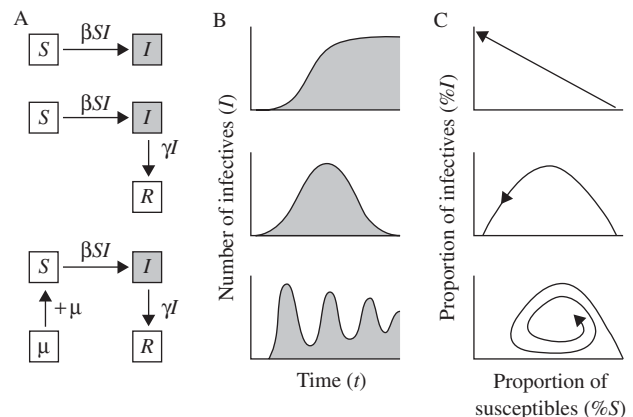

Figure 9 Basic elements in the three simplest mass action models of wave generation. (A) Elements in the model: S, susceptibles; I, infectives; R, recovered; μ , births; β , infection (diffusion) rate; γ , recovery rate. (B) Typical time profiles for the model with number of infectives stippled. (C) Trajectory of typical waves in infective-susceptible space. Table I Mass Action Models: Transition Types and Rates

Transition	Rate
1. $S \rightarrow S - 1; I \rightarrow I + 1; R \rightarrow R$	βIS
2. $S \rightarrow S; I \rightarrow I - 1; R \rightarrow R + 1$	γI
3. $S \rightarrow S + 1; I \rightarrow I; R \rightarrow R$	μ

that cause mixing of people: for example, at the local scale, travel between workplace and home, or shopping and school trips; at the national level, by relocation of homes when seeking new employment; at the international level, by holidays. To allow for the flux of infected and susceptible individuals at all these geographical scales, spatial versions of the basic model are required.

Spatial Versions of the Hamer-Soper Model

Empirical validation of the mass action models described previously was provided by the work of statistician Maurice Bartlett. He investigated the relationship between the periodicity of measles epidemics and population size for a series of urban centers on both sides of the Atlantic. His findings for British cities are summarized in Fig. 10. The largest cities have an endemic pattern with periodic eruptions (type I), while cities below a certain size threshold have an epidemic pattern with fade-outs (type II), or even miss some epidemics altogether (type III cities). For measles, Bartlett found the endemicity size threshold to be approximately a quarter of a million people. Subsequent research has shown that the threshold for any infectious disease is likely to be rather variable, with the level influenced by population densities and vaccination levels, but the threshold principle demonstrated by Bartlett remains intact.

Once the population size of an area falls below the threshold, then, when the disease concerned is eventually extinguished, it can recur only by reintroduction from other reservoir areas. Thus, the generalized persistence of disease implies geographical transmission between regions as shown in Fig. 11. In large cities above the size threshold, like community A, a continuous trickle of cases is reported. These provide the reservoir of infection that sparks a major epidemic when the susceptible population, S , builds up to a critical level. This build-up occurs only as children are born, lose their mother-conferred immunity, and escape vaccination or contact with the disease. Eventually the S population will increase sufficiently for an epidemic to occur. When this happens, the S population is diminished and the stock of infectives, I , increases as individuals are transferred by infection from the S to the I population. This generates the D-shaped

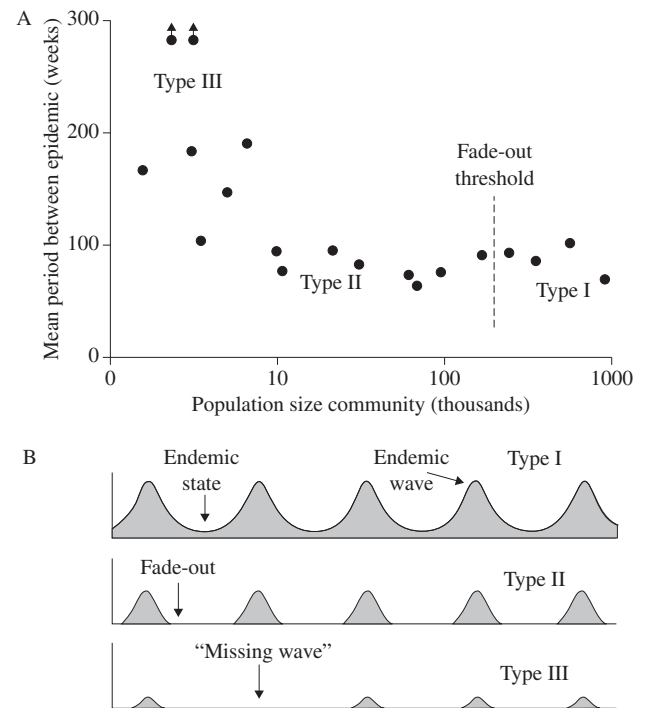

Figure 10 Bartlett's findings on city size and epidemic recurrence. (A) The impact of population size on the spacing of measles epidemics for 19 English towns. (B) Characteristic epidemic profiles for the three types indicated in (A). Reproduced from Haggett (2000, Fig. 1.8, p. 23) by permission of Oxford University Press.

relationship over time between sizes of the S and I populations shown on the end plane of the block diagram.

With measles, if the total population of a community falls below the quarter-million size threshold, as in settlements B and C of Fig. 11, epidemics can, as has been noted above, only arise when the virus is reintroduced by the influx of infected individuals (so-called index cases) from reservoir areas. These movements are shown by the broad arrows in Fig. 11. In such smaller communities, the S population is insufficient to maintain a continuous record of infection. The disease dies out and the S population grows in the absence of infection. Eventually the S population will become large enough to sustain an epidemic when an index case arrives. Given that the total population of the community is insufficient to renew the S population by births as rapidly as it is diminished by infection, the epidemic will eventually die out.

It is the repetition of this basic process that generates the successive epidemic waves witnessed in most communities. Of special significance is the way in which the continuous infection and characteristically regular type I epidemic waves of endemic communities break down as population size diminishes into discrete but regular type II waves in community B and then into discrete

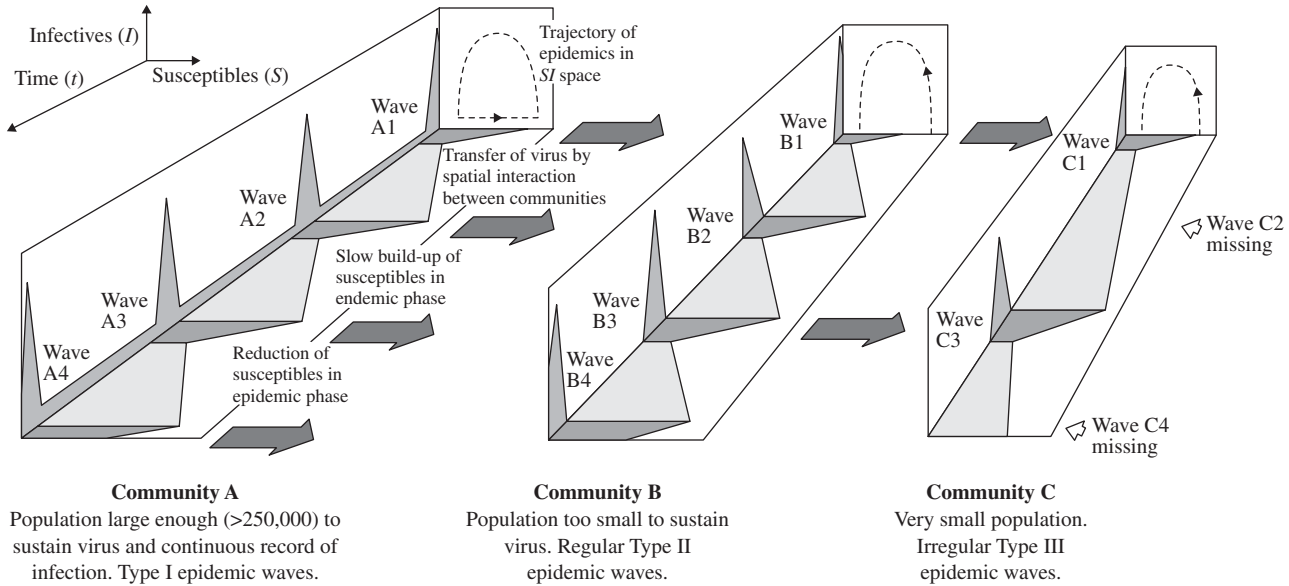

Figure 11 Conceptual view of the spread of a communicable disease (measles) in communities of different population sizes. Stages in spread correspond to the Bartlett model. Reproduced from Haggett (2000, Fig. 1.9, p. 25) by permission of Oxford University Press.

and irregularly spaced type III waves in community C. Thus, disease-free windows will automatically appear in both time and space whenever population totals are small and geographical densities are low.

The Chain Binomial Model

A second set of epidemic models based on chain frequencies has been developed in parallel with the mass action models. A major distinction exists between two types of model in the level of data grouping at which they are designed to operate. The mass action model was constructed for use with aggregated data, and it can be readily adapted to deal with spatial units at the regional, national, and international levels. Conversely, the chain binomial was originally developed for the micro-scale analysis of intra-family chains of transmission of infectious diseases.

Cliff *et al.* adapted the chain binomial to provide forecasts at the aggregated data level used at a regional scale. The basic model for a single district supposes that it is possible to record the state of the system at times $t = 1, 2, \dots$. Ideally, the time interval between recording points should correspond in length to the serial interval of the disease. This ensures that multiple epidemic cycles in a single time period are not witnessed, provided that each infected individual is isolated after the appearance of symptoms. The total population in a given district at the beginning of time period t , denoted by N_t , will contain S_t susceptibles, I_t infectives, who can transmit the disease to susceptibles, and R_t removals. During the r th time period,

N_t may be modified by the addition of A_t arrivals (births and/or immigrants) and the loss of D_t departures (deaths and/or emigrants). Finally, let X_t denote the number of new cases that occur in time period t .

The following accounting identities may then be written down for each medical district:

$$\begin{aligned} N_{t+1} &= N_t + A_t - D_t, \\ N_t &= S_t + I_t + R_t. \end{aligned} \quad (7)$$

If $\alpha_t A_t$ denotes the number of individuals among the new arrivals who are infectives, while $\delta_t D_t$ denotes the number of infectives among the departures, then

$$I_{t+1} = I_t + X_t - [R_{t+1} - R_t] + \alpha_t A_t - \delta_t D_t. \quad (8)$$

The arrivals term in Eq. (8) is vital in cases considering a disease that has to be re-imported into an area after local fade-out; these arrivals are the individuals who trigger a recurrence of the disease when the number of susceptibles is high.

Kendall and Spatial Waves

The relationship between the input and output components in the wave-generating model has been shown by Cambridge statistician David Kendall to be critical. If the magnitude of the input by the diffusion coefficient (β) and the output by the recovery coefficient (γ) is measured, then the ratio of the two, γ/β , defines the threshold (given by the Greek letter rho, ρ) in terms of population size. For example, where γ is 0.5 and β is 0.0001, ρ would be estimated at 5000.

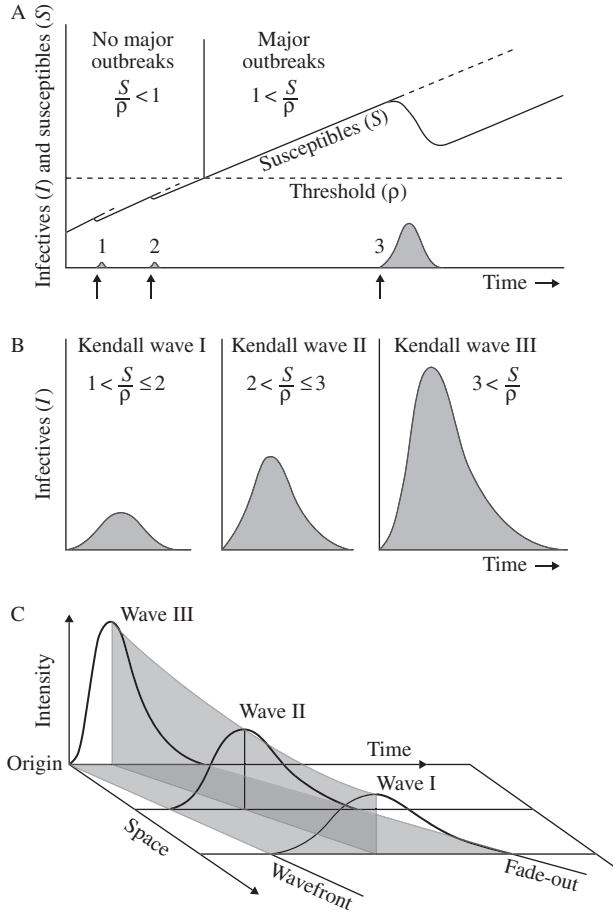

Figure 12 Kendall model of the relationship between the shape of an epidemic wave and the susceptible population/threshold ratio (S/ρ). (A) Growth of a susceptible population over time showing the effect of infections (see arrows). (B) Three typical Kendall waves. (C) Generalized Kendall wave train in time and space. Reproduced from Haggett (2000, Fig. 1.10, p. 27; Fig. 1.11, p. 28) by permission of Oxford University Press.

Figure 12A shows a sequence of outbreaks in a community in which the threshold has a constant value; it is therefore shown as a horizontal dashed line. Given a constant birth rate, the susceptible population increases and appears as the solid diagonal line rising over time. Three examples of virus introductions are illustrated (arrows). In the first two (1, 2), the susceptible population is smaller than the threshold ($S < \rho$), and there are a few secondary cases but no general epidemic. In the third example of virus introduction (3), the susceptible population has grown well beyond the threshold ($S \gg \rho$); the primary case is followed by many secondaries and a substantial outbreak follows. The effect of the outbreak is to reduce the susceptible population as shown by the offset curve in the diagram.

Kendall has investigated the effect of the ratio S/ρ upon the shape of epidemic waves (Fig. 12B). With a ratio of

less than one, a major outbreak cannot be generated; above one, both the probability of an outbreak and its shape changes with increasing S/ρ ratio values. In Kendall type I waves, the susceptible population is only slightly above the threshold value. Such waves will have a low case incidence, are symmetric in shape, and have only a modest concentration of cases in the peak period; as Fig. 12B shows, a Kendall wave I approximates a normal curve. In contrast, wave III is generated when the susceptible population is well above the threshold value. The consequent epidemic wave has a higher incidence, is strongly skewed toward the start, and is extremely peaked in shape with many cases concentrated into the peak period. Wave II occupies an intermediate position and is included to emphasize the changing waveforms as examples from a continuum. A generalization of Kendall waves in both time and space is plotted in Fig. 12C.

Time Series Modeling

Autoregressive-Moving Average Methods

The basic philosophy of these methods is that the past behavior of regional systems provides the key to how they will act in the future, and that this can be modeled using autoregressive and moving average components. Figure 13 illustrates such a space-time propagation system for a measles epidemic that affected Iceland in 1958. Measles virus, which is not endemic in Iceland, was introduced into Reykjavík, the medical district of the capital city, in August. It then spread to the north coast settlement of Akureyrar in September before diffusing on to Ólafsfjarðar and Grenivík by November. Let x_{it} denote the value of a variate in region i at time t —for example, the number of measles cases reported in Akureyrar in October 1958 (see Fig. 13). Time periods earlier than t are indexed by $t - k$, and periods later than t by $t + k$. Let Akureyrar be the reference medical district, i , and let j denote other medical districts. The pattern of dependencies among medical districts outlined above may thus be formulated as shown in Fig. 13.

The dependency of an area's behavior upon what happened in that area in the past is referred to as an autoregressive component, and the dependency upon other areas as space-time covariances. In an extension of the conventional autoregressive notation proposed in Cliff *et al.*, such models may be referred to as space-time autoregressive (STAR) models, and

$$E(X_{it} | \text{past history}) = b_1 x_{i,t-1} + b_2 \sum_j w_{ij} x_{j,t-1}$$

$$i, j = 1, 2, \dots, n; j \neq i$$

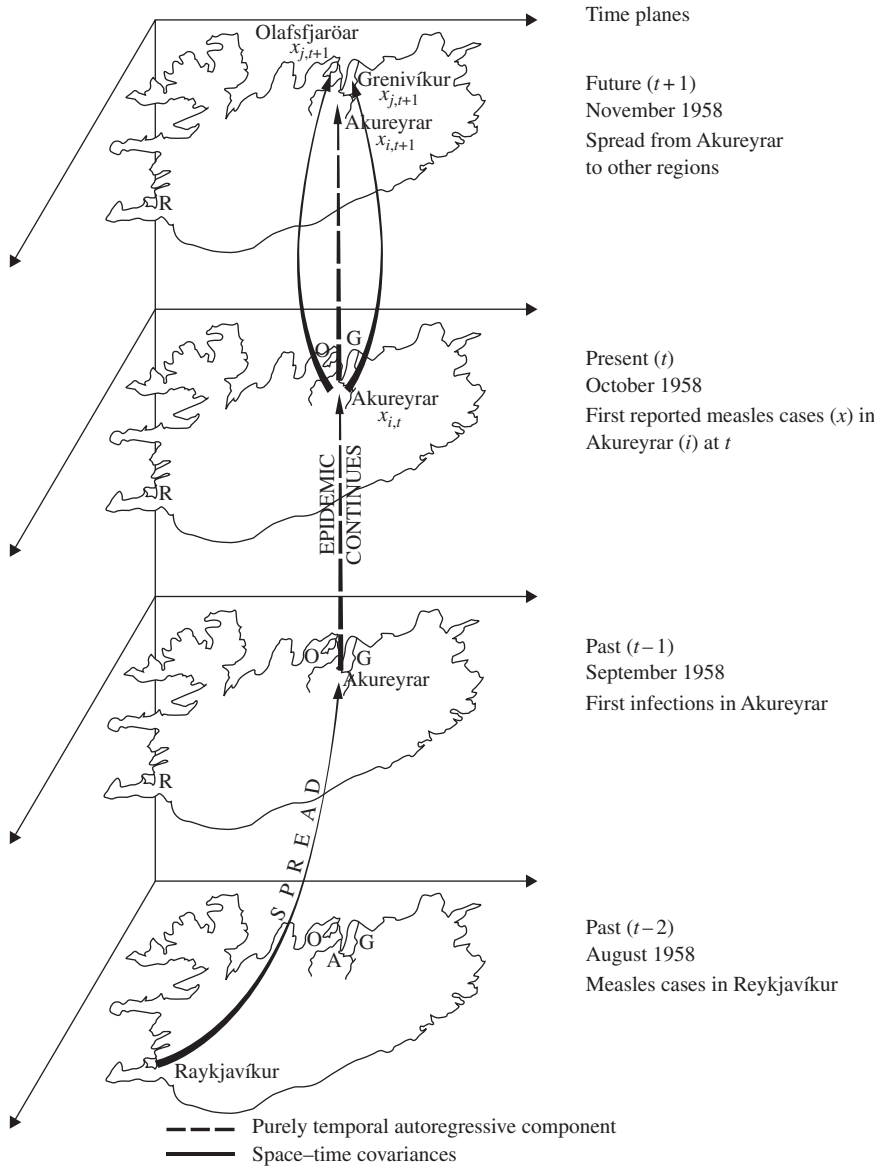

Figure 13 Patterns of dependencies among medical districts for part of the 1958–1959 measles epidemic wave in Iceland. Reproduced from Cliff *et al.* (1981, Fig. 6.1, p. 133) with the permission of Cambridge University Press.

is a typical model. Here, b_1 and b_2 are parameters to be estimated, the w_{ij} are pre-specified, non-negative, structural weights indicating which areas, j , affect i , and the summation is over all areas j for which $w_{ij} \neq 0$. It is assumed that there are n areas of interest in the space-time system. There is no reason why the temporal dependency should be restricted to a single past map, and Eq. (9) could be extended to earlier time periods.

It often happens that change over time cannot be accounted for solely in terms of systematic components such as those in Eq. (9), and random shocks may be envisaged arriving in a region both from other areas and from within itself on past maps. Thus, a space-time

random shocks, or moving average, model (STMA) might be postulated as

$$x_{it} = \varepsilon_{it} + b_1 \varepsilon_{i,t-1} + b_2 \sum_j w_{ij} \varepsilon_{j,t-1}, \quad (10)$$

where b_1 and b_2 are parameters, and the epsilons (ε) are random shocks with zero means, constant variances, and zero intercorrelations. As before, the model could be extended to cover more than one time lag and any order of spatial interaction. Additionally, Eqs. (9) and (10) can be combined to define a general STARMA model.

Writing down Eqs. such as (9) and (10) is the easy part of the task. The difficulties arise in three areas: (1) Which

model is appropriate for the problem in hand—STAR, STMA, or STARMA? (2) What order of spatial and temporal lags should be included in the model once it is selected? (3) How is the model fitted? Problems (1) and (2) constitute the so-called identification and specification problems, while (3) raises issues of estimation and, in turn, whether the assumptions of the model proposed hold for the data set being analyzed.

Adaptive Time-Series Models

Cliff *et al.* considered a number of alternative time-series models and applied them to Icelandic epidemic data. These are the Kalman models, which formulate a diffusion process that is dynamic in its parameters, that is, whose parameters can be changed and updated as fresh information arrives. Other models are the Bayesian-entropy methods, which handle problems associated with (1) the non-stationarity of the process, in particular, how to handle epidemic/no-epidemic changes to avoid lagged forecasts, and (2) growth/decline in the S population due to changes in birth rates and/or net migration.

Assume that, for a particular study area affected by an epidemic, a Poisson process, I_t is observed for the number of infectives at time t , with mean level φ_t , which depends upon past levels of the process. Suppose that, at any time t , the generating model is a random choice between two models (that is, two states):

$$M_t^{(1)}: \text{Model 1 (no epidemic): } \varphi_t = \varphi_c, \text{ where } \varphi_c \text{ is a small positive constant} \quad (11)$$

$$M_t^{(2)}: \text{Model 2 (epidemic): } \varphi_t \text{ is a gamma-distributed random variable.} \quad (12)$$

Equation (11) states that when there is no epidemic, the observations come from a Poisson process with a constant, low-valued rate ($\varphi_t = \varphi_c$). This implies the assignment of a high probability to the occurrence of small-valued observations (depending on the selected value for φ_c), and almost zero probability to the occurrence of high-values observations. On the other hand, with $M_t^{(2)}$ in Eq. (12), φ_t is a gamma-distributed random variable, and the model itself corresponds to the single-steady Poisson-gamma Bayesian-entropy forecasting model.

Applications of the models show that the change from epidemic to no-epidemic conditions in medical districts causes difficulties that can be properly tackled only by having separate models for each state, and then switching from one to the other at the appropriate time. Defining a switching mechanism may not be straightforward. One possibility is to have an online surveillance system to pick up early isolated cases heralding the approach of an

epidemic, and to use this to trigger a switch between state models. Another is to identify disease lead indicator areas (for example, the capital medical district, Reykjavík, in the case of Iceland) and to allow the presence of infection in this district to give the impulse for an epidemic in other areas. Without this spatial trigger, it is doubtful whether it will be possible to forecast epidemic starts with any reliability, although the mixed-state model allows quick identification of a new epidemic. Nevertheless, early warning of the approach of an epidemic is obviously necessary if control is to be effected through vaccination and isolation programs.

Perspectives on Diffusion Modeling

Over the last century an armada of different models has been developed and applied to spatial diffusion data. From the experience gained in applying such models to epidemiological data, the view of the strengths and weaknesses of such models is as follows:

1. No “Rosetta stone” model that gives reasonable projections of (a) epidemic recurrences and (b) epidemic size has yet been found. Generally, if a model such as the Hamer-Soper model that forecasts well epidemic recurrences is devised, epidemic size is overestimated. This is because to forecast recurrences properly, the model has to be made sensitive to changes signaling the approach of an epidemic, with the result that it can overshoot amplitude when the epidemic is in progress.

2. Models that are based only on the size of the infective population in previous time periods—a common feature of some time-series models—consistently fail to detect the approach of an epidemic. Instead, they provide reasonable estimates of cases reported, but tend to run in arrears.

3. Models with parameters fixed through time have a tendency to smooth through the highs and lows of an epidemic because they are unable to adapt to the changes between build-up and fade-out phases of an epidemic. Time-varying parameter models are better at avoiding this problem.

4. Epidemic recurrences can be reasonably anticipated only by incorporating into the model information on the size of the susceptible population and/or properly identifying the lead-lag structure among medical districts for disease transmission. Incorporation of spatial interaction information markedly improves the ability to forecast recurrences in lagging areas. Information on susceptible population levels also serves to prime a model to the possibility of a recurrence. Models based on susceptible populations, but that are single- rather than multi-region, tend to miss the start of

epidemics but rapidly lock on to the course of an epidemic thereafter. Models that are dominated by spatial transmission information at the expense of information on the level of the susceptible population in the reference region produce estimates of epidemic size that reflect the course of the epidemic in the triggering regions rather than in the reference region.

5. Process models, such as the mass action models described previously, can serve to strengthen the time series models and identify a more reliable scheme for forecasting.

The overall assessment is that spatial diffusion modeling has made significant progress over the last half-century. Part of that progress has come from improved understanding of the epidemic process, part from revolutions in computing, part from changes in the mathematics used, and part from improved incorporation of spatial elements into the models. On the negative side, it should be noted that such progress is broadly asymptotic, with each new improvement step being more difficult to achieve than the earlier ones.

Modeling Migration

Michael J. Greenwood

University of Colorado, Boulder, Colorado, USA

Glossary

determinants of migration The personal and regional factors that influence migration decisions.

disequilibrium perspective The idea that wage differentials provide opportunities for utility gains.

equilibrium perspective The idea that wage differentials are compensated and therefore do not offer opportunities for utility gains.

gravity model A place-to-place migration model that assumes that interregional migration is directly related to the population of the origin and of the destination regions and inversely related to the distance between them.

human capital model A model that treats migration as an investment with future expected returns and costs and that discounts these to arrive at a best present discounted value of a move.

migration The change of an individual's usual place of residence from one migration defining area to another during a migration interval.

migration interval The period of time over which a migratory move may occur.

migration propensity The probability of making a migratory move.

model The abstract depictions and simplifications of a complex real-world process, which may or may not be expressed mathematically.

modified gravity model A place-to-place migration model that adds to the basic gravity model additional variables relating to origin and destination characteristics.

Modeling migration refers to ascertaining the factors that underlie decisions to migrate (or not migrate). Such models also address the personal as well as the regional consequences of migration. The models are abstract depictions and simplifications of complex real-world processes that may or may not be expressed mathematically.

Empirical models attempt to ascertain the relative importance of various determinants of migration and, in the case of models of the consequences of migration, to ascertain migration's role, along with other factors, in various economic and social outcomes at the personal and the regional level (such as personal earnings change and regional employment, unemployment, or wage change).

Introduction

Migration is inherently a spatial phenomenon. It entails a change in an individual's usual place of residence from one migration-defining area to another over a given period of time (called the migration interval), which may be a month, a year, a 5-year period, a life time, or some other interval. Because it is a spatial phenomenon, modeling migration must refer to at least two regions, even if the second region is "somewhere else." Migration phenomena may be modeled theoretically or empirically. The best empirical models have strong theoretical underpinnings. Migration models attempt to explain either the causes of personal, family, or aggregate interregional migration or the consequences of migration. Thus, the distinguishing feature of a migration model is that it is an attempt to explain, which is to say that it constitutes an effort to answer the question: Why does a certain migration phenomenon occur? Like any good model, migration models may also allow the investigation to predict, but migration models have not frequently been used for predictive purposes.

All migration models begin with the basic assumption (most frequently made implicitly) that migration is a voluntary human act. However, much migration is clearly involuntary. Examples of involuntary migration are the movement of prisoners and the relocation of military personnel. The migration of refugees of war,

political strife, and religious differences is also regarded as involuntary in the sense that such individuals move to escape persecution and/or death and therefore seek at least initially to get away; the personal consequences of migration for refugees have been studied. Models of voluntary migration seek to explain the presumably utility-maximizing behavior of free individuals.

Migration models address several broad questions: (1) Who migrates? (2) Why do these people migrate? (3) Where do the migrants come from and where do they go? (4) When do they migrate? and (5) What are the consequences of migration for the migrants themselves as well as for others in the origin and destination areas? Theoretical migration models tend to address the “Why?” and the “Where?” questions, and to a lesser extent the “What are the consequences?” question. Very little theoretical work has ever been done on the “Who?” and the “When?” questions, although numerous descriptive accounts of who migrates go back to the nineteenth century. The question “Who migrates?” refers to various characteristics of the migrants, such as age, education, race, income, marital status, and presence of children in the household.

The relationships between age and education, on the one hand, and migration, on the other, are among the most commonly studied migration relationships. Model migration schedules have been developed to shed light on the exact relationship between age and the propensity to migrate for various population subgroups. These schedules indicate that in the United States annual intercounty migration propensities peak at 23–25 years of age (at approximately 7.5%) and decline steadily until approximately 62 years of age (to approximately 1.5%). These propensities differ greatly for various population subgroups. For example, depending on age, migration propensities are between two and four times higher for those with 5 years or more of college compared to those with 8 years or less of elementary school.

Because migration declines sharply with increased distance, propensities to move over longer distances are considerably lower than for shorter distances. Thus, interstate migration propensities, as indicated in Table I, are somewhat lower than the intercounty propensities. The

tendency for annual interstate migration propensities to rise with education and fall with age is clearly evident in Table I. For example, 6.18% of those individuals ages 25–29 with only a bachelor’s degree made a U.S. interstate move between 1993 and 1994, but 3.67% of those in the same age class with a high school diploma only made a similar move during the same period. And whereas 6.18% of the 25–29 age group with a bachelor’s degree made an interstate move, only 2.58% of those in the same education class but ages 45–64 did so.

Theoretical Perspective

Economic models of migration, as well as models that derive from other disciplines, take one of two possible broad theoretical perspectives: (1) the disequilibrium perspective or (2) the equilibrium perspective. The theoretical perspective taken in almost all migration research conducted by economists and others prior to the late 1970s was that of a disequilibrium system. The perspective is called disequilibrium because migration is assumed to be motivated by the existence of a set of nonmarket clearing regional wages. The idea is that spatial differences in wages, earnings, or income reflect opportunities for utility gains that can be realized through migration. In more recent years, this disequilibrium perspective has been challenged by proponents of the equilibrium hypothesis, which assumes that spatial differences in wages are compensating and therefore do not reflect opportunities for utility gains. Thus, a basic assumption underlying models based on one or the other of these perspectives is considerably different.

The disequilibrium approach does not rely on location-specific amenities, and regional wages and regional rents adjust slowly to exogenous disturbances. In the equilibrium approach, migration is conditional on amenities. Moreover, this approach does not rely on long adjustments of wages and rents to disturbances, especially in the United States where institutional and other impediments to factor mobility are relatively low. Systematic long-term forces, such as rising real income in some or all locations, underlie in an important way consumption

Table I U.S. Interstate Migration Propensities by Age and Education Class, 1993–1994^a

Education	Age					
	Under 25	25–29	30–34	35–44	45–64	65 & over
All 25 & over	2.38	4.72	3.26	2.50	1.68	1.22
Less than ninth grade	1.33	3.69	2.01	2.08	1.03	1.00
High school graduate	1.98	3.67	2.60	2.12	1.53	1.06
Bachelor’s degree	3.41	6.18	4.45	2.91	2.58	1.36
Graduate/profession degree	3.14	8.96	5.10	2.79	2.07	2.61

amenity demand growth and provide the rationale for migration. Thus, both the disequilibrium and equilibrium approaches assume that spatial variations in utility underlie the motive to migrate, but the differences spring from the source and persistence of the variations. The perspective taken by the analyst not only shapes the precise form of the model that is specified and estimated, it also contributes to the interpretation placed on the estimated coefficients of wage and other variables.

Gravity and Modified Gravity Models

Although they are not often credited with the development of the gravity law of spatial interaction, in 1938 economists Makower, Marschak, and Robinson clearly laid out the basic concept: "Quite a close relationship was found between discrepancies in unemployment rates and migration of labour where allowance was made for the size of the insured population and the distance over which migrants had to travel." The key to the gravity model is the relationship between migration and distance, as well as between migration and origin and destination population sizes.

During the 1940s, Princeton astronomer Stewart noted that the distance to his students' home towns seemed to behave like the Newtonian law of gravitation. Thus, Stewart expressed the gravity law of spatial interaction as $F = GP_iP_j/D_{ij}^2$, where F = Gravitational or demographic force, G = Constant, P_i = Population of origin i , P_j = Population of destination j , and D_{ij} = Distance between i and j . This relationship states that demographic force is directly related to the origin and destination population sizes and inversely related to the square of the distance between them. If the square on the distance term is replaced by α and the relationship is placed in the migration context by substituting migration from i to j , M_{ij} , for F , we get $M_{ij} = GP_iP_j/D_{ij}^\alpha$. If this model is expressed in double-log form, it suggests that the population parameters are equal to 1.0, meaning that a 1% increase in origin or in destination population results in a 1% increase in migration from i to j . This assumption is clearly restrictive, and the population elasticities are subject to empirical tests. Thus, the gravity model can be written as:

$$M_{ij} = \frac{GP_i^{\beta_1}P_j^{\beta_2}}{D_{ij}^\alpha}.$$

In this form, the values of β_1 and β_2 may be freely estimated, and the hypothesis that they are equal to 1.0 may be tested. This basic form of the gravity model was tested rarely because little additional effort was required to specify and estimate the more appealing modified

gravity model. Moreover, when β_1 and β_2 are estimated freely, their values are rarely equal to 1.0.

During the 1960s, the main thrust of migration research took on a decidedly more formal tone that has continued to the present. Most of the research was not formal in a theoretical sense but rather intuitively generated hypotheses were at first tested formally in an econometric sense with aggregate data, typically (but not always) with place-to-place migration data. These aggregate models of migration frequently were specified in the context of modified gravity models. The models are of the gravity type, in that migration is hypothesized to be directly related to the size of relevant origin and destination populations and to be inversely related to distance. The models are modified in the sense that the variables of the basic gravity model are given behavioral content and additional variables that are expected to influence the decision to migrate are included in the estimated relationship.

The modified gravity models that became common in the migration literature beginning in the 1960s add several additional variables to those of the basic gravity model. Thus, we commonly find studies of place-to-place migration that take the following form:

$$\begin{aligned} \ln M_{ij} = & \ln \beta_0 + \beta_1 \ln D_{ij} + \beta_2 \ln P_i + \beta_3 \ln P_j \\ & + \beta_4 \ln Y_i + \beta_5 \ln Y_j + \sum_{n=1}^m \beta_{in} \ln X_{in} \\ & + \sum_{n=1}^m \beta_{jn} \ln x_{jn} + e_{ij} \end{aligned} \quad (1)$$

where the Y terms refer to income. Other variables that are commonly included (as reflected in terms containing X) are unemployment rates, degree of urbanization, various climatological amenity variables, various measures of public expenditures and/or taxes, and many other factors. For certain variables, some models contain only origin characteristics, such as median age or median number of years of schooling, which are meant as proxies for the characteristics of the population from which the migrants are drawn. Modified gravity models hold an important place in the migration literature because their formulators tried to incorporate behavioral content into the context of the gravity model approach. These efforts subsequently led to formal models of the migration decision process, such as those reflected in many studies that incorporate microdata. Moreover, such models included a mix of disequilibrium and equilibrium notions that anticipated the later, more rigorous development of the equilibrium hypothesis of migration.

The connection between modified gravity models and the migration decision process has not always been tight. The dependent variable in modified gravity models is

meant to proxy the probability of moving from i to j . However, the denominator of the dependent variable frequently has been the population measured at the beginning or end of the migration interval. Such a measure falls short of reflecting the population at risk to make a move from i to j . For example, the beginning-of-period population includes people who die during the period over which migration is measured, as well as those who emigrate from the country and who are thus not available to be counted as migrants. The end-of-period measure includes in-migrants who were not at risk of being out-migrants from the area and also introduces simultaneity between migration and the population measure.

Modified gravity models are frequently estimated in double-logarithmic form, presumably because this functional form yields reasonably good fits and the coefficients obtained from it can be directly interpreted as elasticities of migration's response to changes in the various independent variables of the estimated models. However, common use of the double-logarithmic functional form to estimate modified gravity models has led to arguments for the adoption of nonlinear maximum likelihood logit methods over the double-log form of the model. In part, the argument hinges on the geographic size of the regions for which migration is measured. If all regions had the same population and land area, the migration and non-migration probabilities would reflect the costs and benefits of the various locational choices. However, the regions of any country differ greatly in population and land area. A larger share of all moves will tend to occur within the boundaries of larger regions. Consequently, more non-migration will appear to exist for such regions. The result is that nonmigration is spuriously correlated with origin population size and land area.

In the polychotomous logistic model, the migration probabilities are expressed as ratios and the probability of not migrating is used in the denominator of the expression to normalize the flows. That is, the dependent variable is $\ln[m_{ij}/(1 - m_{ij})]$, which is sometimes called the logarithm of the odds ratio. Here m_{ij} refers to the probability of migration from i to j and is thus measured as M_{ij} , or the actual number of movers from i to j divided by the population at risk to migrate from i . The model can be estimated in one of two ways that make sense in the migration context. First, again assuming the double-log form of the model, the log of the ratio of various destination-to-origin characteristics can be used. This approach, referred to as uniform symmetric, implies that coefficients on variables for corresponding origin and destination characteristics are the same except for sign. Second, a two-step decision process can be assumed in which the decision maker first decides to migrate and then decides where to migrate based on destination characteristics and perhaps other variables (such as distance) that link the areas. In

this case, origin and destination characteristics are introduced separately. In an analogous fashion, nested decision trees could be constructed for other levels of the decision process (e.g., whether to move, where to move, and what house to select). Some dissatisfaction has been expressed with the notion that individuals can decide whether to move independently of deciding where to move. Thus, whether to move and where to move are seen as joint decisions and not discrete and independent decisions.

The standard gravity approach is seen as inefficient because it fails to incorporate information on the relative frequency of nonmigration ($1 - m_{ij}$). However, as the migration interval grows shorter and shorter, the two specifications approach one another because the population at risk to migrate becomes a better measure of the nonmigrating population when the migration interval is very short. In any case, the logit approach provides a more natural transition from the gravity model to the more behaviorally grounded modified gravity model.

Prior to 1975, virtually all migration research was based on aggregate data. In addition to the problem already noted, modified gravity models were characterized by other problems and shortcomings frequently associated with the use of such data. Aggregate data often were used to proxy the characteristics of the population at risk to move, resulting in empirical estimates that did not reflect accurately the influence of personal characteristics on the decision to migrate. With some notable exceptions, studies of aggregate migration failed to account for different types of moves, such as primary (or new), return, and other repeat migration. Aggregate data also concealed differences in the underlying determinants of migration of various population subgroups, although stratification by age and race was not uncommon. Such data failed to account for the institutional population, of which the military was especially important, and they made the study of family migration decisions difficult. Another problem with modified gravity models was that the variables used to explain migration often were measured at the end of the migration interval and were thus subject to simultaneity bias. During the 1970s, several simultaneous equations models were developed to explain the causes and consequences of migration within the same empirical framework, but for the most part during the last several years these models have not been developed further.

The Human Capital Model

Underlying the disequilibrium perspective, at least implicitly, is the simple income-leisure model of labor economics wherein an optimizing agent maximizes a utility function with two arguments, income and leisure, subject to a full-income constraint. One implication of this model

is that the individual will supply labor such that the marginal rate of substitution of consumption for leisure equals the wage rate, which in turn implies that the individual labor supply is a function of the wage rate. If we abstract from mobility costs and accept many other assumptions that underlie this simple yet powerful model, the individual is expected to offer his labor services in the market with the highest wage, which may require migration.

The human capital approach was added to the disequilibrium perspective that was then in vogue. This model provided a paradigm that caught the attention of economists and provided a convenient theoretical framework for their research.

Present Value Comparisons

The potential migrant will select the locality at which the real value of the expected net benefit that accrues to him or her from migration is greatest. The income that the individual expects to earn at each alternative destination enters crucially into his judgment concerning the benefits associated with each location. The relevant income measure for the individual to consider is the present discounted value of his or her expected future stream of net pecuniary returns.

Let the present value of the earnings stream in locality j less that in i be:

$$\sum_{t=1}^n \frac{(E_{jt} - E_{it})}{(1+r)^t} \quad (2)$$

where r is the internal rate of discount, which although written as a constant does not have to be constant. Let the present value of net costs associated with residence in this pair of localities be:

$$\sum_{t=1}^n \frac{(C_{jt} - C_{it})}{(1+r)^t}. \quad (3)$$

The summation is over the individual's remaining life. Then, the present value of investment in migration from i to j , PV_{ij} , is:

$$PV_{ij} = \sum_{t=1}^n \left[\frac{1}{(1+r)^t} \right] [(E_{jt} - C_{jt}) - (E_{it} - C_{it})]. \quad (4)$$

An individual residing in i will presumably select that destination for which PV_{ij} is maximized.

The disequilibrium perspective is clearly evident in this model of migration. In the human capital model, economic opportunity differentials represent potential for household utility gains that can be arbitrated by migration. For all intents and purposes, the human capital model was unrivaled for almost 20 years. Indeed,

disequilibrium forces were presumed to be the primary drivers of migration long before the human capital model provided an explanation for migration. Many of the early authors recognized that both disequilibrium and equilibrium forces were at work, but they clearly emphasized the disequilibrium factors.

The human capital model provided an appealing rationale for the presence of income variables in modified gravity models, as well as in other models of migration. Based on the disequilibrium perspective, in modified gravity models the origin wage or income variable is expected to take a negative sign, whereas the destination wage or income variable is expected to take a positive sign because migrants move out of low-income areas and into high-income areas. A number of studies have tested this assertion regarding the importance of wages in explaining migration by examining the factors affecting interregional migration in the United States and in many other countries. Based on aggregate data, the empirical findings associated with income, earnings, and wage variables in modified gravity models have not been uniformly strong, although it is probably fair to conclude that the weight of available evidence favors disequilibrium results, particularly for rural-to-urban migration. Of course, the exact results are sensitive to many factors, such as the precise specification of the model, the country and period studied, the population subgroup under investigation, the type of functional form assumed, and the estimation technique employed. Moreover, income or wage measures have almost never been refined to reflect real consumption wages. This is to say that the role of taxes and public services has not received the attention it deserves.

Spatial Job-Search Models

Another type of migration model that sprang from the human capital approach places migration in the context of a spatial job search. The human capital model suggests that individuals compare their opportunities in alternative localities with their present situation. However, to learn about opportunities in other areas, they must conduct a search that yields a distribution of wage offers in each alternative. Presumably, these individuals have a reservation wage (the lowest wage they would accept in a potentially new region of residence). If the person is unemployed, this reservation wage may fall over time. However, he or she would reject any opportunities that yielded a wage below the reservation wage. The duration of the search extends until the individual receives a wage offer that is at least equal to the reservation wage. The reservation wage itself is dependent on the person's age, education, marital status, family situation, and numerous other personal characteristics, as well as on regional characteristics, such as the unemployment rate.

More on the Equilibrium Perspective

Due in part to the fairly consistent tendency for empirical studies based on aggregate data to fail to confirm the importance of wages or income in migration decisions, the equilibrium approach has been offered as an alternative to the traditional disequilibrium perspective. The equilibrium theorists begin by assuming that households and firms are in proximate equilibrium at any point in time. This assumption means that the marginal household and firm, while maximizing utility and profit, respectively, are spatially arrayed so as to receive zero consumer and producer surplus from their location. Any movement from the general equilibrium configuration cannot improve utility or profit.

According to the equilibrium approach, changes in life-cycle factors or generally rising real incomes continuously change the demand for consumer amenities. Real incomes may rise due, for example, to persistent technical progress. Because amenities are not evenly distributed spatially, migration occurs and quickly re-equilibrates households. Net in-migration to amenity-rich areas tends to drive down wages and drive up the prices of locally produced goods, services, and land, *ceteris paribus*. In amenity-poor areas, opposite patterns of change occur. Wages and local prices diverge across regions until they just compensate households for the differing amenity bundles that the various regions supply.

The equilibrium approach has another important facet. A number of studies use the level of regional wages or rents to measure regional environmental quality, including the quality of the climate. The assumption underlying these studies is that equilibrium prevails so that wage and rent differentials are compensating differentials and thus serve as accurate proxies for differentials in environmental quality. For equilibrium to prevail, regional markets must be efficient so that regional wages and prices quickly realign to clear such markets subsequent to any disequilibrating exogenous disturbances. The equilibrium proponents believe that, at any point in time, it is highly likely that regional wages and prices have adjusted to their equilibrium values.

In the equilibrium approach, regional differentials in wages and prices do not generally reflect utility differences that can be arbitrated through household migration. Only those noncompensating regional differentials that remain after controlling for amenity differentials across regions should represent utility differentials that would induce migration. As previously noted, the implication of this view for migration analysis is that a properly specified migration equation should include both regional amenity and regional wage and rent variables. For this reason, proponents of the equilibrium

hypothesis typically include a wide variety of regional amenities in their empirical models. Among the variables frequently included are climatological amenities (e.g., average temperature at some time during the year, average humidity, and degree days) and topological amenities (e.g., the presence or absence of a sea coast, variety of terrain, and national forest lands).

From an economist's perspective, an equilibrium process makes great sense. Without the operation of such forces, economists would be hard pressed to develop a reasonable theory to explain interregional movements and the adjustments that result therefrom. However, for the most part, until recently tests of the equilibrium hypothesis in the context of the migration literature have not been fully convincing.

Modeling Migration with Microdata

As already noted, prior to 1975 virtually all empirical migration models employed aggregate cross-sectional data. However, during the 1970s a number of important advances occurred in the modeling of migration that were contingent on the development of new data sets. Two types of data were critical in the sense that the advances simply could not have occurred without them. The first and certainly the most important involved the development of microdata and micro-based panel data that included a migration component; the second involved the development of aggregate time series migration data.

Aggregate data have a number of limitations for studying migration behavior.

1. Aggregate data, such as census data, have an inherent fixed migration interval, so that, for those who move multiple times, only the first and last location are available for study. Thus, an individual may move from i to j to k , but a move from i to k is recorded for the individual based on original and final places of residence. Moreover, an individual who moves from i to j and back to i during the migration interval appears as a nonmover. Although this objection also applies to certain microdata sets, such as the U.S. Census Public Use Microdata Samples (PUMS), microdata are in many instances better in avoiding this type of problem.
2. Aggregate data conceal the differences in the underlying determinants of migration for various population subgroups that are lumped together. Thus, the motives for migration may differ for the young versus the old, high-income versus low-income people, blacks versus whites, and so on. Some stratification is possible with aggregate data, but it is

generally limited. Thus, in general only variations between groups can be explained with aggregate data, not variations within groups.

3. Aggregate migration studies, with some notable exceptions, fail to account for the different types of moves, namely, new, return, and other repeat migration and long- and short-distance migration. However, in more recent years, with the availability of microdata, these types of distinctions have been more common, and several studies have uncovered significant differences in the magnitudes of the influence of various migration determinants on these different types of moves.
4. Aggregate data frequently fail to account for the movements of institutional populations, for examples, movements of military personnel and college students. Because the motives for such movements may have little or nothing to do with the migration determinants typically studied, these moves obscure the behavioral relationships of interest. Of course, it is often possible to remove institutional populations from the data being studied.
5. Aggregate data, given the heterogeneity that exists within the large regions between which migration is measured, may not represent the average characteristics of many of the moves that actually occur. For example, U.S. migration is frequently measured between states and even between the nine census divisions and between the four census regions. Moreover, many moves over substantial distances are omitted because they occur within the region. To some extent, this type of problem can be avoided by using finely defined regions as the spatial unit, such as counties or metropolitan areas.
6. Aggregate data allow the study of the regionwide consequences of migration, but in no way do they allow the study of the personal consequences of migration. Thus, any assessment of the personal consequences of migration was not possible until the development of microdata sets that included a migration component.

The development and use of several microdata and panel data sets during the 1970s and 1980s led to many important breakthroughs in the social sciences, including the study of migration in economics and sociology. Several data sets particularly stand out. The 1967 Survey of Economic Opportunity was one of the earliest microdata sets used to study migration. The PUMS from various censuses have been invaluable in allowing investigators to introduce personal characteristics into their models. Microdata from the Current Population Surveys have also been used to good advantage. Two panel data sets of particular note are the Panel Study of Income Dynamics (PSID) and the National Longitudinal Surveys (NLS).

Canadian microdata, particularly census data, have also been valuable. These are not the only microdata and panel data sets that have allowed major advances in migration modeling, but they are probably the most important.

In general, three types of migration models employ microdata and panel data: (1) those that use a dichotomous or polytomous dependent variable reflecting migration status (e.g., moved, did not move, or moved, changed job; or moved, did not change job; did not move, changed job) or destination choice as a function of various personal, household, and place characteristics; (2) those that use a measure of earnings or wages as a dependent variable and distinguish migrant vs. nonmigrant status and perhaps other characteristics of a move, such as distance—this latter type of study is couched in the human capital framework because it involves the estimation of earnings (or wage) functions; and (3) a small number of studies that use employment status or hours worked as a function of migration status, among other variables. Note that the last two types of studies relate to the personal consequences of migration.

Models of migration based on microdata have had a major impact on four general topics that have received considerable attention from students of migration.

1. They have allowed the development of important insights regarding the relationship between employment status and migration. Models based on aggregate data have frequently found unanticipated signs and/or insignificant coefficients on unemployment rate variables, but the availability of microdata has gone far toward clearing up the earlier puzzles regarding this relationship.
2. They have allowed more proper and more precise estimations of the monetary returns to migration. Studies in this general area have been based on the human capital model and have involved the estimation of earnings functions.
3. They have allowed the study of the relationship between various personal and life-cycle characteristics, on the one hand, and migration, on the other; these relationships are almost impossible to understand in any fundamental way in the absence of microdata and panel data. Although general tendencies are often discernible from aggregate data (e.g., migration propensities decline with age and increase with education), in the absence of microdata investigators are unable to control for many other factors when studying the relationship between any given factor and migration. An associated point is that family migration decisions are difficult to understand in a substantive way without the use of microdata.
4. They have encouraged researchers to examine primary, return, and nonreturn repeat migration more

closely than was possible using aggregate data. Based on microdata, a number of important differences have been uncovered in the responsiveness of different migrant types to the various determinants of migration.

Sample Selection Problems

With the development and use of microdata, a number of new econometric opportunities have become available, but at the same time certain econometric problems have been introduced. One of the most important of these problems in the migration context concerns sample selection.

Sample selection problems arise from situations in which a population subgroup is not representative of the entire population whose behavior is under study. Stated more formally, in the Manski's 1989 formulation, the problem is one "of estimating a regression $E(y|x)$ when realizations of (y, x) are sampled randomly but y is observed selectively." Some unobservable variable may distinguish population subgroups. The natural temptation is to analyze only the subgroup for which data are available, but this procedure may result in parameter estimates tainted by selectivity bias.

Sample selection problems in migration studies have many sources; four of the most common are (1) sampling design or population coverage, (2) panel attrition, (3) time-dependent disturbances, and (4) differential behavioral responses. The last of these is the typical cause of sample selection bias.

Sampling Design or Population Coverage

The first possible problem originates in the data used to study migration. Due to sampling design or, if the data are from an administrative source, population coverage, the data may not be representative of the entire population. For example, migration data derived from U.S. Internal Revenue Service files are selective of those with sufficiently high incomes that they are required to file an income tax return, and annual migration data for Canada derived from the Family Allowance System are selective of families with children. Many similar examples are available. This type of data shortcoming does not cause the usual sample selectivity problem, which refers to bias in the estimation of certain parameters. Rather, it leads to an inability to generalize from accurately estimated parameters.

Panel Attrition

Over time, some attrition is almost certain to occur within any panel. Families move and are difficult or impossible to trace. Others do not wish to put up with the effort of being interviewed repeatedly. For others, payments to

participants in the panel may become insufficient. Even though the lost panel members may be replaced with seemingly otherwise comparable individuals and families, systematic differences may well exist between those who remain in the panel and those who drop out. This causes bias when the attrition is correlated with the dependent variables in migration studies. Some unobservable differences may distinguish the groups, such as attitudes in general or attitudes toward risk. An advantage of panel data is that fixed-effect estimates may remove this source of bias. Any investigator who uses panel data sets such as the PSID and the NLS should study what is known about panel attrition in the data set and understand how attrition problems might affect the particular study under consideration.

Time-Dependent Selectivity Problems

A third potential source of sample selection problems also arises from the data, but specifically from the time period of the sample. Time-dependent selectivity problems occur when migrants from different periods are compared. The idea is that the model applies over a span of years, but the disturbance term is time-dependent (and perhaps a function of some latent, unobservable variable). Although this type of selectivity problem may occur in many contexts, two are particularly relevant to migration: secular problems and cyclical problems.

Secular Problems The education and training received by individuals during one period may differ from the education and training received during a later period. Thus, estimates of the monetary returns to different cohorts of migrants may be tainted. This type of bias may be especially important in the study of the returns to different cohorts of immigrants, who may differ systematically not only in education, training, and other personal characteristics, but also in the self-selective nature of their decision to migrate.

Cyclical Problems Little or no research has directly addressed the issue of changes in migrant quality over the business cycle, but such changes are expected to occur. Migrants tend to be self-selected in the sense that they are typically of greater innate ability and possess greater motivation for personal achievement than otherwise comparable nonmigrants. The self-selective nature of the migration decision should be more pronounced the greater the costs of migration, including the probability of finding a job and the costs of subsequent adjustment in the new occupational environment. During periods of relatively poor economic conditions, as indicated by slow national growth of job opportunities, the costs associated with migration are higher. These higher costs are due to more intensive job-search activities because access to entry-level jobs, as well as jobs providing

specific skill training, is more difficult. In contrast, during periods of more rapid national economic expansion, the probability of gaining access to jobs is increased and, consequently, the costs of migration are lower. Because the costs associated with migration are expected to be lower during a period of economic expansion, a lower degree of self-selection occurs in periods of relatively good economic conditions. In other words, when economic conditions are generally favorable, the average quality of the migrant flow is relatively lower. This lower quality may be manifested in labor force participation patterns or work motivation, as well as by general skill level. Virtually no research has addressed these issues.

Differential Behavioral Responses

The fourth potential source of a selectivity problem is also behavioral and is analogous to the classic selectivity bias. For examples, in 1976 Heckman wrote about the relationship between wage levels and female labor force participation. In the migration context, at least three types of self-selection may occur: favorable opportunities, remigration, and productivity.

Favorable Opportunities Migrants may be selective of those individuals with the most favorable opportunities, as suggested by Marshall in 1948. Rational economic agents select their chosen alternative because they have some basis for believing that it will yield a higher return than their other options. Consequently, those individuals who select a given alternative are not randomly drawn from the population as a whole. The fact that individual A migrates, whereas the otherwise comparable B does not, suggests that an important difference exists between the individuals. These differences may be in the way they view costs or in the way they view future benefits, and therefore could be due to differences in discount rates. Individual A, for example, may be more highly motivated to invest in human capital formation, not only in migration, but in other forms as well. If this is the case, the earnings of the remaining cohort from which the migrant is drawn may not provide an accurate estimate of the earnings the migrant would have received in the absence of migration. The resulting selectivity bias, if not properly taken into account, poses potentially serious problems in econometric attempts to estimate the return to migration. As Lewis pointed out in 1974, due to this type of problem the returns to nonmigrants are also biased.

Remigration Among those who migrate, some stay in the new place, whereas others move back to the original place or move on to a third location. If those who move back or move on are the economically least successful migrants, then the remaining migrants will bias upward any estimate of the returns to migration. The selectivity bias problem as associated with the remigration phenomenon

was raised by Yezer and Thurston in 1976: "The departure of unsuccessful migrants from a destination leaves a residual of successful lifetime migrants. Calculation of the returns to migrations based on these individuals alone results in an upward bias." Although remigration selectivity is potentially important in assessing the returns to internal migration, it seems especially relevant in estimating the returns to international migration because the presumably less successful immigrants who later leave are lost completely from any data collection system in the original country of immigration.

Productivity Individuals may sort themselves based on their productivity. In 1951, Roy discussed such self-selection in terms of occupations (hunting and fishing), but the same argument can be made for region of residence as well as for occupation. The sorting could be based on the individual's absolute advantage in a region (and occupation) or on his or her comparative advantage, but the basic idea is that he or she will locate in the region and work in the occupation that yields the highest expected relative earnings.

Controlling for Sample Selection Bias

The effects of sample selection bias are similar to those caused by left-out variables. Controlling for these left-out variables yields consistent estimates. Although a number of econometric procedures are available to accomplish this control, a frequently used approach is to estimate a first-stage (structural) probit in order to form an estimate of the missing expectations in the earnings equation. In the migration context, an example of this probit is to estimate a regression to predict migrant status (i.e., migrant vs. nonmigrant). A practical difficulty is identifying the earnings equation.

Models for Paired Comparisons

Ulf Böckenholt

McGill University, Montreal, Quebec, Canada

Glossary

conjoint measurement Facilitates the identification of a quantitative structure of variables without using operations of concatenation or physical addition.

intraclass correlation A measure of the degree of resemblance between microunits that belong to the same macrounit in a multilevel model.

multilevel models Statistical models that contain variables measured at different levels of a hierarchy. Regression coefficients of lower level representations are regressed on higher level explanatory variables to investigate dependencies among the multiple levels.

random utility model Assumes that observed choices are indicators of latent utilities that are specified to be functions of the decision makers and characteristics of the alternatives. The probability that a particular decision maker will choose a particular alternative is given by the probability that the utility of that alternative is greater than the utility of all other available alternatives for that decision maker.

transitivity A relation is transitive relative to a class if and only if, for all x , y , and z in that class, if $R(x, y)$ and $R(y, z)$ then $R(x, z)$.

In the method of paired comparisons, judges are presented with pairs of items and, for each pair, they are asked to choose the preferred item according to some criterion. Paired comparison judgments are collected in a wide range of applications, ranging from sensory testing to investigations of preference and choice behavior. Since L. L. Thurstone's seminal work in 1927 on the measurement of values, attitudes, and preferences, many advances have been made on modeling paired comparison data. These models are useful for investigating the degree to which respondents are consistent in their comparisons and for analyzing the underlying mean and covariance structure of the items that are being compared.

Introduction

The popularity of the paired comparison (PC) method as a data collection tool can be traced back to three reasons. First, by asking for a comparison of two items at a time, the PC method imposes minimal constraints on the response behavior of a judge. Especially when differences between items are small, the PC method is attractive because it is less prone to the influence of context effects that are caused by the presence of other items. Second, internal consistency checks are available; these facilitate the identification of judges who discriminate poorly. Third, paired comparison data provide a rich source of information about the effects of individual differences and perceived similarity relationships among items.

It is important to distinguish two different sampling schemes in the collection of paired comparison data. In the single-judgment case, each judge compares one pair of items only. Typically, this approach is used when substantial carryover effects from one pairwise judgment to the next would interfere with the evaluation of the items. Because a large number of judges are required to determine differences among the items, the second sampling scheme of asking each judge to compare multiple item pairs is used more frequently. An analysis of multiple paired comparisons by each judge must take into account that the data contain variation among judges as well as momentary fluctuations within each person. Disregarding systematic individual differences in the evaluations of the items is a serious model misspecification that can lead to incorrect statistical and substantive conclusions.

An attractive feature of the method of paired comparisons under the multiple-judgment scheme is that in pairwise comparisons of three or more items, the internal consistency of judgments can be investigated by determining the number of "circular triads." For example, when item j is preferred to item k , and item k is preferred

to item l , it is expected that item j is also preferred to item l . If a judge selects item l in the last comparison, then this indicates an intransitivity in the judgmental process that may be either systematic or reflective of the stochastic nature of choice behavior.

To account for random violations of the transitivity conditions, a number of probabilistic choice models have been suggested. Perhaps because of its computational convenience and easy interpretation, the family of linear paired comparison models has been used most frequently for the analyses of paired comparison data over the years. Prominent members of this family include the Bradley–Terry–Luce and the Thurstonian models. These models can accommodate single- and multiple-judgment data. In the multiple-judgment case, it is assumed typically that the individual evaluations can be represented by a multivariate normal distribution. The mean vector and covariance matrix of the normal distribution describe the average evaluation of the items and their variability, respectively, in the population of judges. Because multiple-judgment PC models belong to the general class of hierarchical models, they can be fitted with standard multilevel software packages. Instead of requiring every judge to compare all items with each other, incomplete paired comparison designs can be utilized to reduce the judgmental burden of the respondents significantly. Covariates describing the judges and the items to be compared can also be included readily in this statistical framework.

Linear Paired Comparison Models

According to linear paired comparison models, each item j is associated with a parameter μ_{ij} that represents the mean evaluation or utility for this item of person i . Consequently, a comparison between two items reduces to computing the difference between the respective mean evaluations. Fluctuations in the evaluations of the two items j and k are captured by a random variable, ϵ_{ijk} , which is assumed to be identically and independently distributed for all item pairs. Based on these assumptions, the comparative judgment between items j and k can be written as

$$y_{ijk} = \mu_{ij} - \mu_{ik} + \epsilon_{ijk}. \quad (1)$$

Depending on the distributional assumptions that are made about ϵ_{ijk} , different members of the family of linear paired comparison models are obtained. For example, when ϵ_{ijk} is normally distributed, a Thurstonian model is obtained. Specifying a logistic distribution yields the Bradley–Terry–Luce model.

The Within-Judge Level

For multiple comparisons involving r items, the paired comparison judgments can be written conveniently as a linear model. For example, a comparison of the items j , k , l , and m obtains

$$\begin{pmatrix} y_{ijk} \\ y_{ijl} \\ y_{ijm} \\ y_{ikl} \\ y_{ikm} \\ y_{ilm} \end{pmatrix} = \begin{pmatrix} 1 & -1 & 0 & 0 \\ 1 & 0 & -1 & 0 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{pmatrix} \begin{pmatrix} \mu_{ij} \\ \mu_{ik} \\ \mu_{il} \\ \mu_{im} \end{pmatrix} + \begin{pmatrix} \epsilon_{ijk} \\ \epsilon_{ijl} \\ \epsilon_{ijm} \\ \epsilon_{ikl} \\ \epsilon_{ikm} \\ \epsilon_{ilm} \end{pmatrix} = \mathbf{A}_i \boldsymbol{\mu}_i + \boldsymbol{\epsilon}_i, \quad (2)$$

where $\boldsymbol{\mu}_i$ is an r -dimensional vector containing the item parameters for the mean evaluations by person i , $\boldsymbol{\epsilon}_i$ is an $\binom{r}{2}$ -dimensional pair-specific error component, and \mathbf{A}_i is a design matrix describing the difference structure of the paired comparisons for person i . Each column of \mathbf{A}_i corresponds to one of the items, and each row corresponds to one of the $\binom{r}{2}$ paired comparisons. Note that a constant can be added to each of the item values, which cancels out when computing a pairwise difference between the scale values. Thus, only $(r - 1)$ item scale values can be estimated and the r th scale value can be set equal to an arbitrary constant without affecting the fit of the paired comparison model. This result has significant implications for the interpretation of individual differences, because they can be assessed only by selecting one of the items as a reference category.

With minor modifications of the design matrix \mathbf{A}_i , comparisons between composite stimuli (for example, in the form of risky choice options) can be investigated. Standard examples are gambles of the form (j, p_s) , where item j can be won with probability p_s , and nothing otherwise. By using the mean evaluation of the status quo (i.e., “winning nothing”) as a reference category, the origin of the individual utility scales can be defined in a natural way. Let μ_{i0} denote the mean evaluation of the status quo outcome. Then, by setting $\mu_{i0} = 0$, the expected utility of lottery (j, p_s) can be written as

$$y_{ij(p_s)} = p_s \mu_{ij} + (1 - p_s) \mu_{i0} + \epsilon_{ij(p_s)} = p_s \mu_{ij} + \epsilon_{ij(p_s)},$$

and the comparative utility judgment of two lotteries is given by

$$y_{ij(p_s)k(p_u)} = p_s \mu_{ij} - p_u \mu_{ik} + \epsilon_{ij(p_s)k(p_u)}. \quad (3)$$

To distinguish a risky from a nonrisky choice mode, the winning probabilities are listed in parentheses next to the option label. As an illustration, consider the following scenario in which the items j , k , and l are presented pairwise, first in a nonrisky presentation mode and, next, in the form of gambles:

$$\begin{pmatrix} y_{ijk} \\ y_{ijl} \\ y_{ikl} \\ y_{ij(0.8)k(0.2)} \\ y_{ij(0.8)l(0.2)} \\ y_{ik(0.8)l(0.2)} \\ y_{ij(0.2)k(0.8)} \\ y_{ij(0.2)l(0.8)} \\ y_{ik(0.2)l(0.8)} \end{pmatrix} = \begin{pmatrix} 1 & -1 & 0 \\ 1 & 0 & -1 \\ 0 & 1 & -1 \\ 0.8 & -0.2 & 0 \\ 0.8 & 0 & -0.2 \\ 0 & 0.8 & -0.2 \\ 0.2 & -0.8 & 0 \\ 0.2 & 0 & -0.8 \\ 0 & 0.2 & -0.8 \end{pmatrix} \begin{pmatrix} \mu_{ij} \\ \mu_{ik} \\ \mu_{il} \end{pmatrix} + \begin{pmatrix} \epsilon_{ijk} \\ \epsilon_{ijl} \\ \epsilon_{ikl} \\ \epsilon_{ij(0.8)k(0.2)} \\ \epsilon_{ij(0.8)l(0.2)} \\ \epsilon_{ik(0.8)l(0.2)} \\ \epsilon_{ij(0.2)k(0.8)} \\ \epsilon_{ij(0.2)l(0.8)} \\ \epsilon_{ik(0.2)l(0.8)} \end{pmatrix} = \mathbf{B}_i \boldsymbol{\mu}_i + \boldsymbol{\epsilon}_i.$$

For example, the fourth and last rows of the design matrix \mathbf{B}_i indicate the choices of person i between the lotteries $(j, 0.8)$ and $(k, 0.2)$ and between the lotteries $(k, 0.2)$ and $(l, 0.8)$, respectively. The latter case obtains

$$y_{ik(0.2)l(0.8)} = 0.2 \mu_{ik} - 0.8 \mu_{il} + \epsilon_{ik(0.2)l(0.8)}.$$

It is important to note that the design matrix \mathbf{B}_i is of full rank. Thus, although only difference judgments are observed, the mean evaluations and their covariance matrix can be fully identified, provided the expected utility representation of Eq. (3) is in agreement with the data.

Although the latent difference judgment y_{ijk} is specified to be continuous, the response of a judge is typically binary or ordinal. It is assumed that these discrete responses are obtained by mapping the continuous judgments onto a discrete response scale according to a threshold

comparison process. For example, in a comparison between items j and k , the response category h is selected when

$$\tau_{h-1} < y_{ijk} < \tau_h, \quad h = 1, \dots, H,$$

where $\tau_0 < \tau_1 < \dots < \tau_H$ are threshold parameters with $\tau_0 = -\infty$ and $\tau_H = \infty$. Under the hypothesis of no order effect in the comparison of two items, $\tau_h = -\tau_{H-h}$, and the sum of the threshold parameters is equal to zero. For binary response categories, $\tau_1 = 0$ is obtained. Another special case of interest includes PC models with an “indifference” category. The three outcomes—that person i selects item j , item k , or is indifferent to both items—are represented by the trinary variable $R_{ijk} = 1$, $R_{ijk} = 2$, and $R_{ijk} = 3$, respectively. The probability that item j is preferred to item k can then be written as

$$\Pr(R_{ijk} = 1) = \Pr(\mu_{ij} - \mu_{ik} \geq \tau_2 + \epsilon_{ijk}), \quad (4)$$

where τ_2 is a (nonnegative) indifference threshold. By denoting the distribution function of the stochastic choice component by $\Psi(\cdot)$, the probability of observing the three paired comparison judgments is

$$\Pr(R_{ijk} = 1) = \Psi(\mu_{ij} - \mu_{ik} - \tau_2),$$

$$\Pr(R_{ijk} = 2) = \Psi(\mu_{ik} - \mu_{ij} - \tau_2),$$

$$\Pr(R_{ijk} = 3) = \Psi(\mu_{ij} - \mu_{ik} + \tau_2) - \Psi(\mu_{ij} - \mu_{ik} - \tau_2).$$

If $\Psi(\cdot)$ is specified to be a logistic distribution function $1/\{1 + \exp[-(\cdot)]\}$, the Rao and Kupper model is obtained. When instead of the logistic distribution function, the standard normal distribution function is selected, the paired comparison model by Glenn and David is obtained. Although both distribution functions are rather similar in form, the logistic distribution seems preferable because it offers computational advantages over the standard normal. The paired comparison probabilities can be expressed in closed form and the interpretation of the model parameters is simplified by an exponential transformation of the model parameters, i.e., $\pi_{il} = \exp(\mu_{il})$ ($l = 1, 2$), which yields

$$\Pr(R_{ijk} = 1) = \pi_{ij}/(\pi_{ij} + \tau_2 \pi_{ik}),$$

$$\Pr(R_{ijk} = 2) = \pi_{ik}/(\pi_{ik} + \tau_2 \pi_{ij}),$$

$$\Pr(R_{ijk} = 3) = \pi_{ij} \pi_{ik} (\tau_2^2 - 1) / [(\pi_{ij} + \tau_2 \pi_{ik})(\pi_{ik} + \tau_2 \pi_{ij})].$$

The Between-Judge Level

Individual difference effects can be investigated by decomposing the person-specific utility values into fixed and random components. The fixed model part consists of the overall group mean, μ_j , for each item j . The random component, v_{ij} , captures the degree to which the evaluation of judge i differs from μ_j . Thus, mean evaluations are written as $\mu_i = \boldsymbol{\mu} + \mathbf{v}_i$, with $\boldsymbol{\mu} = (\mu_1, \dots, \mu_r)'$ and $\mathbf{v}_i = (v_{i1}, \dots, v_{ir})'$.

Frequently, in paired comparison studies, information is available about the options to be compared. The effects of the covariates may be either the same for all judges or may vary from judge to judge. In the former case, the mean evaluations can be expressed as $\boldsymbol{\mu} = \mathbf{X}\boldsymbol{\beta}$, where \mathbf{X} contains the values of the design variables and $\boldsymbol{\beta}$ is a regression vector. In the latter case, the covariate information may be incorporated by specifying $\mathbf{v}_i = \mathbf{X}\boldsymbol{\zeta}_i + \boldsymbol{\delta}_i$, where $\boldsymbol{\zeta}_i$ is a regression vector for person i , and $\boldsymbol{\delta}_i$ is an error term representing the effects that are not accounted for by the covariates. The distributions of the random effects \mathbf{v}_i , or $\boldsymbol{\zeta}_i$, and $\boldsymbol{\delta}_i$, may be either selected *a priori* from some parametric family or estimated from the data.

One special, important case is obtained when specifying the random-effects distributions for the random effects on the within- and between-judge levels to be normal: Let $\boldsymbol{\epsilon}_i$, and \mathbf{v}_i , be normally distributed with $\boldsymbol{\epsilon}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$, $\mathbf{v}_i \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_v)$, and $\boldsymbol{\epsilon}_i$ and \mathbf{v}_i are independent. Then the joint distribution of \mathbf{y}_i , and \mathbf{v}_i , can be written as

$$\begin{bmatrix} \mathbf{y}_i \\ \mathbf{v}_i \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} \mathbf{A}\boldsymbol{\mu} \\ \mathbf{0} \end{bmatrix}, \begin{bmatrix} \mathbf{V} & \mathbf{A}\boldsymbol{\Sigma}_v \\ \boldsymbol{\Sigma}_v \mathbf{A}' & \boldsymbol{\Sigma}_v \end{bmatrix}\right), \quad (5)$$

where the $\binom{r}{2} \times \binom{r}{2}$ matrix $\mathbf{V} = \mathbf{A}\boldsymbol{\Sigma}_v \mathbf{A}' + \sigma^2 \mathbf{I}$. Covariates can be taken into account by specifying that $\boldsymbol{\zeta}_i \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_\zeta)$, $\boldsymbol{\delta}_i \sim \mathcal{N}(\mathbf{0}, \sigma_\delta^2 \mathbf{I})$, and $\boldsymbol{\zeta}_i$ and $\boldsymbol{\delta}_i$ are independent. In this case, $\boldsymbol{\Sigma}_v = \mathbf{X}\boldsymbol{\Sigma}_\zeta \mathbf{X}' + \sigma_\delta^2 \mathbf{I}$ is obtained.

Identification of Individual Differences

The interpretation of individual differences in the evaluation of the items is complicated in two ways. First, only binary or ordinal judgments of an underlying continuous variable are observed. Second, because paired comparison judgments are conceptualized as difference judgments, the location of the latent judgment \mathbf{y} cannot be identified except when additional assumptions are made about the origin. Thus, in general, only the covariance matrix of $(r-1)$ scale values can be estimated and the scale value of the r th item needs to be set equal to a constant to fix the origin of the item scale. In this case, the set of covariance matrices $\boldsymbol{\Sigma}_v^*$ that are observationally equivalent to $\boldsymbol{\Sigma}_v$ is given by $\boldsymbol{\Sigma}_v^* = \boldsymbol{\Sigma}_v + \mathbf{d}\mathbf{1}' + \mathbf{1}\mathbf{d}'$, where \mathbf{d} is an arbitrary real-valued vector and the variance of $\boldsymbol{\epsilon}_i$ is specified to be a constant. For example, the hypothesis that the utilities of the options are independently distributed with unit variance, i.e., $\boldsymbol{\Sigma}_v = \mathbf{I}$, is indistinguishable from the hypothesis that the utilities have variances equal to $1+e$ and covariances equal to e , i.e., $\boldsymbol{\Sigma}_v^* = \boldsymbol{\Sigma}_v + e\mathbf{1}\mathbf{1}'$. When covariates are available to describe the choice options with $\boldsymbol{\Sigma}_v = \mathbf{X}\boldsymbol{\Sigma}_\zeta \mathbf{X}' + \sigma_\delta^2 \mathbf{I}$, both $\boldsymbol{\Sigma}_\zeta$ and σ_δ^2 can be identified,

provided there exists no $\mathbf{d}(\neq \mathbf{0})$ such that $\mathbf{R}(\mathbf{d}\mathbf{1}' + \mathbf{1}\mathbf{d}') \subseteq \mathbf{R}(\mathbf{X}')$, where $\mathbf{R}(\mathbf{M})$ denotes the row space of matrix \mathbf{M} .

These difficulties in interpreting the covariance matrix of the item utility differences can be alleviated by including composite items in a paired comparison experiment. In this case, it is possible to identify the covariance matrix of the r scale values although only difference judgments are observed.

Consistency Analyses

The paired comparison task belongs to a small group of techniques that provide explicit information about the consistency of individual- and group-level judgments. Individual judgments are rarely deterministically consistent. Only when the perceived differences between items are large can it be expected that a person will arrive at the same response in repeated comparisons. Several probabilistic consistency rules have been proposed in the literature. The most well-known conditions, weak stochastic transitivity (WST), moderate stochastic transitivity (MST), and strong stochastic transitivity (SST), are defined as follows: for all j, k , and l in a given choice set,

$$\text{WST: } [\Pr(j \rightarrow k) \geq 0.50 \text{ and } \Pr(k \rightarrow l)] \geq 0.50$$

$$\Rightarrow \Pr(j \rightarrow l) \geq 0.50,$$

$$\text{MST: } [\Pr(j \rightarrow k) \geq 0.50 \text{ and } \Pr(k \rightarrow l)] \geq 0.50$$

$$\Rightarrow \Pr(j \rightarrow l) \geq \min[\Pr(j \rightarrow k), \Pr(k \rightarrow l)],$$

$$\text{SST: } [\Pr(j \rightarrow k) \geq 0.50 \text{ and } \Pr(k \rightarrow l)] \geq 0.50$$

$$\Rightarrow \Pr(j \rightarrow l) \geq \max[\Pr(j \rightarrow k), \Pr(k \rightarrow l)].$$

For example, under the SST condition, it is expected that if item j is preferred to item k more than 50% of the time, and item k is preferred to item l more than 50% of the time, then item j should be preferred to item l more often than items j and k are preferred in the (j, k) and (k, l) comparisons, respectively.

Although Luce's paired comparison model satisfies SST and hence MST and WST on the individual level, it allows for violations of SST and requires only MST to hold for group-level data. Investigations of stochastic transitivity relationships are valuable only insofar as they provide consistency evaluations of group judgments. They do not allow any inferences about the behavior of the individual judges. Similarly, inconsistencies in group-level judgments cannot be predicted on the basis of individual-level data. Even if judges are perfectly consistent in their paired comparisons, it cannot be concluded that the group-level data exhibit coherence as well.

For multiple-judgment data, individual consistency can be assessed by analyzing the incidence of circular triads. When circular triads are a result of random variability in the judgmental process, intransitive judgments

are expected only when the perceived differences between items are small. Similarly, hypotheses about combination rules that are used in assessing composite stimuli can be tested by examining whether the conditions defined for a conjoint measurement structure are satisfied. As an example, consider the double-cancellation condition in risky-choice comparisons. Let $(j, p_t) \succeq (k, p_s)$ denote that gamble (k, p_s) is not preferred to gamble (j, p_t) , and let j, k , and l be items from a specified set of items and p_s, p_t , and p_u be any values on the interval $(0, 1)$, then \succeq satisfies double-cancellation if and only if $(k, p_s) \succeq (j, p_t)$ and $(l, p_t) \succeq (k, p_u)$, then $(l, p_s) \succeq (j, p_u)$. When $p_s = p_t = p_u = 1$, double cancellation reduces to the transitivity test in nonrisky choice.

Figure 1 illustrates how the probability of observing violations of the double-cancellation and transitivity conditions depends on mean differences between the items, the size of the winning probabilities, and the intraclass correlation between two latent pairwise judgments. Five different mean specifications are depicted in Fig. 1 ranging from $(\mu_j = 0, \mu_k = 0, \mu_l = 0)$ to $(\mu_j = 1.5, \mu_k = 0, \mu_l = -1.5)$. The within-pair evaluative responses is specified to be normally distributed with a variance of 1 and the between-pair responses are specified to be uncorrelated. The two panels differ in the winning probabilities assigned to p_s, p_t , and p_u , which are listed at the top of each panel in Fig. 1. For example, the second dashed line in the left panel corresponds to the gamble triplet $[(j, 0.5), (k, 0.5), (l, 0.5)]$ with means $(\mu_j = -0.5, \mu_k = 0, \mu_l = -0.5)$. The right panel of Fig. 1 contains the likelihood of observing intransitive responses because all winning probabilities are set equal to 1. Figure 1 shows that for zero mean differences, the likelihoods of observing violations of the double cancellation and transitivity conditions reach their maximum of 0.25 when gambles are judged independently of each other (intraclass correlation = 0) and diminish gradually as the intraclass correlation increases to 0.5. Larger mean differences between gambles lead to a smaller percentage of consistency violations.

Because violations of the transitivity and the double-cancellation conditions are by-products of random variability in the repeated evaluation of an item, the two intransitive cycles $j \succeq k \succeq l \succeq j$ and $j \succeq l \succeq k \succeq j$, as well as the two choice patterns that are inconsistent with the double-cancellation condition, have an almost equal probability of occurring. Significant differences in the probabilities of observing the two intransitive cycles can indicate that intransitive choices are systematic and not random. Similarly, violations of the double-cancellation condition may be systematic when the frequencies of the two choice patterns that are inconsistent with the double-cancellation condition differ appreciably from each other. Thus, examining whether inconsistent choice patterns are equally likely can be of diagnostic value in detecting true deviations from transitivity or double cancellation.

Figure 1 Probability of transitivity and double-cancellation (DC) violations as a function of the intraclass correlation coefficient, winning probabilities, and selected item mean values.

Conclusion

The formulation of linear paired comparison models by postulating latent utilities has a long tradition in biometric, econometric, psychometric, and sociometric disciplines. Applications and technical developments in each of these areas have led to many improvements in the statistical apparatus for estimating and validating paired comparison models. Although the notion that each item can be represented by a person-specific value has proved to be useful in a wide range of applications, its limitations are equally obvious. Important extensions concern the evaluation of cognitive abilities or skills that may vary over time, and the modeling of context-sensitive behavior that takes into account that assessment of an item's utility may depend on pair-specific comparisons drawn between it and another item. Linear paired comparison models are most useful in providing parsimonious descriptions of how judges differ in their evaluations at a particular point in time or over time. However, by emphasizing interindividual differences, this approach

can render only limited insights about intraindividual processes influencing a pairwise choice.

Glossary

cooperative game A game model that assumes that players can make coalitions and agree on side payments outside of the formal rules.

game theory A mathematical theory to model and analyze conflicts arising from economic, social, and political situations.

Nash equilibrium The solution concept for noncooperative games: a strategy profile is a Nash equilibrium if no player can profit by unilaterally deviating from the solution.

noncooperative game A game model such that the rules of the game fully describe the situation; all possibilities for coalition formation or side payments are explicitly included in the rules.

stable set The solution concept for cooperative games introduced by von Neumann and Morgenstern; a stable set satisfies both internal stability (no element in the set dominates another element in the set) as well as external stability (every element outside is dominated by an element from inside).

von Neumann–Morgenstern utility theory An axiomatic theory of individual decision making under uncertainty; if an individual's choice behavior satisfies certain assumptions, he/she will have a numerical utility function and will evaluate each lottery (random outcome) by its expected utility.

Together with John von Neumann, Oskar Morgenstern wrote *The Theory of Games and Economic Behavior*, one of the great social science books of the 20th century. The book argues strongly that traditional models and methods are unsuited to develop a general theory of rational behavior, and it proposes an alternative based on game theory. Besides expounding the theory of zero-sum two-person games that had earlier been developed by von Neumann, the book contains at least three seminal contributions

(the theory of expected utility, the concept of a cooperative game, and the stable set solution concept) and it provides the first applications of game theory to economics and political science. Morgenstern also worked and wrote on economic growth, on predictability of stock prices, on the accuracy of economic observations, and on methodological issues. Morgenstern's work and influence are described here, focusing on his work in game theory.

Early Work: Impossibility of Perfect Foresight

Oskar Morgenstern was born in Görlitz (Germany) on January 24, 1902. When he was 14 years old, the family moved to Vienna, where, in 1925, Oskar received his doctorate for a thesis on marginal productivity; this enabled him to describe himself as a product of the Austrian School of Economics. In the same year, he was awarded a Rockefeller Fellowship, which allowed him to continue studying in London, Paris, and Rome and at Harvard and Columbia. In 1928, he returned to the University of Vienna, where he defended his habilitation thesis *Wirtschaftsprognose* and where he was appointed as Privatdozent in 1929. In this second thesis, a study of the theory and applications of economic forecasting, Morgenstern pointed out two problems in making predictions in the social sciences: that the predictions may influence the predicted events and that an individual makes predictions about the behavior of other individuals, behavior that in turn is guided by their predictions about his own behavior. This raises the issue of whether a (good) prediction is possible at all, and by means of an example, Morgenstern suggested that the answer is no:

Sherlock Holmes, pursued by his opponent, Moriarty, leaves for Dover. The train stops at a station on the

way, and he alights there rather than traveling on to Dover. He has seen Moriarty at the railway station, recognizes that he is very clever, and expects that Moriarty will take a special faster train in order to catch him at Dover. Holmes' anticipation turns out to be correct. But what if Moriarty had been still more clever, had estimated Holmes' mental abilities better and had foreseen his actions accordingly? Then obviously he would have traveled to the intermediate station. Holmes, again, would have had to calculate that, and he himself would have decided to go on to Dover. Whereupon Moriarty would have "reacted" differently. Because of so much thinking they might not have been able to act at all or the intellectually weaker of the two would have surrendered to the other in the Victoria Station, since the whole flight would have become unnecessary. Examples of this kind can be drawn from everywhere. [Morgenstern, 1928, p. 98]

In the same year that Morgenstern published *Wirtschaftsprognose*, John von Neumann published *Zur Theorie der Gesellschaftsspiele*. Morgenstern's example can be viewed as a two-player game in which each of the players, Holmes and Moriarty, has two strategies: to take a slow train that stops at the intermediate station and get out there, or to take a fast train to Dover. Assume that Holmes escapes for sure if they take different types of trains, that he is caught otherwise, and that Holmes (respectively, Moriarty) wants to maximize (respectively, minimize) the probability of escape. Obviously, no player has a *deterministic* optimal strategy and it is not possible to make a determinate prediction of the outcome: if the prediction is that Holmes will take the slow train, Holmes will realize that Moriarty will know this, inducing Holmes to violate the prediction, and similar for every other possibility. In modern game theoretic language, this is a game without pure strategy equilibrium. In his paper, von Neumann, however, showed that equilibrium can be obtained if we allow for randomized decisions: a player that bases his decision on the toss of a coin cannot be outsmarted by his opponent and will be happy with his choice; we can confidently predict that Holmes will escape with probability 1/2. The main result in von Neumann's paper shows that mixed strategies not only solve the prediction problem in this example, but in two-person constant sum games in general.

In 1931, Morgenstern succeeded Friedrich von Hayek as director of the Austrian Institute for Business Cycle Research, but he continued to be bothered by problems of prediction and foresight. He also became editor of the *Zeitschrift für Nationalökonomie*, in which he published his paper *Vollkommene Voraussicht und Wirtschaftliches Gleichgewicht*, returning to issues from the 1929 thesis and arguing that the theory of general economic equilibrium crucially depends on this paradoxical assumption of perfect foresight and, hence, is unsatisfactory. After a presentation of this paper in Karl Menger's Vienna

Colloquium, the mathematician Eduard Čech pointed out to Morgenstern that his work was related to that of von Neumann, and he urged Morgenstern to read the latter's paper. Morgenstern's many duties apparently prevented him from doing so (in addition to being director of the Austrian Institute for Business Cycle Research, he was an advisor to the Austrian National Bank, an advisor to the Ministry of Commerce, and a member of the Committee of Statistical Experts of the League of Nations).

In January 1938, with support of the Carnegie Endowment for International Peace, Morgenstern left for the United States. In March of that year, the Nazis took over in Austria and Morgenstern was dismissed from his Vienna position. Finding himself unable to return to Austria, he accepted a 3-year appointment in political economy at Princeton University, in the hope that he would get to know von Neumann and would be able to work with him.

Collaboration with von Neumann

In Morgenstern's 1976 article in the *Journal of Economic Literature*, the impression is given that, even though von Neumann did most of the work on which Morgenstern and von Neumann had collaborated for the *Theory of Games and Economic Behavior*, and certainly was responsible for the mathematical parts, the writing that they had produced was a truly cooperative effort: "We wrote virtually everything together and in the manuscript there are sometimes long passages written by one or the other and also passages in which the handwriting changes two or three times on the same page." Viewing Morgenstern's diaries, however, it is possible to conclude that this account is somewhat misleading: rather, von Neumann did the bulk of the writing. Morgenstern's direct contributions reside mainly in Chapter 1, in his insistence on the measurement of utility, and in the economic examples, but the indirect contribution should not be underestimated: he succeeded in getting and keeping von Neumann interested in economic problems and inducing him to spend his great intellectual powers on these, thereby advancing social science. As Morgenstern wrote in 1963, "Scientific activity consists largely in asking the right kind of question. There comes a point where economists and mathematicians must get together to do precisely this in order to advance our knowledge." Andrew Schotter wrote in 1976 that "without Oskar Morgenstern we would not have the theory of games as we know it today. . . . Game theory would probably not have been introduced into the social sciences until many years later. . . . I can think of no other economists at the time who could have walked into a room with John von Neumann and walked out later with a 600-page book on the theory of games complete with economic examples." By combining their respective comparative advantages—von

Neumann as a creative innovator and Morgenstern as a visionary entrepreneur and arbitrageur between two fields—the two constructed a unique product.

When Morgenstern first met with von Neumann in 1938, the latter had again seriously taken up his interest in game theory. The first intensive discussions between the two took place in October 1939 when Morgenstern was starting to write down the material on “maxims of behavior” that would eventually be published in Chapter 1 of *Theory of Games and Economic Behavior* (*TGEB*); this effort continued till the summer of 1940, when von Neumann gave three lectures on games to the department of mathematics at Washington University in Seattle. After Morgenstern returned to Princeton, von Neumann’s cooperation with Morgenstern intensified. He informed Morgenstern about the progress that he had made and wrote two papers, and Morgenstern supplied von Neumann with criticism about established economic thinking and with an agenda of things to do. In the summer of 1941, von Neumann proposed to Morgenstern that they write a paper together and this induced Morgenstern to work on von Neumann’s manuscripts, the explicit purpose being to write an introduction to them. The period from June 1941 to Christmas 1942, during which the book was written, probably was the intellectually most stimulating and most productive period of Morgenstern’s life. On July 30, 1941, he wrote in his diary, “This is the book I have been dreaming of for years.”

Axioms and Measurable Utility

From the outset, the authors of *TGEB* make clear that their work is solidly based on methodological individualism: “In the course of the development of economics, it has been found, and it is now well-nigh universally agreed, that an approach to this vast problem is gained by the analysis of the behavior of the individuals which constitute the economic community.” Of course, this approach requires an adequate representation of the motives of the individuals. In 1944, the standard approach in economics was to represent an individual’s preferences by a set of indifference curves, which corresponds to an ordinal ranking of alternatives. Even though this standard approach is based on the strong assumption that preferences are complete (the individual is able to compare all possible prospects), it has only limited applicability because it does not allow for uncertainty, and working with it is also somewhat clumsy. von Neumann and Morgenstern argue that the theory should be able to deal with uncertainty, and that willingness to assume completeness of preferences as well as certain other “natural” properties actually obtains a much simpler, numerical representation. Specifically, in the second edition of *TGEB*, von Neumann and

Morgenstern propose axioms that imply that utility is measurable, unique up to a positive affine transformation, and linear in the probabilities that represent the uncertainty. *TGEB* provides one of the first applications of the axiomatic method in economics and it shows that this method, which had already been successfully used in mathematics, is equally promising in this domain. In 1963, at the Philadelphia symposium of the American Academy of Political Sciences, Morgenstern provided a brief description of the axiomatic method in general; John F. Nash’s work on bargaining and work by Lloyd S. Shapley on value and on measuring political power are excellent examples illustrating how fruitful the approach can be in dealing with economic problems.

It is useful to illustrate the axiomatic approach pioneered by von Neumann and Morgenstern by explicitly deriving their utility function. Assume an individual can choose from a (finite) set of possible outcomes X . The traditional approach assumes that i has a complete preference ordering over X ; that is, for each two alternatives $x, y \in X$, he can say whether he (weakly) prefers x to y (written $x \succeq y$) or y to x ($y \succeq x$), and the relation is reflexive ($x \succeq x$ for all x) and transitive (if $x \succeq y$ and $y \succeq z$, then $x \succeq z$). Clearly, associated with \succeq , there is a strict preference relation \succ ($x \succ y$ if $x \succeq y$ but not $y \succeq x$) and an indifference relation \sim ($x \sim y$ if $x \succeq y$ and $y \succeq x$). Because X is finite, it follows that there is a best element b in the set ($b \succeq x$ for all x) as well as a worst element w ($x \succeq w$ for all x).

von Neumann and Morgenstern now assume that the individual can also compare uncertain prospects yielding outcomes in X , as long as these are associated with known, objective probabilities. Formally, if P denotes the set of all lotteries on X , i.e., probability distributions with outcomes in X , we assume that the preference \succeq relation can be extended to a complete, reflexive, transitive relation on P . Now take $x \in X$, assume $b \succ x \succ w$, and write $\langle \lambda; w, b \rangle = (1 - \lambda)w + \lambda b$ for the lottery that yields b with probability λ and w with the complementary probability $1 - \lambda$. It is natural to assume that $w \sim \langle 0; w, b \rangle$, $b \sim \langle 1; w, b \rangle$ and that the preference relation is continuous, i.e., there exists some $\lambda \in (0, 1)$ such that $x \sim \langle \lambda; w, b \rangle$. It is equally natural that if $\lambda > \mu$, then $\langle \lambda; w, b \rangle \succ \langle \mu; w, b \rangle$, and in this case there exists a unique number, denoted, say, by $u(x)$, such that $x \sim \langle u(x); w, b \rangle$. Note that $u(w) = 0$ and $u(b) = 1$; we have obtained that the utility of any outcome $x \in X$ is measurable: $u(x)$ is simply the probability needed to put on the good outcome to make the individual indifferent between x and the lottery.

What can be said about the utility of a lottery? Can $u(\cdot)$ be extended from X to P , similarly as we have extended? With an additional assumption, the answer is affirmative. Assume that the individual can also compare compound lotteries, that is, objects of the type $\langle \alpha; p, q \rangle$, where $p, q \in P$. The final axiom that we need is independence: $p \succeq q$ if and only if $\langle \alpha; p, r \rangle \succeq \langle \alpha; q, r \rangle$ for all $\alpha \in [0, 1]$

and $r \in P$. Again, this appears to be natural: each of the compound lotteries yields r with the same probability, hence, preference should not be guided by that event; in the alternative event, the lottery coincides with p or q , hence, preferences are determined by these lotteries. This assumption implies that the individual is indifferent between a compound lottery and the simple lottery that induces the same distribution on X . Consequently, if $p \in P$ is the lottery that yields outcome x with probability $p(x)$, we have $p \sim \langle u(p); w, b \rangle$, where $u(p) = \sum_{x \in X} p(x) u(x)$. We have derived our main result: if preferences \succeq on P are complete, transitive, continuous, and satisfy the independence axiom, then there exists a function u on X such that $p \succeq q$ if and only if

$$\sum_{x \in X} p(x) u(x) \geq \sum_{x \in X} q(x) u(x). \quad (1)$$

Preferences can thus be represented by a numerical utility function, and one lottery is preferred to another if and only if it yields higher expected utility. Furthermore, the utility function $u(\cdot)$ is determined up to a positive affine transformation: because $x \sim \langle u(x); w, b \rangle$, we must have $v(x) = u(x)v(b) + (1 - u(x))v(w)$, or $v(x) = v(w) + u(x)(v(b) - v(w))$ for any alternative utility representation $v(\cdot)$ that satisfies Eq. (1).

This approach has been extended to the case in which the probabilities are subjective. The axiomatic approach makes clear what are the “critical” assumptions underlying expected utility theory; as such, it allows attacking the theory on its weakest points and offers room for alternative development and improvement. Even though these axioms appear natural, actual human behavior violates them in systematic ways. This should not belittle the contribution of von Neumann and Morgenstern; as Morgenstern wrote in 1972, “Each problem solved usually suggests new ones which could not have been stated without a given problem first having been solved.”

Games and Solutions

von Neumann and Morgenstern were quick to point out in *TGEB* that a participant in a social-exchange economy faces a much different problem from that just discussed: “He too tries to obtain an optimum result. But in order to achieve this, he must enter into relations of exchange with others. If two or more persons exchange goods with each other, then the result for each one will depend in general not merely upon his own actions but on those of others as well.” Obviously, because actions depend on expectations, we are back in the setting of the Holmes–Moriarty example. von Neumann and Morgenstern pointed out that this conceptual problem is neglected in traditional economics and that this kind of problem is nowhere dealt with in

classical mathematics. They then proposed an alternative game theoretic solution.

The traditional economic method abstracts away from strategic interaction by focusing on the case in which the number of players is large. Although it may indeed be hoped that the influence of every particular participant is negligible in that case, von Neumann and Morgenstern were right to argue that this had not been formally proved and that such a proof requires explicit consideration of the finite-player case. As they also argued, the traditional approach is all the more unsatisfactory because it makes several assumptions (such as the existence of a price system, the fact that individuals know prices and take them as given, and the absence of coalitions of traders that could wield power) that should preferably be derived from more primitive ones.

An example may make this clear. Suppose that there is one seller who owns one indivisible unit and who values this at a . Also suppose that there are two potential buyers and that each of these values the unit at b , with $b > a$. As trading generates a surplus, the natural questions are who will trade and how the surplus will be divided. The traditional approach assumes the existence of prices and searches for a price that clears the market. As is clear, the unique price, when supply is equal to demand, is $p = b$, hence, the standard prediction is that the short side of the market appropriates the entire surplus. There is no prediction about who will actually trade, but, because, in equilibrium, each buyer is indifferent between trading or not, this really is irrelevant. However, where do the prices come from? Why focus on a market institution? Why is it justified to assume that the buyers do not form a cartel and negotiate with the seller as a team?

von Neumann and Morgenstern want to address these more basic questions. They clearly state their goal: “We wish to find the mathematically complete principles which define rational ‘behavior’ for the participants in a social economy, and to derive from them the general characteristics of that behavior.” Furthermore, these rules have to deal with all possible situations that may arise: “if the superiority of ‘rational behavior’ over any other kind is to be established, then its description must include rules of conduct for all conceivable situations—including those where ‘the others’ behaved irrationally, in the sense of the standards which the theory will set for them.”

Noncooperative Games

In defining what should be understood as a solution, it is important, using terminology that was introduced by John Nash, to distinguish between cooperative and noncooperative games. In many parlor games, the rules offer a complete description: it is clear what is allowed and what is not. Such games are said to be noncooperative, i.e., it is not possible to move outside of the game. Note

that the game being noncooperative does not mean that coalitions cannot be formed; it simply means that all such possibilities are included in the rules. For such a game, a solution is “a set of rules for each participant which tell him how to behave in every situation which may conceivably arise.”

Given Morgenstern's interest in predictability, it is remarkable that Chapter 1 of *TGEB* circumvents the question of what constitutes “rational behavior” in a non-cooperative game. For the special zero-sum two-person case, the issue is, however, discussed later in the book. There it is argued that, if a complete and absolutely convincing theory of rational behavior exists, then each player should still be willing to play according to this theory, even if he knows that other players know that he will play that way. von Neumann and Morgenstern use this argument to justify the minmax solution that was originally advocated, and proved to exist in by von Neumann in 1928; that is, they recommend that each player chooses a strategy that guarantees the highest possible payoff under the assumption that his strategy has been found out by the opponent. In later work, John Nash turned around this argument and reasoned that, when a convincing theory exists, each player should not be able to profit from knowing what the others will do: each player's plan should be a best response against the plans of the others. A strategy profile satisfying this condition is known as a Nash equilibrium of the game, hence, the von Neumann and Morgenstern argument seems naturally to lead to the Nash equilibrium concept, by now the most important solution concept for noncooperative games. The Holmes–Moriarty example shows that a Nash equilibrium in pure strategies need not exist, but Nash proved that there is always at least one equilibrium in mixed strategies. He also showed that his concept coincides with that of von Neumann for two-person zero-sum games. Because Nash's concept seems the natural solution to the problem of “perfect foresight” that occupied Morgenstern since the start of his career, it is remarkable that this concept is not discussed in *TGEB*, neither to reject it nor to endorse it. Perhaps von Neumann and Morgenstern rejected this concept because it does not have good “defensive” properties (an equilibrium strategy need not do well when the others do not play according to the solution), but what they thought about this is not known because they did not discuss it, although they mention Nash's work in the preface to the third edition of *TGEB*. In fact, it is quite remarkable that also in his later work Morgenstern never discussed the Nash concept.

Cooperative Games

von Neumann and Morgenstern are, obviously, mainly interested in situations with more than two players, in which coalitions play an important role, thus the bulk of *TGEB* is devoted to cooperative games. What is

even more important, and is stressed in *TGEB*, if there are more than two players, they will typically have incentives to agree to coalitions and to make side payments *outside of the formal rules* of the game: it must be expected that a player will be willing to compensate another in order to secure the latter's cooperation. Consequently, even if the rules of the game do not explicitly allow for these possibilities, the formal analysis has to take them into account, and this induced von Neumann and Morgenstern to introduce a different game form, the so-called characteristic function, which describes for each coalition S of players that might form, the total value $v(S)$ that these players can divide among themselves. Note that in moving to this representation, von Neumann and Morgenstern assume that utility is freely transferable between the players. For cooperative games, the question that *TGEB* seeks to answer concerns which coalition S will form and how its members will divide the value $v(S)$?

It should be immediately clear that the theory cannot be expected to give a unique answer to the first question. For example, in the three-person symmetric game in which each two-person coalition has value 1 and all other coalitions have value 0, it may be expected that two players will agree on an equal split $(1/2, 1/2)$, but which players this will be is unknown. As von Neumann and Morgenstern stressed, the competition between coalitions will determine which one will form and how it will divide the surplus. A second example may make this clear. Suppose we have a three-player game with $v(12) = 3$, $v(13) = 2$, $v(23) = 1$, and $v(S) = 0$ otherwise. Clearly, the coalition $\{1, 2\}$ is most attractive, but how should it divide the spoils? Each of the players in this coalition will look at what he can get with the outside player, and the outside player (player 3) will clearly investigate what bribe he has to offer to each of the other two in order to induce one of them to form a coalition with him. Consequently, a statement about the division in one coalition can be made only by simultaneously looking at the other coalitions. In this case, if $x = (x_1, x_2, x_3)$ satisfies $x_1 + x_2 = 3$, $x_1 + x_3 = 2$, and $x_2 + x_3 = 1$, and each coalition $\{i, j\}$ expects $v(ij)$ to be divided according to x , then, in each coalition, each inside player will be satisfied because he cannot get more by switching; hence, x determines a stable division for each possible coalition that might form. Obviously, the unique x that satisfies these conditions is $x = (2, 1, 0)$. Even if the coalition $\{1, 2\}$ is eventually formed, the payoff division $(2, 1)$ associated with this coalition derives its stability only from consideration of the other possible coalitions. The solution consists of a triple $\langle \{1, 2\}, 2, 1 \rangle$, $\langle \{1, 3\}, 2, 0 \rangle$, $\langle \{2, 3\}, 1, 0 \rangle$; it is the system that is stable, not the single imputations from which it is composed.

Accordingly, von Neumann and Morgenstern came to the conclusion that “A solution should be a system of imputations possessing in its entirety some kind of balance

and stability the nature of which we shall try to determine." The stability notion that they proposed makes use of the concept of dominance. An imputation x is said to dominate another imputation y ($x \succeq y$) if there exists a coalition S of individuals, each of whom strictly prefers x to y and such that S is able to enforce x . Note that this dominance relation typically will not be transitive: in the one-seller two-buyers example discussed previously, let x_i be the imputation resulting from a trade at price x between S and buyer B_i ; then, if $b > x > y > z > a$, we have $y_1 \succeq z_2$ (through the coalition $\{S, B_1\}$) and $x_2 \succeq y_1$, but there is no dominance relation between x_2 and z_2 . As a result, a single imputation that dominates all others, in general, need not exist.

When can a set X of imputations be considered stable? A necessary requirement is that X should be free of inner contradictions; no element in X should dominate another element of X . Second, von Neumann and Morgenstern insisted that any alternative imputation (i.e., one that is not in X) can be discredited by referring to some element that is in X : if $y \notin X$, then $x \succeq y$ for some $x \in X$. A set X that satisfies both internal and external stability is called a stable set. von Neumann and Morgenstern argued that such sets correspond to stable standards of behavior for a society: "once they are generally accepted, they overrule anything else and no part of them can be overruled within the limits of the accepted standards. This is clearly how things are in actual social organizations."

The one-seller two-buyers example may be used to illustrate this concept. The characteristic function is given by $v(12) = v(13) = v(123) = 1$ and $v(S) = 0$ otherwise. The competitive solution allocates all surplus to the seller, hence, it produces the imputation $(1, 0, 0)$, and the reader may verify that this imputation is undominated by any other one. However, as a singleton set, this imputation is not stable: for example, it does not dominate the imputation $(1/2, 1/4, 1/4)$ that results if the two buyers decide to collude, bargain with the seller as a team, and insist that the seller gives up half of the pie. Stable sets have to allow for such collusion. It turns out that many stable sets exist. Suppose that the buyers agree that, whatever they get out, they will split this in proportion $(\alpha, 1 - \alpha)$, and assume, with von Neumann and Morgenstern, that in the bilateral bargaining game between the seller and the team, any distribution of the surplus is possible. Then an outcome in the set $X(\alpha) = \{(1 - x, x\alpha, x(1 - \alpha)) : 0 \leq x \leq 1\}$ is predicted and any such set is stable. It is possible to conclude, as Morgenstern had conjectured all along, that other forms of social organization, different from unbridled competition, will be stable.

The fact that a game may have multiple stable sets did not bother von Neumann and Morgenstern: "this has a simple and not unreasonable meaning, namely that given the same physical background different 'established orders of society' or 'accepted standards of behavior' can

be built." On the other hand, they write that "there can be, of course, no concessions as regards existence." In 1969, William Lucas constructed an example of a game without a stable set. This counterexample, as well as the others that have been constructed, is, however, contrived and does not correspond to an actual economic, political, or social reality. Given Morgenstern's emphasis on "realistic modeling," it is, hence, unlikely that he would have been bothered by these examples. In "realistic models," stable sets have been found to exist, but stable set theory has nevertheless found only relatively few applications, mainly as a consequence of the fact that the concept is difficult to work with.

Other Contributions

In the preface of *The Selected Economic Writings of Oskar Morgenstern*, Schotter writes:

This book contains a selection of writings of one social scientist whose entire scholarly life has been devoted to both building up as well as tearing down the basic traditions of economics. As a builder, he has helped to introduce a radically new way of looking at economic problems, along with hastening the introduction of more powerful mathematical techniques. As a critic, he has constantly attacked economics for refusing to address itself to the empirically given problem, and has asked his profession to confront head-on the enormous complexity of the social world rather than hide behind methodological tools borrowed from other disciplines.

This characterization is accurate and in line with that of other observers. For example, in his chapter in Weintraub's *Toward a History of Game Theory*, Robert J. Leonard writes that Morgenstern has taken a "position as an arbiter of ideas, an intermediary between theorists in disparate fields, and one ultimately most capable of giving his energy to penetrating criticism rather than alternative theoretical construction." Looking at Morgenstern's later work, it is hard to come to a different conclusion.

Schotter's volume is divided into six sections: game theory and utility theory, linear economic systems, economic theory, economic statistics, methodology, and history of economic theory. Morgenstern's early work on the first topic has already been extensively described; after the death of von Neumann in 1957, new developments in Morgenstern's work in this area are not evident. For sure, there are papers written until the 1970s, but these elaborate on ideas that were already present in earlier work. A similar remark applies to Morgenstern's work on methodology. Morgenstern's main work in economics since the mid-1950s has been on the von Neumann model of the expanding economy. This work successfully relaxed several assumptions in the

seminal von Neumann growth model from 1937. In econometrics and statistics, especially noteworthy is Morgenstern's collaboration with Clive Granger, Nobel Prize winner in 2003, on the predictability of stock market prices. This work showed that the short-run movements of prices are well described by a simple random walk, but that for the longer run, the random-walk hypothesis performs less well, and that there is a surprisingly small connection between prices and quantities, thus casting doubt on the standard competitive model of price formation. A lot of work has been done in this area since the collaboration with Nobel Prize Winner Clive Granger.

Morgenstern not only was an arbiter between different fields of science, he also intermediated between science and the community of business and politics. He was a consultant to the Rand Corporation, the Atomic Energy Commission, and the White House and he was active in business as director of the consulting firm Mathematica. This firm was responsible for a large-scale project for the military on games with incomplete information; it gave an important impulse to game theoretic research, and Morgenstern took pride in the fact that Mathematica was a profitable enterprise delivering high-quality work. Morgenstern also employed his entrepreneurial talents elsewhere; he was instrumental, in 1954, in the founding of *Naval Research Logistics Quarterly* and in 1971 he founded the *International Journal of Game Theory*, the first field journal for game theory. In 1963, together with Paul Lazarsfeld, he was one of the founders of the Institute of Advanced Studies in Vienna.

As early as 1957, Morgenstern received an honorary doctorate from the University of Mannheim. He got a second such doctorate, from the University of Basel, in 1960. Later, he also received an honorary doctorate from the University of Vienna. In 1970, Morgenstern left Princeton for New York University. He became an honorary member of the American Economic Association and of the American Academy of Sciences in 1976. Oskar Morgenstern died on July 26, 1977, regretting that he had not received the Bank of Sweden Prize in Economic Sciences in Honor of Alfred Nobel.

Glossary

diplomacy Seeking to mitigate and minimize conflicts among nations that may lead to war. Through diplomacy, the nation aims to determine its own objectives and power for pursuit of its objectives, the objectives and power of other nations, the extent to which these different objectives are compatible with each other, and the means suited to the reformulation of objectives when they conflict.

elements of national power Comprising some elements that are relatively stable such as geography and others that are subject to constant change such as the relative military power between Germany and France in the interwar period between World Wars I and II. Quality of government and of diplomacy have often changed as one state lost its superior position to another. Such power is relative however, although Britain and America have had advantages for extended periods of time in past centuries.

ethnicity A more primordial force emerging in countries in the Balkans and Eastern Europe where tribal groups and clans have demanded independence and imposed harsh and brutal forms of ethnic cleansing on rival ethnic groups in their struggle for national identity.

force Distinguished from political power by physical violence, which characterizes the abdication of a psychological relationship. The exercise of force is physical while the quest for political power is primarily psychological.

idealism Found in various forms, including a belief in the infinite malleability of human nature, the transforming effects of new international institutions, the good intentions and motivations of particular statesmen, and the belief that for every problem there are resources, financing, and organizations that can solve them. It affirms that no problems are really insoluble, however hopeless they may appear, given well-meaning, well-financed, and up to date scientific approaches.

interest The main sign post that helps political realism find its way through the landscape of international politics. Interest links reason and the facts to be understood and

sets politics apart from economics. George Washington wrote: "Small knowledge of human nature will convince us, that, with far the greatest part of mankind, interest is the governing principle." Max Weber wrote: "Interests (material and ideal), not ideas, dominate directly the actions of men."

morality In international politics, morality is significant in political action but takes form in the inevitable tension between the moral command and the requirements of political action. Moral principles must be filtered through the circumstances of time and place and there can be no true political morality without prudence or without consideration of the political consequences of seemingly moral action. Prudence requires the weighing of the consequences of alternate political actions in moral and political terms.

nationalism A social and political force that was the predominant force in the 18th and 19th centuries. Although it proved more powerful than competing forces such as socialism based on common interests of workers in World Wars I and II, it has somewhat weakened after World War II especially in the developed countries such as France and Germany. It has intensified in the less developed countries of Africa and Asia.

power Man's control over the minds and actions of other men and the psychological relation between those who exercise it and those over whom it is exercised. Power derives from three sources: the expectation of benefits, the fear of disadvantages, or the respect for men or institutions. Power is relative, fungible, and subject to change in the ending competition between individuals and groups.

realism The assertion that politics is the result of forces including rivalry and the struggle for power which are inherent in human nature. One must work with these forces as we do internationally through the balance of power and domestically with the separation of powers in the presidency, the Congress, and the courts. It distinguishes between the "is" and "the ought." In such a world, moral principles can never be fully realized but must at best be

approximated through the ever temporary balancing of interests and the ever precarious settlement of conflict.

Hans J. Morgenthau is generally considered the father of political realism in the United States. More than a half century after its publication in 1948, his greatest work, *Politics Among Nations: The Struggle for Power and Peace*, remains a leading text for courses in international relations. We have few precedents for a work of this kind to continue as one of the dominant writings for 55 years. As I write, a seventh edition is being planned for publication in 2004 with defenders and critics still in evidence.

In evaluating Morgenthau's contribution to the study of international relations, focusing only on *Politics* would be less than half the story. Indeed, running through Morgenthau's life and work are two underlying commitments, one to philosophy and the other to politics. Two years before *Politics Among Nations*, Morgenthau published *Scientific Man vs. Power Politics*, a treatise that challenged the overall scientific approach to the social sciences. He set forth the idea of a "Philosophy of International Relations," which sought to integrate some of the themes that had marked his earliest writings on legal norms. In 1952, he gave the Walgreen Lectures at Chicago on Marxism and he wrote elsewhere on liberalism and its problems. What emerged was unmistakable evidence of a dual commitment in which his concern with politics was accompanied by a devotion to philosophy, an understanding of which takes us back to his birthplace in Coburg and to Germany during the period 1904–1932.

Youth in Search of Enduring Purpose for His Life

Morgenthau's childhood and youth constituted a quarter of his life, some 19 years of immense promise darkened by overwhelming loneliness. His formative years are remembered more for suffering and unhappiness without as much as a trace of the normal joys of youth; they were spent in the beautiful hills and valley that made up Coburg, which became the capital of the Duchy of Saxony-Coburg in the middle of Germany. His father was a medical doctor and a conservative patriot; he was a Jew who wanted to be a German and who worshipped the Emperor Wilhelm II. The Emperor had abandoned the strategic views of Otto von Bismarck and by his flamboyant policies helped bring on World War I. Yet Hans' father, Dr. Ludwig Morgenthau, wishing to show his patriotism, gave him the middle name of the Emperor youngest son, Prince Joachim. Worse than that, he continuously belittled and criticized Hans often unmercifully until he fell ill with what became a serious respiratory

disease. When it came time to choose a college, the father told Hans he could never be admitted to the University of Berlin. His father's ridicule was matched by the scorn fellow students had shown for him and the name calling when they marched in formation. When he received the "First in His Class Award" as the top student of his class preceding the graduating class, he was to climb a high ladder, place a laurel wreath on the statue of the school's founder and give a farewell address to the graduates. Printed leaflets were distributed by townspeople the morning of the ceremony instructing the citizenry to give "Mister Abendnebel" (evening fog) a lesson. It was a pun on Hans' last name—Morgenthau (morning dew). People spit on him and shouted anti-Semitic insults. The former duke appeared at the gymnasium and held his nose at the sight of Morgenthau. From the memory of this harrowing experience, he took refuge in his studies. He wrote a Gymnasium assigned competition on "hopes for the future" inspired by Goethe. In the essay, he addressed two goals he might pursue: (1) to lessen the social apprehension and anti-Semitism from which he suffered and (2) to select one of two types of vocations he would pursue throughout the rest of his life. For each of these, he resolved: (1) to withstand the social ostracism and painful insults from representatives of anti-Semitism, and (2) to choose between two kinds of vocations or goals for his life, one of piling up mountains of wealth accumulating year after year as he became richer and richer or the other of working in the service of some great idea, the fruits of which would outlive him. He chose the latter goal which was to guide him until the end of his life. Such a lesson, discovered at an early age, was to remain with him until the end. As for Coburg, it was to become a battleground between Nazis and the defenders of the Weimar Republic. On October 14 and 15, 1923, Hitler, backed by eight units of 100 men each and his own band of 43 warriors, triumphed.

University Education and Formation

One limiting factor in Morgenthau's education was the harsh evaluation of his father that he was not qualified for admission to the University of Berlin. No doubt this influenced him until the end of his life, perhaps later in life in coveting a permanent appointment at Harvard. His father was determined he study law but from earliest childhood his interest was history. In the beginning it was wars from Cannae to Waterloo, then the Balkan Wars and World War I. Next in his evolving interests was German literature, and from this he was drawn to becoming a writer. Following this, his interest turned to philosophy directed to the ultimate questions of human

existence. However, when he chose philosophy in his studies at the University of Frankfurt he became bitterly disappointed. It was a discipline then totally absorbed in epistemological questions that were wholly rational and pseudo-scientific. Moreover, philosophy like literature had little to offer by way of possible financial rewards. A compromise for him was jurisprudence or legal philosophy, and to study this he transferred from Frankfurt University to Munich University. There he was an indifferent student except for courses by two extraordinary professors who offered courses in art history and Max Weber's political thought. He transferred from Munich to the Friedrich Wilhelm University in Berlin where he attended courses in international law, especially with Professor Karl Neumeyer who inspired his interest in the subject.

He passed his first law exam in February, 1927, making this choice partly because of his father's strong urging that he seek academic degrees in law. However, for him a career in law was to have few attractions. He accepted a legal internship appointment with assignments in the Bavarian Ministry of Justice in Munich but then fell ill with tuberculosis and one of his lungs had to be removed. He was allowed to continue his internship in Frankfurt, where he joined the staff of a professor of labor law at the University of Frankfurt who for the rest of his life remained his friend and adviser. Professor Hugo Sinzheimer was a Social Democrat in the National Assembly in Weimar and served on a committee to investigate "the stab in the back theory." According to that theory, Germany with no foreign troops occupying it after World War I, had not been defeated but was a victim of Jews and other groups who conspired against it following the war. Sinzheimer retired from politics as a Deputy in the German Assembly and partially retired from the practice of the law, turning more and more of his duties over to his younger intern. Throughout his association with Sinzheimer, Morgenthau met some of the most famous scholars of the day and was drawn into their discussions. Then he returned to his thesis, approaching it less from the canons of international law and more from the sociology of law and the social forces that shaped the law. The thesis was approved and published with the title: *The Judicial Sanction in the International Realm: Its Nature and Limitations*. All the reviews were full of praise. His thesis adviser wrote that the thesis deserved a *summa cum laude* and was equivalent to the second degree for habilitation, the degree above the thesis, which qualified the writer for a tenured position in universities in Germany, Austria, and Switzerland. Professor Paul Guggenheim praised the author for "an astonishing familiarity with the literature." Yet on its completion, Morgenthau found, perhaps because of rising inflation and political uncertainties in Germany, that no academic positions were available. None being available, Morgenthau sought

other openings and learned of one at the University of Geneva primarily designed for a professor who would be responsible for German students who came to Geneva to learn French and complete their law training. Morgenthau applied again and again for permission to present himself for the habilitation degree in Geneva. He was accepted provisionally and invited to give a probationary lecture but in French not German. On February 17, 1932, which was his 28th birthday, he crossed the Alps into Geneva expecting to return to Germany with a final degree qualifying him for a professorship.

Education Continues in the Real World

He could not have anticipated the events that followed. His probationary lecture in French was judged to qualify him only for quite limited teaching in Geneva. He appealed to be allowed to give the lecture in German but even here he was only granted permission to teach on a limited basis until he had demonstrated his skills more fully. At first he attributed this ruling to two anti-semitic German professors on the committee. Soon he realized, however, after several appeals to the Dean of the faculty, that the opposition must have come from one or the other of two sources. He decided the one was most likely a result of philosophical differences that were unbridgeable. That left a second referee who turned out to be his so-called friend, Paul Guggenheim. Morgenthau concentrated his response to him. He pointed out that Guggenheim completely misunderstood what his book was all about. Moreover, he noted that his study had been quoted in detail by famous international lawyers such as Hersch Lauterpacht who gave it far more attention than any of Guggenheim's writings. Morgenthau sent copies of his thesis to other professors abroad requesting their evaluation. Finally, he requested that a new commission evaluate his thesis. The commission was appointed and Hans Kelsen was made its chairman. After deliberating, the Kelsen commission approved the thesis and granted habitation. Once approved, however, Morgenthau learned that no positions were available in Germany, the country to which he had planned to return after his habilitation. In fact, German scholars of great repute had already left Germany for positions in the Netherlands, Turkey, and Switzerland. Morgenthau once again turned elsewhere for an appointment.

He found it almost by accident in Spain, where an American international lawyer, Leo Gross whom Morgenthau knew, turned down a little advertised position in Madrid. Morgenthau was recommended by Hans Kelsen and he was appointed. His days in Spain were among the happiest in his life, measured in terms of hap-

piness if not scholarly output. He was appointed to the staff of the *Institute de Estudios Internacionales Economaeos* in Madrid to give courses in international law, write a research study about international law, and prepare a compilation of international law topics and interests. He went to Madrid where he was married to his longtime friend, Irma Thornvaun. He was appointed for 12 months subject to renewal. He arrived in the spring of 1935 but when civil war broke out he took leave in 1936. He and his wife fled and went to Merano, Italy; Paris; and Switzerland, spending all their resources as they moved across the continent. He turned elsewhere to seek alternatives.

The New World: At Last, the United States

After all that had happened in Spain and Switzerland, Morgenthau decided to make one last effort to find employment in Europe and, if that failed, to obtain a visa to emigrate to the United States. At the end of 1936, Madrid was the scene of the most violent fighting in the Spanish civil war. Returning there was ruled out. Morgenthau tried for a position as foreign editor of the Dutch newspaper *Del Telgraaf* without success. He sought a teaching position in The Hague at the Academy of International Law only to be turned down again. He considered Palestine as a possibility but dropped the idea. He thought seriously about South America if some kind of academic position turned up. Once more he applied to the Rockefeller Foundation to finance a research visit to Argentina but was rejected for the second time. For a time he thought of the United States as the last place worth considering. If he had known the way foundations operate with their own programs and priorities, he might not have been so disappointed. His odyssey in search of opportunities in Amsterdam, the Hague, Merano, Geneva, and Paris were all failures. Then a young Swiss woman tipped him off that the resident American Counsel, who was anti-Semitic, was on vacation. The fact he had lived in Geneva for three years made it appear he had had permanent residence there. His wife received an affidavit from a rich cousin, which impressed the vice consul in Geneva who granted the visa in a few days. A visit to Italy to say goodbye to Morgenthau's parents and to settle financial matters concluded his preparation. They left for the United States with \$1200 in their pockets—hardly enough to start over again in the United States. On July 17, 1937, they boarded the steamer *Konestein* in Antwerp happy that they would finally be catching sight of the Statue of Liberty and to a new life in the United States.

On arriving, Morgenthau started his job hunting by immediately traveling to Indiana, Illinois, and Wisconsin. Everywhere the question was the same. Had he experience in teaching in English? If not, no one was ready to take a chance with him. He had known one professor of Semitic languages in Paris who was said to be teaching at Columbia. He climbed the long stairs at the entrance to Low Library and knocked on Professor Richard Gottheil's door only to learn that he had died unexpectedly a few weeks earlier. A German lawyer he met introduced him to Columbia University international law professor Philip Jessup who gave him numerous letters of introduction and names and addresses of scholars who might help. By October 1937, he was still on the street and beginning to apply for nonacademic jobs. He turned down a job as an elevator operator but made it known he would have accepted a job as a proofreader in a publishing house. He left his name and address at various universities and in this way learned that an instructor at Brooklyn College had fallen ill. When the colleague's health did not improve, the temporary job became a regular position for Morgenthau if he wanted it. He taught from eight to eleven o'clock in the evening three times a week, for \$3.50 an hour. Even with his wife working as a hat salesperson at Macy's, they earned a combined \$180 a month. Long hours, low pay, and a restless, rebellious, and radical student body led him to consider other opportunities. After one year at Brooklyn College, he joined the two faculties of law and the liberal arts college at the University of Kansas City. He remained there from January 1939 until the autumn of 1943, a move that proved to have even more disturbing qualities, mostly revolving around the character of the president. While the Morgenthau enjoyed mid-west friendliness, he soon complained about tight office space, inferior library resources that featured only one book in international law, and a course load that he found required him to give up to a dozen courses in law from administrative to testamentary law. He also ended up teaching European politics in the college. He taught 18 hours a week and colleagues approached that number. The American Association of University Professors surveyed the problem and denounced conditions in its annual report for 1942, recommending the faculty be allowed to assume more responsibility for its courses. In a vote by the faculty for membership in a committee of three to examine the situation, Morgenthau received the highest vote. Once the United States entered World War II, President Decker at the end of 1942–43 fired faculty members including Morgenthau citing lack of qualified students. Decker refused to accept the AAUP action against him and presented his case before the Association of University Professors and the Association of American Law Schools. After hearing the evidence, the two bodies insisted that President Decker withdraw the dismissal of faculty members. By the

time this happened, Morgenthau had already left the University. He sought to enlist in the military but was turned down for health reasons, particularly the absence of a lung. In the summer of 1943, he wrote to over one hundred universities from the Ivy League and some third class institutions in Nebraska. None offered him an appointment. Just as he was preparing to give up, Professor Fredrick S. Dunn who was head of the Institute of International Studies at Yale wrote offering him a temporary job in a research project at the Institute. Very shortly after writing to Dunn to accept the offer he received a letter from the University of Chicago asking him if he would be interested in replacing Quincy Wright for six months at a salary of \$2600 for the period. With Dunn's approval, he returned the Yale offer and accepted Chicago. He had written earlier in the *Neue Zürcher Zeitung* that the University of Chicago was "one of the greatest, wealthiest, and scientifically most prominent in the country," little imagining he would someday become a member of the faculty.

After all his suffering and disappointments, it would seem that a life rewarded by success and happiness was his due. Yet that was not to be. He joined a department that some have described as "Merriam's Department." Charles Merriam had introduced a brand of political science that was viewed as largely scientific, in the spirit of the age. Not only did it draw inspiration from the age of the enlightenment but he defended his approach as primarily scientific although there was little evidence of this in his writings. It was grounded less in testing and experimentation than in the claims that were made for it. The government department was Merriam's department and he passed judgment on everything that went on in its name. For example, when Morgenthau published *Scientific Man vs. Power Politics*, Merriam promptly advised the newest member of the Department that perhaps he should offer a course in administrative law. The younger faculty whose work attracted Merriam were scholars such as David Easton, Gabriel Almond, and Harold Lasswell, not all of them as yet in the Department. With Merriam's or his allies' strong and energetic support, they became members. The next two chairmen of the Department were Leonard White, who was to write the basic text in public administration, and Herman Pritchett, whose work in administrative law and administrative regulation and the process of change taking place in judicial opinion in the Supreme Court introduced a form of science that Merriam considered appropriate. It was not science as such but it was rather a new methodology that bore the title scientific, using it with supreme confidence as representing the wave of the future. When they thought of additions to the Department, they almost always thought in these terms.

In yet another respect, this approach differed from Morgenthau. He brought to the subject an interest in

traditional political theory. He saw his roots in the same kind of political theory that was associated with Aristotle and Plato, not Harold Lasswell or Merriam. The majority of faculty members claimed they were less concerned with the ancients than current political thinkers. None were so extreme as Charles Hyneman of Northwestern University who went on to become president of the American Political Science Association and who once asked "Why study the thought of dead men?" Without using these words, Merriam and others saw the work of present day writers as pointing the way to a new and modern political science. If this suggests that Morgenthau was "on the outside looking in" as a member of the political science department, that was true. It became commonplace that departmental meetings chaired by Leonard White separated difficult and controversial questions, resolved before departmental meetings, from items on the agenda. The sessions that followed dealt largely with housekeeping details such as assignment of office space or of secretaries.

In a word, Morgenthau's brand of political science was not "the wave of the future" as Merriam saw it. Yet as time went on this began to change. Students and GI's returning from military service in World War II had read the literature. They came prepared to study with Merriam, Quincy Wright, or Leonard White. They found they were assigned to these more prestigious figures as assistants for grading student papers or helping with the organization of classes. Yet little by little they came to recognize the teaching and research of the newest and latest addition to the department. At the outset, rumor had it that Morgenthau was a hard grader and a stern taskmaster. Rumor had it that if you were likely to have a thesis or a dissertation questioned and perhaps turned down, Morgenthau was probably your adviser. On the contrary, he graded most student papers himself and was intensely interested in the findings his students reached and the route they followed in reaching them.

My work with Morgenthau began when he sought an assistant to work with him on his major treatise, *Politics Among Nations*. Until then, I mainly assisted Quincy Wright grading term papers, examinations, or helping prepare questions for examinations. Once I began work with Morgenthau, I found him business like and exacting but not someone hell bent to prove I lacked the necessary talents or preparation to be a political scientist. He needed help and I was determined I would assist him according to his kind of schedule. Yet, among some students the image persisted of a gruff and hostile professor with little interest in his assistants or students as distinct and unique personalities. Instead, I found he was always willing to work with and help me in any way he could. It was true that since he worked at virtually every hour of the day and late at night, an assistant had to adjust his schedule to the professor's. Morgenthau had his own work plan which continued

well into evening hours. His wife, Irma, had spoken of his bringing sandwiches from home and a container of tea he himself had brewed so that he could continue to work. But I found all this worthwhile for my intellectual growth and development. Hardly a work session passed that I did not gain fresh new insights.

The route to success was fairly obvious for Morgenthau. It differed sharply from Merriam's or Wright's. Charles Merriam's reputation was such that he spent part of most weeks in Washington. He and his colleagues kept an apartment in the Hay Adams Hotel, not far from the White House. This was President Franklin D. Roosevelt's era and his aides were seeking to reorganize and reform the Executive Office. The report of the President's Committee on Administrative Management begins "The President Needs Help." A blue ribbon committee led by Luther Gulick and colleagues sought to map out a plan for reforming the administration of the executive branch of government. Some of the younger faculty in public administration at Chicago "cut their teeth" on this mission. Lurking in the background of the effort was Charles Merriam. He was the *eminence grise* who marked out the course that was to be followed. On the outskirts of the campus of the University of Chicago a substantial center was created called "1313" after its address on 61st Street. It co-opted those who were engaged in the work of the Committee on Administrative Management. When Morgenthau arrived in Chicago, "1313" was the focal point for collaborative work for departmental persons to work with staff at "1313." Some members of the Government Department had joint appointments. There were few other points of contact for the most recent new member of the department faculty.

Notwithstanding, cooperative efforts with Quincy Wright evolved for Morgenthau. One example is the exchange of information by students. Morgenthau asked Quincy Wright for suggestions of a graduate student who might assist him with *Politics Among Nations* and Wright recommended me. I was sorry to leave Professor Wright but working with Morgenthau was an opportunity I could not turn down. When Wright retired from the University of Chicago, he moved to Charlottesville and accepted an appointment as a visiting professor. He continued at the University of Virginia until his death. When Morgenthau participated in a conference at the Miller Center organized by James Sterling Young, Wright had only recently passed away.

The main encouragement Professor Morgenthau received at Chicago came from the University's top leadership, a few junior or lesser colleagues, and most of all from his students. The latter are the easiest to account for because the pattern was so predictable. Most of them came to his classes inclined to make invidious comparisons. They left with moderate to evangelical commitment to his ideas. Idealistic students found they could preserve

their ideals at a deeper level while shedding the utopian illusions that earlier moral and political education had given them. Their first weeks in Morgenthau's classes were a time of encounter. His lectures rarely if ever went uninterrupted. As time passed, students saw more clearly that his conception of international politics had coherence because of its grounding in an evolving philosophy of international politics. Students transmitted and exchanged his thinking with others, including Professor Wright, who more and more sensed that questions were being raised with which he had to come to terms. In my time as an assistant to both Wright and Morgenthau, I marveled at their restraint in talking about each other's work. Their days at Chicago were the golden age of international studies. No one doubted to which of the two scholars they were responsible. Both were men of integrity and each had the ability of taking the other's views and subjecting them, as distinct from some outsider's interpretations of them, to searching analysis and criticism. Wright's most deeply held commitment was to the science of international relations, reflected in his *Study of War* and his *Study of International Relations*. Yet throughout a long and varied career, he remained conscious that philosophy had a necessary place in the vast eclectic array of approaches he discussed that comprised international relations.

Multiple Success Stories at Last

Whatever role Morgenthau's friends or foes played in the unfolding of his career, once he emerged as a leading figure in international relations, he alone deserved full responsibility and credit for his ascendancy. From years of intensive study and late nights of laborious drafting of every fragment of his intellectual legacy, he earned his stature. That is not to say that he did not receive help from loyal friends and students or colleagues with whom he had ongoing communication. Students whose devotion to him knew no bounds prepared texts of his lectures. One of his students, Mary Jane Beneditz, made a stenographic transcript of the lectures given in the Winter Quarter of 1946 as well as of the class discussions. Morgenthau paid tribute to her saying "her intelligent and painstaking labor made available the only written record of those lectures; without that record the book could not have been completed in little more than a year." (*Politics Among Nations*, foreword to the first edition, 1988.) Those of us who worked with him were all too familiar with his notes and citations in German shorthand. Through my years of working as an assistant while also enrolled in his classes, I never ceased marveling at the intense concentration he achieved in rapidly reviewing his notes before going into class. It was as though he went into some kind of trance behind the closed doors of his office. We had no doubt

that in this interval he would brook no interruptions. Once in class he lectured for the full hour, always without a note or reference. As time went on he lost some of this ability, but to the end he remained free of all notes and texts as he spoke. His reputation spread abroad wherever he went and to whomever he spoke. The world became his classroom as he lectured to groups whose invitations he always treated with respect. From being a professor at a single university, he taught a new generation here and abroad. He traveled and spoke in Asia, Canada, Europe, and South America long before ordinary channels of communications were fully open to distant parts of the globe. He responded especially to invitations in which his students had a hand, occasionally receiving substantial fees but more often than not only what the traffic could bear. It was as if the mission he outlined for himself when a fledgling student "of working in the service of some great idea, the fruits of which outlive him" merited every ounce of his energy in travel and speaking out wherever his goals and purposes carried him. He learned from his travels and questioned oversimplified interpretations, for example, about Asian nationalism. In India and China he looked in vain for the type of revolutionary nationalism often attributed to it by western writers. Instead he argued that for nations there were basic purposes and objective standards by which their foreign policies could be measured. American interests in Asia began in a political and military sense at the turn of the century. Our Open Door policy under Secretary Hay was commercial in the beginning, seeking to keep China open for trade and development by all the major powers. The aim was to keep any one European or Asian power from controlling the great economic and political potential of China. What began as a commercial policy became military and political to prevent any European or Asian power from dominating all Asia. In this way the Open Door policy was transformed into a balance of power policy for Asia. When Russia overcame Japan in 1905, Theodore Roosevelt sought to limit Russian power much as we did after Japan's invasion of Manchuria. In the Summer of 1941 when President Roosevelt and Secretary of State Hull declared we would not countenance any further Japanese expansion, Pearl Harbor became inevitable. After World War II, the United States saw Japan as a check on what was seen as a nearly imperialist power, China. Yet under the postwar policy of the United States, we had convinced the Japanese they should embrace pacifism and rule out regular Japanese military bases. Japan's postwar constitution was inspired and shaped by General Douglas MacArthur. When Morgenthau went to China in 1955 he was convinced that China was being restored, that India and China were not going to be locked in a struggle of competing nationalisms but rather China's goals, especially to its west and southwest, were ones of restraint and not of conquest. China would follow a policy of traditional cultural

expansion and not of military conquest. Morgenthau's study of China's history and his 1955 visit led him to an outlook at odds with General MacArthur's. Morgenthau agreed with the policy best defined by Secretary of State Dean Acheson in a speech before the National Press Club in Washington in January 1950.

The New York Story

In 1968, Morgenthau left Chicago and moved to New York. As the years passed, he had discovered that some of his closest friends were no longer in Chicago but in Washington and New York. They included Hannah Arendt, the foremost woman political philosopher, who over the years had encouraged Morgenthau to return to his earlier scholarship in political philosophy, and Robert J. Myers, former publisher of *The New Republic* and *The Washingtonian* and director of the Council on Religion and International Affairs, later the Carnegie Council on Ethics and International Relations. Over the years, his happiest reunions took place in New York and Washington with many of his former students. When he returned from them, he would speak of being renewed and reinvigorated. Of the 26 scholars in international relations who wrote chapters for the Morgenthau festschrift (*Truth and Tragedy: A Tribute to Hans J. Morgenthau*) 17 were in the east, most of them from the Washington to Boston corridor. If the attraction of this group constituted the pull for Morgenthau, the push was the passing or relocation of many of his closest and dearest friends and colleagues and before long his wife in Chicago. Moreover, New York and Washington in particular were the centers of decision making in public policy and that increasingly concerned Morgenthau. He recognized that at some point he would be cutting back on international travel and for this reason these centers became more attractive.

An important factor in his moving to New York was when he received an offer of the Leonard Davis Distinguished Professor of Political Science at City College of the City University of New York. It provided an opportunity to continue teaching, something that he cherished until the end of his life; after leaving City College, he taught at the New School for Social Research. When it appeared that that appointment would be terminated, he asked me to contact President John Everett to correct a possible misunderstanding. I did so and he continued to teach once it was definite that doing so was his wish. He took satisfaction from the fact, despite all his earlier disappointments with foundations, that he was called on repeatedly to serve on advisory committees of the Rockefeller Foundation and others. When someone once asked him why he attended their meetings and served on their committees, he answered "because they

asked me.” He not only was an officer of an organization that now bears the name of the Carnegie Council on Ethics in International Relations but on his death they established the Hans J. Morgenthau Lectures.

If he felt disappointment that he was not called upon to the same degree he had been earlier, he came to understand that nothing lasted forever. Sometimes when he was asked to participate, he discovered that his research and writing was more an object for criticism than a subject that earned him praise. He was invited to be a scholar in residence at the Council on Foreign Relations in New York only to discover that the study group that oversaw his work on *A New Foreign Policy for the United States* included a number of his critics. Among members of his committee were Henry Wriston, president of Brown University, Philip Moseley, Columbia professor and director of studies at the Council, Frank Altschul who was friendly and sympathetic, and John J. McCloy. A debate between him and members of his committee developed and eventually Morgenthau withdrew and published his book outside the jurisdiction of the Council. Debates were staged in such a way that he was a minority voice but this had been true throughout much of his career. The final verdict was that he was a giant in his field well ahead of his time.

If there were disappointments in New York, there were also rewards. Friends planned receptions in which he was the guest of honor. He had dinners with close friends like Hannah Arendt and she was his companion at anniversaries and lectures of organizations boasting highly distinguished memberships. He enjoyed going to movies with younger friends such as my son Paul and they returned the favor. All in all, he found a rich and stimulating environment even as he contributed to the process.

His trip to China and his critical response to the view that China’s military buildup was not for conquest but for cultural expansion was linked with his evolving perspective on Vietnam. For many, his crusade against American policy in Vietnam was a departure from much of his earlier emphasis on power. Many who were his critics saw no connection between his earlier emphasis on power and military strength and his policy for Vietnam. They failed to remember the distinction he always drew between power, which was inevitable in politics, and force, which was a last resort. In effect, he became the number one critic of American policy in the small Asian country. He argued that we had stumbled into the conflict without any plan or well-considered program. First military admirers, next 15,000 troops, and eventually 500,000 troops were sent to Vietnam as one intervention followed another. He could find no basis for our policy either in national interest or compelling international agreement. He took exception to the argument that it was the protocol to the SEATO Agreement that required members to come to the aid of beleaguered fellow members. Because of con-

cern over France’s participation in organizations like NATO in Europe, we were taking up the conflict in Asia after France’s defeat at Dienbienphu. In Secretary John Foster Dulles’ words “we got involved in Vietnam to see what we could salvage.” What was unusual about Morgenthau’s response to Vietnam was his taking up the unaccustomed role of being the foremost spokesman against a major U.S. policy.

In effect, Morgenthau crisscrossed the country making speeches against our policy in Vietnam. For some he became a leader of the cultural revolution in which the largest number of young people in our history were campaigning against a policy but also against the mainstream culture both in society and the academy. This group turned to him and urged him on at a point in his life when he might have been expected to rest on his laurels. He took part in televised debates on Vietnam with administration spokesmen such as MacGeorge Bundy and Zbigniew Brzezinski, debates about which he complained that his opponents had used heavy handed and dubious arguments and tactics. Vindication came when many in the public took up his cause but by then he was weary and dispirited from what had seemed a losing battle with the more outspoken military and reactionary spokesmen elements in society. Some of his friends asked was this not a role in which he had not been involved earlier? Was he faced to pander to outspoken and radical young people incapable of viewing the subject in the language of international politics? The Vietnam chapter in Morgenthau’s life was both courageous and at times unbecoming for a great scholar. Make no mistake however, he might well have used the words of Churchill that he too was not always mistaken. Now that Vietnam is the subject of succession of highly critical monographs and historical studies viewing it as a tragic chapter in U.S. history, it seems clear he had not been engaged in a futile and useless endeavor.

The Crisis and Morgenthau’s Legacy

His interpretation was ahead of its time and by the 1970s there was growing discussion of the issue of the decline of the West. Oswald Spengler’s book with that title attracted attention in Europe and the United States. The Club of Rome represented an influential group of intellectuals and scholars who saw evidence that the West had suffered significant setbacks both intellectually and morally. There is reference in the preface to *Scientific Man* to the rise and fall of the Roman Empire. The political crisis about which he wrote had grown increasingly obvious in the first four decades of the 20th century. The crisis had roots in a general decay of political thought that for Morgenthau

took form in the belief that science could solve all problems, including political problems. The period leading up to World War II was dominated by the rise of Nazism and the failure of many to identify its deeper underlying sources. Critics warned that liberal illusions weakened a more coherent understanding of the threat. What *Scientific Man* offered by contrast was a restatement of fundamental political principles as the basis for political action most of them set forth in classical political philosophy. By juxtaposing the principles of classical political thought and the belief that science could solve all problems, and particularly political problems, Morgenthau sought to demonstrate the superior nature of the former. The idea that both the national and international system as presently constructed made the struggle for power among its units the central phenomenon of political life is discussed as it relates to the quest for political stability. Opposed to this view, the Wilsonian philosophy of liberalism sees an essential harmony of interests underlying the relations among nation states. Morgenthau recognized that political philosophy is an art and not a science, and what is required for its use is not the rationality of the engineer but the wisdom and moral strength of the statesman. He sought to put political philosophy and statesmanship at the center of things political. This was his goal rather than the wholesale reconstruction of political life by new concepts and designs.

Some observers have argued that *Scientific Man* is a call for Western Civilization to rediscover its ultimate purposes and to reconcile traditions with the experiences and exigencies of modern life. The statesman seeks to create an emerging society out of his knowledge of the nature of man. However, neither science nor ethics can resolve the conflict between politics and ethics and bring them into harmony. We have no choice between the pursuit of politics and power and the common good. He wrote: "to act successfully, that is according to the rules of the political art, is political wisdom. To know with despair that the political act is inevitably evil, and to act nevertheless, is moral courage. To choose among several expedient actions the least evil one is moral judgment. In the combination of political wisdom and moral courage and moral judgment, man reconciles his political nature with his moral destiny." (*Scientific Man*, p. 203).

In 1951, Morgenthau published a third book that focused on American foreign policy. The book contained an enlarged version of lectures he gave in the Spring of 1950 at the University of Chicago under the auspices of the Charles A. Walgreen Foundation. For those who attended the lectures and expected a call for a new American foreign policy, they heard a defense of returning to an older American foreign policy. Little did I know when I began working with him on *Politics* that we would soon be engaged in preparing another book, *Principles and Problems*

of *International Politics*, which was published in 1950, a year before *In Defense of the National Interest*. The earlier chapters of the two books overlap, whether or not they coincide. Our book contained selections from opposed viewpoints: Hamilton and Madison, Disraeli and Gladstone. Morgenthau in *In Defense* identifies three periods in American foreign policy: the *realistic*—thinking and acting in terms of power represented by Alexander Hamilton; the *ideological*—thinking in terms of moral principles but acting in terms of power represented by Thomas Jefferson and John Quincy Adams; and the *moralistic*—thinking and acting in terms of moral principles represented by Woodrow Wilson. The three periods in American foreign policy roughly correspond with their definitions, the first covering the opening decades in the history of the United States as an independent nation, the second the 19th century culminating in the Spanish American War and the half century after that war. Morgenthau qualifies his periodization by acknowledging that the three definitions refer only to prevailing tendencies without precluding the appearance of other tendencies in the same period. In *Principles*, Morgenthau and I also tried wherever possible to contrast different points of emphasis, for example, we compared Wilson and W. R. Gladstone as representatives of the idealist view, and then both with Benjamin Disraeli and Lord Salisbury. The book *In Defense* is outmoded in certain respects but in other respects it remains applicable to the present era. In a section on *The Three Revolutions of Our Age*, Morgenthau discusses the Political Revolution, the Technological Revolution, and the Moral Revolution. While the Cold War between the United States and the Soviet Union constitutes the main focus, topics on the rise of political religions and the revolt of Asia are discussed and in this way the rise of Alcaeda and Moslem attitudes toward war and peace are foreshadowed. The use of broad principles and categories advanced in an earlier period opens the door to thinking about developments that have occurred in the last quarter century.

The final volume published in 1960 is *The Purpose of American Politics*, a study of normative and ethical aspects of international relations. One distinguishing feature that stands out in contrast to most normative studies is its consistent use of an historical context. The spotlight is on American history and the extent to which normative concerns, and in particular freedom and equality for the United States, are ordering and defining principles. The study begins with the founding and tracks American history through wars and their resolution, the depression, civil rights and a developing globalization. For our time, it traces the development of U.S. hegemony. The picture is one of advance and retreat. It moves from a strong emphasis on the American purpose to its subordination to partisan and lesser interests and the setting aside of

a broader national purpose. As a means to exposing students to the rise and fall, the decline and the rediscovery of moral purposes, the study is a textbook on political morality. I have used it as such for more than a quarter of a century.

While *Scientific Man is Power Politics* came out two years before *Politics*, it was in a certain sense painted on a broader canvas. The opening sentence in *Politics* reads: "This book purports to present a theory of international politics." By contrast, *Scientific Man* was intended as a critique of the social, political, and moral philosophy of contemporary society in the West. If *Politics* received criticism on publication, it came primarily from theorists and historians of international relations more than philosophers of history. In assisting Morgenthau, I remember reading prepublication reviews of *Politics* by Princeton's Harold Sprout and Yale's Arnold Wolfers. Their questions were methodological rather than philosophical. *Scientific Man* was deeply pessimistic in terms of its judgment of history, while *Politics* held out the hope that diplomacy might move the world toward some form of a more unified system of world government. It reflected an attitude of qualified optimism regarding the future, another difference. If *Politics* was primarily a treatise on international peace and order, *Scientific Man* contained the core of principles and prevailing philosophy of political realism in which hope resided for the West. Partly because Morgenthau was less well known when he wrote *Scientific Man*, the critics were more outspoken and more sweeping in defense of science than were the opponents of *Politics* in their evaluations. In turn, at least a select number of those who championed his approach became staunch and outspoken defenders of his political theory and that has continued down to the present day. Whether the issue was relations with the Soviet Union in the Cold War or the War against Terrorism they looked for a reasoned, pragmatic, and sequential approach to the problem at hand rather than a complete and total solution which some

would call hard Wilsonianism. Thus, Morgenthau's collection of studies beginning with *Scientific Man*, extended through his systematic and comprehensive study of *Politics* and ending up with *Purpose*, provide a framework for understanding his overall approach to the unfolding crisis in international relations.

Multicollinearity

D. Stephen Voss

University of Kentucky, Lexington, Kentucky, USA

Glossary

collinearity A special case of multicollinearity in which one variable is a linear function of another. Social scientists often use the two terms synonymously.

full multicollinearity When two or more explanatory variables overlap completely, with one a perfect linear function of the others, such that the method of analysis cannot distinguish them from one another. This condition prevents a multiple regression from estimating coefficients and the equation becomes unsolvable. Also called perfect multicollinearity.

multiplicative model A model that presumes the dependent variable is a multiplicative function of the explanatory variables rather than an additive function. Researchers sometimes induce full collinearity in these models when they attempt to include interaction terms or ratio variables.

partial multicollinearity When two or more explanatory variables overlap, such that they are correlated with one another in a sample but still contain independent variation. This condition limits the extent to which an analysis can distinguish their causal importance, but does not violate any assumptions required for regression.

Multicollinearity (or, as it is sometimes abbreviated, collinearity) describes a condition that may appear when analysts simultaneously consider more than one explanation for a social outcome. It occurs when two or more of the explanatory variables in a sample overlap. Because of the overlap, the methods of analysis cannot fully distinguish the explanatory factors from one another or isolate their independent influence. Social scientists usually apply the term when discussing multiple (linear) regression, in which case it refers to a situation in which one independent variable is fully or partially a linear function of the others; however, many forms of

quantitative and qualitative analysis have their own version of the multicollinearity problem. Thus, although this entry explores multicollinearity formally using the notation of linear regression, it outlines the analytical issues more broadly as well.

Introduction

Multicollinearity stands out among the possible pitfalls of empirical analysis for the extent to which it is poorly understood by practitioners. Articles in social science journals often expend an extensive amount of space dismissing the presence of this condition, even though it poses little threat to a properly interpreted analysis.

At its extreme, when explanatory variables overlap completely, multicollinearity violates the assumptions of the classical regression model (CRM). Full (or perfect) multicollinearity is easy to detect, however, because it prevents the estimation of coefficients altogether; an equation becomes unsolvable. This is not the sort of multicollinearity that customarily worries analysts. Full multicollinearity rarely appears in social science data unless the sample is exceedingly small. Otherwise, it generally results from some kind of simple error in the data handling or model specification, one that is easy to diagnose and painless to address. When practitioners speculate about a possible “multicollinearity problem,” therefore, they mean some sort of linear relationship among explanatory variables that falls short of complete overlap.

Partial multicollinearity—the use of overlapping variables that still exhibit independent variation—is ubiquitous in multiple regression. Two random variables will almost always correlate at some level in a sample, even if they share no fundamental relationship in the larger population. In other words, multicollinearity is a matter of

degree; it is not a problem that either does or does not appear. Furthermore, partial multicollinearity violates absolutely none of the assumptions of linear regression: It does not bias coefficient estimates, does not result in inefficient use of the data available, and does not cause falsely confident conclusions. The sole effect of this data limitation is that it makes conclusions more ambiguous or hesitant than they otherwise might have been. Despite the omnipresence and relative harmlessness of the multicollinearity problem, however, practitioners often write as though it represents an analytical flaw for which everyone must test and that must be solved if it appears. They may select solutions for dealing with multicollinearity that harm an analysis more than they help it. In short, practitioners take partial multicollinearity much more seriously than statistical theory or the methodological literature justifies.

The remainder of this entry proceeds in four sections. First, we treat full multicollinearity in depth, both substantively and statistically. Next, we provide the basic intuition for why collinear variables confound an analysis, using specific examples, and offer various mathematical illustrations of how full multicollinearity prevents the classical regression model from producing coefficient estimates. We then turn to partial multicollinearity, distinguishing the effects of this data condition according to the purposes for which an analyst has included a particular variable. Next we briefly reviews the various symptoms of and tests for multicollinearity customarily used by social scientists. In the last section, we consider the array of methods for dealing with multicollinearity that analysts have available to them.

Full Multicollinearity

Full (or perfect) multicollinearity results when one explanatory variable contains no fluctuation independent of the movement in the others. Because the problem variable is indistinguishable from the remainder of the explanatory variables in such a situation, an empirical analysis cannot parse it out. Conventional techniques break down in the face of such uninformative data, even when the empirical model is not actually a linear one. A maximum likelihood estimation, for example, becomes unsolvable if explanatory variables overlap so completely that they produce a flat likelihood curve and do not allow the method to converge on a set of coefficients. Comparative case analysis, similarly, cannot determine objectively which of the many traits that separate two cases actually account for differences in their outcomes. Additional assumptions or a more detailed analysis become necessary.

Intuitive Discussion

The symptoms of full multicollinearity differ depending on the analytical method, but the overarching problem remains the same: two concepts that cannot be separated from one another within a sample cannot be distinguished from one another empirically in any analysis conducted solely on that sample. In a causal analysis, it becomes impossible to separate out the effects of the problem variable from the effects of the others. In an analysis oriented toward prediction, it becomes impossible to determine how much weight the problem variable should receive, compared to the other variables, when computing forecasts outside of the sample.

The presence of full multicollinearity does not mean that the explanatory concepts are theoretically indistinct in the population or even that the conceptual differences would be indistinguishable in another data set produced using the same sampling method. It does mean that, without incorporating some kind of outside information, the current sample does not allow any way to avoid conflating the overlapping explanatory factors.

Let us start with a simple example. Suppose that a researcher wishes to understand why nations adopt strict censorship laws. One possibility might be to compare the United States, where expressive rights have become relatively permissive, with Canada, where public officials enjoy wide leeway when banning questionable forms of expression. Any number of important traits separate these two nations and therefore could explain the different realities. They achieved independence from Great Britain at a different time and in a different fashion. One elects an independent president, whereas the other selects a prime minister in parliament. One contains two major political parties, whereas the other sustains several. One allows the judiciary more flexibility and authority than the other does. Without incorporating some type of additional information, an analyst cannot say which feature of the two governments caused policy outcomes to deviate, nor would a forecaster know how to predict censorship levels in a third country that shared some traits in common with the United States and others in common with Canada.

This problem becomes even clearer with a statistical analysis. Suppose that an engineering firm faces two simultaneous discrimination lawsuits. An African-American male files the first one, claiming that the company engages in wage discrimination against black employees. A white female files the second one, alleging that the company discriminates against women. An analyst collects a random sample of engineers in the firm, recording each person's race, gender, and salary. However, by chance, the sample ends up containing only two sorts of people: white men and black women. The analyst can compute average salaries for the two sorts of engineers and determine whether they differ more than should be true by chance

alone. Indeed, the results might show that black women tend to suffer in their paychecks relative to white men, for one reason or another. This computation would be useless, however, for purposes of deciding which of the lawsuits had merit because the sample conflates the two explanatory factors of race and gender. It is impossible to say how much of the gap reflects racial differences between the two sets of engineers and how much of it represents gender differences. In these data, the two explanations for wage differences are indistinguishable.

These two examples may seem artificial. How likely is it that researchers would try to explain a complicated policy outcome using only two cases, without digging into the underlying policy-making process to parse out the different institutional explanations? How likely is it that a random sample would exclude white women and black men? Of course, neither situation will occur often.

On the other hand, these examples may not be as far-fetched as they seem. Full multicollinearity rarely occurs in quantitative social science research. When it does appear, the problem almost always results from some kind of simple data-handling error created by the analyst. For example, the analyst might accidentally copy from the same column in a data table twice or might accidentally copy one variable over another within a software package. This sort of error would produce two identical variables with different names. An analyst might not realize that a model contains more variables than the sample contains observations, in essence mimicking the United States versus Canada confusion, or might divide up a sample and not realize that within a given subset of data a “variable” actually does not vary. These sorts of theoretically indefensible mistakes, resulting from poor data handling or careless model specification, produce most instances of full multicollinearity that practitioners will encounter. Fixing the mistakes automatically removes the estimation problem.

Formal Presentation

Full multicollinearity appears when one explanatory variable in a regression analysis is a direct linear function of the others. The underlying population relationship among the random variables might or might not be deterministic; the term “multicollinearity” only defines the condition in the sample.

In the classical regression model, full multicollinearity violates the assumptions necessary for successful estimation—a regression model becomes unsolvable. The technique should not even be able to estimate coefficients, although statistical software packages might produce an output if rounding errors create artificial variation sufficient to remove the perfect relationship among variables. More commonly, software packages either will refuse to

give results for an unsolvable equation or will drop variables until the model becomes solvable.

There are various ways to illustrate why multivariate linear regression becomes impossible when an explanatory variable is statistically dependent on the others. For example, the notation partly depends on whether we approach the CRM and its assumptions from the vantage of scalar algebra or matrix algebra.

Scalar Notation

The classical regression model selects slope coefficients according to the least-squares criterion. It reports coefficient estimates that minimize the sum-of-squared prediction errors within the sample. For this reason, successful performance requires that some particular set of coefficients meet the least-squares criterion. If two or more sets of coefficients could produce the same minimized sum-of-squared errors, then it becomes impossible to say which one is correct.

Full multicollinearity actually produces a situation in which an infinite number of coefficients would satisfy the least-squares condition. Consider a simple analysis with only two explanatory variables, in which one of them (X_2) is a direct linear function of the other (X_1). We can summarize this relationship as $X_2 = c + dX_1$, where c and d are constants. The usual regression equation poses that the outcome of Interest—the dependent variable (y)—is a linear function of the explanatory variables and a random error term (e). The population model looks like this:

$$y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + e \quad (1)$$

where β_0 is the intercept, and β_1 and β_2 are the slope coefficients for their respective explanatory variables. If we suppose that X_2 in the sample is a multiple of X_1 (that is, $X_2 = dX_1$), just to keep things simple, then the regression needs to find the coefficient estimates b_1 and b_2 that produced the best predictions **:

$$\begin{aligned} y &= b_0 + b_1 X_1 + b_2 X_2 \\ &= b_0 + b_1 X_1 + b_2 (dX_1) \\ &= b_0 + (b_1 + db_2) X_1 \end{aligned} \quad (2)$$

An infinite number of coefficient pairs could produce the same values for **, as long as any change in b_1 from one possible value to another (δb_1) is matched by corresponding change in b_2 to compensate for it ($\delta b_2 = -\delta b_1/d$). Thus, an infinite number of (linearly related) coefficient pairs could produce the minimum sum-of-squared errors, $(y - **)^2$. Presume, for example, that X_1 is a percentage and X_2 is simply a proportion measure of the same variable, such that $d = 100$. For any possible solution, b_1 and b_2 , another pair could produce

the same predicted values as long as the increase (or decrease) in b_1 is matched by a decrease (or increase) in b_2 by 1/100 of that amount.

A couple of other common model specification errors can illustrate how full multicollinearity might appear in an analysis and how it foils the estimation. Suppose, for example, that a researcher collects a sample of state-level electoral data for a single year. The dependent variable is the Republican proportion of a state's congressional delegation after a given year's election (Y). The researcher hypothesizes that Republican electoral success is a function of the following explanatory variables:

1. The GOP presidential contender's success in that state in that year, through some sort of coat-tail effect (X_1).
2. The GOP presidential contender's success in that state in the previous election, some sort of signaling effect that influences the quality of candidates fielded by each party (X_2).
3. The state's change in support for the GOP presidential candidate between the two elections, to capture some sort of bandwagon or trend effect ($X_3 = X_1 - X_2$).

Described in this way, these three hypotheses may all sound reasonable. In fact, however, the bandwagon effect is not distinguishable from the other two variables and in any sample it is a perfect linear combination of the other two:

$$\begin{aligned} y &= b_0 + b_1X_1 + b_2X_2 + b_3X_3 \\ &= b_0 + b_1X_1 + b_2X_2 + b_3(X_1 - X_2) \\ &= b_0 + (b_1 + b_3)X_1 + (b_2 - b_3)X_2 \end{aligned} \quad (3)$$

For any estimate of b_3 , another will produce the same prediction as long as either b_2 shift in the same direction by the same amount or b_1 shift in the opposite direction by that amount. The equation will permit an infinite number of possible solutions.

Theorists sometimes posit multiplicative rather than additive regression models, such as the Cobb-Douglas function in economics or the gravity model in the study of international trade. Here is an example of a multiplicative model:

$$Y = \beta_0 X_1^{\beta_1} X_2^{\beta_2} \dots X_K^{\beta_K} e^\varepsilon \quad (4)$$

where K represents the number of explanatory variables in a properly specified model and e represents the constant 2.718... This precise specification is convenient, presuming it is theoretically appropriate,

because it means the model is linear with respect to the natural logs (\ln) of the variables. Suppose, for example, a three-variable version of the model:

$$\begin{aligned} \ln(Y) &= \ln(\beta_0 X_1^{\beta_1} X_2^{\beta_2} X_3^{\beta_3} e^\varepsilon) \\ &= \ln \beta_0 + \beta_1 \ln X_1 + \beta_2 \ln X_2 + \beta_3 \ln X_3 + \varepsilon \end{aligned} \quad (5)$$

What practitioners may overlook is that, when using a multiplicative model of this sort, the way we think about model specification must change. In particular, common practices such as taking a ratio or creating an interaction term can create full multicollinearity. For example, suppose that we wish to predict a nation-state's yearly imports. The three hypothesized explanatory variables might be features of each country's economy:

1. The gross national product, to serve as a measure of the economy's size (X_1).
2. The population, to serve as a measure of consumer needs (X_2).
3. The per capita income, to serve as a measure of wealth ($X_3 = X_1/X_2$).

These three explanations may make superficial sense, but they are not theoretically defensible in such a multiplicative model because $\ln(X_1/X_2) = \ln(X_1) - \ln(X_2)$, which creates a situation directly parallel to Eq. (3). Attempting to create a multiplicative interaction term will create the same problem if the model also includes the two components of the interaction because $\ln(X_1X_2) = \ln(X_1) + \ln(X_2)$.

It is worth considering the effect of full multicollinearity on the measure of uncertainty for multivariate regression coefficients as well. Of course, it may seem silly to investigate standard errors for coefficients that cannot be estimated, but this perspective once again shows how the usual computations fall apart when variables are perfectly collinear. Scalar algebra textbook discussions of multiple regression often present a formula for the standard error (s) of a coefficient (b) for a particular explanatory variable (X_j) along the following lines:

$$S_{b_j} = \sqrt{\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (x_i - \bar{x}_i)^2 (1 - R_j^2)(n - k)}} \quad (6)$$

Most of this notation is standard. The important portion to discuss here is R_j^2 , which represents the coefficient of determination that would result if X_j were regressed on the other explanatory variables. In the case of full multicollinearity, $R_j^2 = 1$ because the other explanatory variables account for 100% of the variation in X_j ,

which means that $(1 - R_j^2) = 0$, the entire denominator therefore becomes 0, and the ratio becomes undefined. Once again, the regression equations fall apart in the face of full multicollinearity.

Matrix Notation

Matrix-based regression customarily expresses the explanatory variables as a single matrix (X), that might take the following form:

$$X = \begin{bmatrix} 1 & x_{12} & x_{13} & \cdots & x_{1k} \\ 1 & x_{22} & x_{23} & \cdots & x_{2k} \\ 1 & x_{32} & x_{33} & \cdots & x_{3k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n2} & x_{n3} & \cdots & x_{nk} \end{bmatrix} \quad (7)$$

where n represents the number of observations and k represents the number of independent variables, inclusive of the constant. The first column contains a series of 1s because it corresponds to the intercept, or constant, term in the regression. The dependent variable y , meanwhile, would represent a single column of numbers (a vector) of order n by 1.

The classical regression model's solution for computing its vector of coefficients (b) necessitates the following step:

$$X'Xb = X'y \quad (8)$$

$$b = (X'X)^{-1}X'y \quad (9)$$

where X' is the transpose of X . Going from Eqs. (8) to Eq. (9) requires $X'X$ to be invertible and $(X'X)^{-1}$ actually to exist. In other words, $X'X$ (sometimes written as Q) has to be square and nonsingular. It will always be square because, by definition, the transpose X' will have as many rows as X has columns. When one column of X is a linear combination of the other columns of X , however, the matrix will be singular. One row/column of Q will be a multiple of another row/column, such that the formula $Qb = X'y$ allows an infinite number of solutions for b . The rank of X will be less than k , the determinant of Q will equal zero, and no inverse will exist. In short, the formula cannot produce coefficient estimates in the presence of full multicollinearity. The coefficient standard error equation ($\sigma^2 Q^{-1}$) also requires $X'X$ to be invertible and therefore produces no results in these cases.

One example of how full multicollinearity often appears becomes easy to illustrate using this notation. Researchers often perform regression on secondary data sets that include categorical variables. For example, a survey of individuals might include a variable to represent each person's religion. If the options include only

Protestant, Catholic, Jewish, and Other, the data in X might look like this:

$$X = \begin{bmatrix} \text{Constant} & \text{Faith} \\ 1 & \text{Protestant} \\ 1 & \text{Protestant} \\ 1 & \text{Protestant} \\ 1 & \text{Catholic} \\ 1 & \text{Catholic} \\ 1 & \text{Catholic} \\ 1 & \text{Jewish} \\ 1 & \text{Jewish} \\ 1 & \text{Other} \end{bmatrix} \quad (10)$$

It should be obvious that the Faith variable cannot be included in a regression as is because it is not an ordinal variable, let alone an interval variable. Even if the data processor entered these faiths numerically rather than using text strings, the numbers assigned would be entirely arbitrary. The customary solution is to create a series of binary variables, one for each religion, in which individuals receive a value of 1 if they profess the pertinent faith and a 0 otherwise. One common mistake is for analysts to include all of these dummy variables computed from the categorical variable in a regression. The new data matrix would look like this:

$$X = \begin{bmatrix} \text{Constant} & \text{Protestant} & \text{Catholic} & \text{Jewish} & \text{Other} \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (11)$$

As long as we assume that no individual professes more than one faith, each row will have a positive value in one and only one of the four religion columns, which means that the constant term is a perfect linear combination of the four dummy variables:

$$\text{Constant} = \text{Protestant} + \text{Catholic} + \text{Jewish} + \text{Other} \quad (12)$$

Including them all with the constant produces full multicollinearity. The analyst must choose between (1) dropping the constant, in which case each of the

religion dummies generates an intercept term for people of that faith, and (2) dropping one of the religion dummies, in which case the coefficients for the remainder represent an intercept shift for those who do not appear in the baseline category (that is, the one excluded from the regression).

Is Partial Multicollinearity a Problem?

Whereas full multicollinearity rarely appears in social science data unless sample sizes are tiny or the analyst makes some kind of mistake, partial multicollinearity is rarely absent. One explanatory variable almost always correlates with the other explanatory variables because that happens by chance in a sample most of the time even if the variables have no underlying relationship in the population. Sometimes the theory underlying a model directly mandates some degree of partial collinearity. A parabolic model, for example, includes both an explanatory variable and its square term; these must be correlated. A regression with nested binary variables, in which one singles out a subset of the other, also must exhibit multicollinearity. In short, multicollinearity is a matter of degree rather than one of kind.

Unreliable Coefficient Estimates

Partial multicollinearity violates none of the assumptions required to perform multiple regression, so it undermines none of the desirable features of the classical regression model (such as unbiasedness or efficiency). It also does not prevent accurate measures of uncertainty. Unfortunately, severe cases of multicollinearity can cause that uncertainty to be rather high.

Recall the intuitive example of full multicollinearity previously discussed, in which an analyst attempting to test for wage discrimination against both blacks and women could not distinguish the two cases because the sample only included white men and black women. Suppose that the analyst collected one additional case, a black male. At this point, the two explanatory variables—race and gender—would no longer be perfectly collinear. It would be possible to compute average salaries by race and average salaries by gender without the two gaps necessarily being the same. In particular, when testing for racial discrimination the final engineer would appear among the potentially disadvantaged class, whereas when testing for gender discrimination he would not.

The results of this analysis, however, would not be terribly reliable because they depend entirely on the salary of one randomly selected person. If he happened to collect a salary similar to the other men, the analysis would

estimate that the company did not discriminate by race but seriously discriminated by gender; if he happened to collect a salary similar to that of the black women in the sample, by contrast, the analysis would estimate that the company did not discriminate by gender but seriously discriminated by race. If his salary fell at the midpoint between the black women and the white men, the analysis would indicate relatively moderate levels of discrimination against both groups. Adding a single person might have permitted estimates, but it hardly made those estimates trustworthy.

More generally, a high degree of partial multicollinearity adds to the instability of estimates such that the few discordant cases—the limited independent variation across the overlapping explanatory variables—strongly shape the final results. Consider, for example, the results worked out in Eq. (2), but with X_2 only a partial linear function of X_1 , $X_2 = c + dX_1 + u$, where c and d are again constants, and u represents the remaining random variation in X_2 , centered at 0. Dropping c again for convenience, the ultimate computation becomes:

$$\begin{aligned} y &= b_0 + b_1X_1 + b_2X_2 \\ &= b_0 + b_1X_1 + b_2(dX_1 + u) \\ &= b_0 + (b_1 + db_2)X_1 + b_2u \end{aligned} \quad (13)$$

In this case, multiple regression does allow a solution. If we shift from one possible value of b_2 to another, the sum-of-squared errors change because of alterations in the b_2u term. However, the changes in R^2 resulting from different possible choices for b_2 will be relatively minor if u contains little variation (that is, if the variables are highly collinear). Adjustments in b_1 could compensate for most of the shift in b_2 , allowing a wide range of (b_1, b_2) values to appear roughly equivalent. Furthermore, the estimated balance between b_1 and b_2 would depend heavily on the limited variation in u that happened to appear. If y happened to be particularly high when u crept upward, then the b_2 estimate would be positive and the b_1 estimate would compensate by anchoring predictions downward. If y happened to be notably low when u crept upward, by contrast, b_2 would be selected to drag the predictions down and b_1 would swing in the other direction. In other words, the coefficient estimates will be unstable and negatively correlated with one another.

Regression output will not hide the uncertainty created by a high degree of multicollinearity. Review Eq. (6), which presents the formula for a coefficient standard error in multiple regression. Roughly speaking, errors go down when X and y covary significantly (the numerator) and when the sample size is large relative to the number of explanatory variables (the rightmost term in the denominator). They also go down when the

explanatory variable bounces around a lot (the leftmost term in the denominator), but only insofar as this variation is independent of the other explanatory variables, as indicated by the middle term $(1 - R_j^2)$. When partial multicollinearity is high, the middle term $(1 - R_j^2)$ for a variable drops, decreasing the denominator and so ultimately increasing the standard error. In short, the coefficient standard errors from multiple regression correctly indicate the uncertainty, and therefore unreliability, of coefficient estimates produced for variables that offer little to distinguish one from another.

The Implications of Partial Multicollinearity

Explanatory variables subject to partial multicollinearity might appear in an analysis because they interest the researcher as potential causal explanations for the outcome being studied. They might appear in an analysis because the researcher believes they will help forecast outcomes beyond the sample. Or the multicollinear variables might appear simply to hold certain concepts constant—control variables that allow the researcher to isolate the independent effects of one or more other variables that do not exhibit such a high degree of collinearity. The implications of partial multicollinearity differ depending on whether a researcher intends to draw causal inferences and whether the coefficient on the variable in question represents a particular quantity of interest.

Statistical Control

Predictive models often contain a wide variety of explanatory variables, only some of which directly concern the researcher. The remainder, usually called control variables, appear in an analysis simply to increase the accuracy of the theoretically important coefficient estimates. The researcher need not worry whether coefficient estimates for control variables are close to the truth, nor does an analyst necessarily mind if these coefficients are accompanied by high standard errors (that is, whether they achieve statistical significance). What matters is that these rival explanations appeared in the analysis at all, thereby protecting other coefficient estimates from omitted variable bias.

Partial multicollinearity among control variables is almost entirely harmless. It does not undercut their effectiveness in eliminating omitted variable bias. It does not produce any sort of bias. It does not reduce the fit of a regression. Coefficient standard errors properly report the uncertainty attached to each estimate; there should be no opportunity to place more stock in a given coefficient than it deserves. The only risk is if, aside from random noise, the control variables lack independent variation, overlapping so completely that they are redundant.

This circumstance would create inefficiency in a regression model, which could be problematic in very small data sets. But such costs appear any time analysts include unnecessary variables in a model; they are not unique to cases of partial multicollinearity. Otherwise, unless the researcher places more confidence in coefficient estimates than is warranted by their level of uncertainty—an indefensible flaw—partial multicollinearity in the control variables does not disrupt an analysis.

Optimizing Prediction and Forecasting

Researchers sometimes care more about the predictive power of a statistical model than they do about identifying causal effects. Forecasting models need not place as much emphasis on why one variable is correlated with another or on the causal ordering among various independent variables, as long as the overall model generates accurate out-of-sample predictions.

Of course, this distinction between forecasting and causal analysis is more conceptual than real. A forecasting model based on causally unrelated, and therefore theoretically inappropriate, independent variables is not likely to perform well outside of the sample on which it is based. A successful causal model that appropriately captures the theoretical process underlying data generation is likely to be successful at forecasting. Nonetheless, to the extent forecasting and causal analysis represent different analytical projects, partial multicollinearity poses little risk to the forecasting side of the enterprise.

Multiple regression takes into account the joint variation in various independent variables when it minimizes the sum-of-squared errors. The technology will not be able to assign responsibility directly to one variable or another, given their covariance, but it does adjust coefficient estimates and predicted values according to the relationship between that shared variance and the dependent variable. Therefore, the regression model milks multicollinear variables of any predictive power that they might bring to the task of forecasting. It uses variables in the sample as efficiently as possible.

Partial multicollinearity does carry some cost in a forecasting situation. Instability in the coefficient estimates for these variables naturally reduces confidence in predictions, increasing standard errors around them. An analyst naturally would like to reduce the imprecision caused by partial multicollinearity, if that is an option. Nevertheless, the problem is only as bad as the standard errors around the predictions. If these errors are already small enough that they produce predictions with an acceptable level of uncertainty, then partial multicollinearity may be ignored.

Determining Causation

Partial multicollinearity really only matters when it interferes with the precision of important coefficient estimates and therefore limits the researcher's ability to identify the causal process leading to a dependent variable. As indicated in Eq. (6), partial multicollinearity drives coefficient standard errors upward. A coefficient that might have passed conventional standards of statistical significance outside the presence of multicollinearity could flunk a hypothesis test because of inflated standard errors. An analyst therefore might fail to reject the null hypothesis only because an explanatory variable of interest overlaps with other variables in the sample.

Partial multicollinearity most resembles a pathology when variables unrelated or only thinly related in the larger population somehow end up highly correlated within our sample because it prevents a precision that otherwise should have been achievable. In essence, this condition means that the analyst possesses poor data with insufficient information about a substantial portion of the larger population, much as is true when the sample simply contains too few observations (which, Goldberger in 1991 termed, tongue in cheek, *micronumerosity*). Indeed, accidental cases of multicollinearity bear a particularly close relationship to the small- n problem because chance correlations among explanatory variables become increasingly improbable as the sample grows. Leaving aside small samples, therefore, partial multicollinearity usually results when two or more variables actually have some sort of causal relationship among them.

The severity of partial multicollinearity depends on the overall nature of an analysis. For example, as Eq. (6) indicates, a model with impressive predictive power will produce small coefficient standard errors because the numerator in each case will be small. Large data sets also will produce small standard errors, because $(n - k)$ will be large. Even in the presence of heavy multicollinearity, coefficient estimates may be precise enough to satisfy the analyst. Specifically, coefficient standard errors may be small enough for explanatory variables of interest to achieve statistical significance and establish a causal relationship, even if the analyst ignores partial multicollinearity entirely.

Even if some coefficients of interest fail to achieve statistical significance, partial multicollinearity still may pose no barrier to causal analysis, depending on the level of theoretical or causal precision that an analyst requires. For example, it is not uncommon for researchers to include multiple variables intended to capture the same basic theoretical concept: socioeconomic status, trust in government, social anomie, postmaterialist values, and so on. These variables are not multicollinear by chance, through the collection of an unfortunate sample; they covary in the larger population. A package of variables

selected to triangulate on a concept naturally will be multicollinear to whatever extent the variables are tapping the same underlying social phenomenon. In fact, the better they perform as proxies for the underlying concept, the more they ought to covary and therefore the greater the multicollinearity—a paradoxical instance in which more multicollinearity is in fact a healthy sign. If the point of model specification is to establish the causal significance of a core concept, not the independent significance of each given proxy, then multicollinearity poses no problem at all. Individually, the variables might fail to pass a significance test, but the package of variables will increase the fit of the model measurably.

At some point the idea of “variable packages” becomes hazy. Two variables may not capture the exact same underlying concept, but researchers nevertheless may be aware that they are causally related to one another in the larger population, so that multicollinearity in the sample is no accident. This sort of multicollinearity, although theoretically meaningful, nonetheless can pose an obstacle to the analyst who wishes to distinguish two or more concepts statistically; it can hinder an analysis based on fine theoretical distinctions. The appearance of such multicollinearity may be helpful because it offers a warning that concepts may not be as theoretically distinct as a modeler initially assumed, but it still risks leaving the analyst with regrettably hesitant causal conclusions. The analyst would only be able to generalize about the overlapping variables as a package, even if a project's needs demand otherwise.

Social science practitioners sometimes express concern when control variables are partially collinear with variables of interest. This worry is symptomatic of the misunderstandings revolving around the “multicollinearity problem.” Overlap between control variables and variables of interest in fact serves an important function—it is another instance when the appearance of multicollinearity should be reassuring rather than a cause for concern.

Control variables appear in a model primarily to ward off omitted variable bias. When an analyst omits relevant explanatory variables, the coefficient estimates expected for the remaining variables takes the following form in matrix algebra:

$$E(b_1) = \beta_1 + F\beta_2 \quad (14)$$

where β_1 is a column vector containing the correct population parameter(s) for the included variables; β_2 is a column vector of population parameters for the omitted variable(s), representing their underlying relationship with the dependent variable; and F is a matrix representing the relationships among the omitted variables and those remaining in the estimated equation. If the term $F\beta_2$ represents a null vector—which it does if

either F is a null matrix or β_2 is a null vector—then excluding the variables will not produce omitted variable bias. The expected result of an uncontrolled (that is, restricted) regression will be the correct population parameters, β_1 .

What does this mean for multicollinearity? The only time unbiasedness requires the inclusion of a control variable is when we theorize that F is not null—in other words, when that control term *should* be partially collinear with a variable of interest. Including the control variable implicitly acknowledges that variables are expected to be multicollinear. It is therefore odd, if not inexplicable, that practitioners become concerned when the multicollinearity appears as theorized. Omitted variable bias undermines an important statistical property in an analysis—unbiasedness. In contrast, the inflated standard errors that result from multicollinearity are not an analytical flaw but a defense mechanism, an indication of the uncertainty attached to a coefficient of interest once we take into account how much it overlaps with other plausible explanations captured by the statistical controls. Multicollinearity is the solution to a problem, not the problem itself, in these instances.

Special Cases

Some forms of model specification necessarily induce partial multicollinearity and so are worth a separate look: parabolic models, interaction terms, and models with nested binary variables. Parabolic models are one means of rigging linear regression to accommodate nonlinear systematic relationships between dependent and independent variables. If X_1 is the root explanatory variable, for example, the model might include $X_2 = X_1^2$:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_1^2 + e \quad (15)$$

The inclusion of an explanatory variable in its squared form allows a bend in the systematic component of their relationship. Throwing in the cubed form of the variable allows for a second bend, and so on:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_1^2 + \beta_3 X_1^3 + \cdots + \beta_k X_1^k + e \quad (16)$$

Because the exponential variables in this sort of model are simply manipulations of the core variable, they naturally covary (although the nature of the collinearity depends on the scale and direction of the source variable).

Does multicollinearity in a parabolic model prevent causal analysis? Not at all. As with using other package variables, applying multiple versions of the source variable does not remove any explanatory power from it. Coefficients will minimize the sum-of-squared errors, taking into account the joint variance among the different manipulated forms of the variable as well as the variance

independent to each of them. It is possible that an important variable will fail to achieve statistical significance in any of its exponential forms simply because they overlap so much. But this is an important finding; it means that, even if the variable matters in general, the regression cannot determine with confidence whether the systematic component contains a significant bend. It is a hypothesis test for the functional form rather than for the variable itself. The biggest risk associated with including exponential versions of a variable is that they may be unnecessary, thereby reducing the efficiency of the estimation.

Another form of variable manipulation that necessarily produces multicollinearity is the multiplicative interaction term. For example, the systematic functional form might be:

$$y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 (X_1 X_2) + e \quad (17)$$

The purpose of this sort of model is that it allows the coefficient on one variable (say, X_1) to depend linearly on the value of the other variable (in this case X_2). As X_1 increases by one unit, y increases by $\beta_1 + \beta_3 X_2$. The multiplicative term necessarily correlates with its own components. To whatever extent this drives up coefficient standard errors, however, it is not pathological. As always, the joint variation still contributes to coefficient estimates and the model's fit. The inflated standard errors may cause some of the variables to fall short on a hypothesis test, but this is not a test of the overall package; it simply tests the functional form. If the interaction term fails to achieve significance, that means the data do not allow an analyst to conclude that the effect of one variable depends on the value of another.

A final special case that inherently produces multicollinearity is when the researcher uses nested binary variables. For example, suppose that a scholar wishes to gauge the effect of equal protection lawsuits on funding across school districts. The dependent variable might be a measure of inequality in the state's funding system. The explanatory variable of interest might be a representation of the lawsuit. Rather than include only a single variable, however, the analyst might opt for one binary variable representing whether a lawsuit had been filed and another representing whether the complainant won. Because it is necessary to file the lawsuit to win it, the two binary variables will be collinear; a zero on the first variable necessitates a zero on the other.

This collinearity would drive up their standard errors. As with the other special cases, however, this is healthy. The two variables as a package capture the effect of the lawsuit; their independent effects merely probe whether it is the filing or the winning that makes the difference. If the two variables exhibit a high degree of multicollinearity—say, for example, because most legal challenges ultimately prove successful—they may not return

significant coefficients. But this is a useful and important result. It means that the act of filing and the act of winning a legal challenge cannot be distinguished theoretically within the bounds of the data.

Symptoms of Partial Multicollinearity

Despite the relative innocuousness of partial multicollinearity, practitioners show a high degree of sensitivity to it. The methodological literature has responded to this concern by outlining a number of ways to detect multicollinearity. The result of this effort is a wide variety of diagnostic tools, more or less rigid in their application. These various diagnostics actually test for a variety of phenomena, no doubt in part because the ill-defined “multicollinearity problem” itself is not a distinct infringement of any statistical principle and does not undermine any important statistical property—it is not entirely clear what we need to test for.

The most informal, and probably the most useful, diagnostic tool is to compare the fit of a model with the uncertainty reported for its various coefficients. When a package of explanatory variables jointly assists in predicting the dependent variable, the variables will markedly improve the model’s fit, but they may fail to achieve independent significance if they are highly multicollinear. The partial (or multiple-partial) F test for joint significance formalizes this comparison by determining whether the inclusion of a package of variables—moving from a restricted to an unrestricted model—significantly increases the model’s coefficient of determination (R^2):

$$F(k_U - k_R, n - k_U) = \frac{(R_U^2 - R_R^2)/(k_U - k_R)}{(1 - R_U^2)/(n - k_U)} \quad (18)$$

where n is the total number of observations, k indicates the number of explanatory variables (constant term included), the subscript R indicates the relevant statistic from a model with the package of variables excluded (i.e., their coefficients restricted to be zero), and the subscript U indicates a statistic from a model with the package of variables included (i.e., their coefficients unrestricted and so subject to estimation). A package of variables can achieve statistical significance in a partial F test even if none of them does so individually on the conventional t test.

One common practice in empirical journals is to include a covariance matrix, showing the bivariate relationships among all the difference explanatory variables. As a diagnostic tool, this sort of table serves little purpose. It does not detect complex forms of multicollinearity, when one explanatory variable is a function of several of them. It provides no way to distinguish accidental and population-based forms of

multicollinearity and it does not address the substantive question of whether partial multicollinearity undermines the goals of a research project. An alternative but related solution is to present a series of partial regressions, in which each independent variable in turn is regressed on the others. This sort of diagnostic does not address the theoretical difficulties with the bivariate method, but at least it gives a clearer picture of how much independent variation each explanatory variable actually contains.

A number of specific tests for multicollinearity have been proposed. Some people have used the determinant of $(X'X)$ from the matrix regression equation, for example. An even better solution (because it is bounded and unaffected by the dispersion of the explanatory variables) is simply to look at the coefficient of determination, as appears in Eq. (6), for each explanatory variable. Perhaps the most popular test, in recent times, is the variance inflation factor (VIF). It simply represents the inverse of the middle term in Eq. (6):

$$\text{VIF} = \frac{1}{(1 - R_j^2)} \quad (19)$$

The conventional wisdom or rule of thumb seems to be that a VIF of 10 or more signifies trouble, although others use more conservative standards (i.e., higher thresholds). All of these tests share the same basic shortcoming, however—they attempt to systemize what should be a substantive judgment, a matter of analysis and interpretation. Recent scholarship therefore seeks to define the costs of including multicollinear variables in terms of the predictive impact of their presence.

Methods of Dealing with Partial Multicollinearity

Practitioners generally perceive multicollinearity as troublesome. Once in a while partial multicollinearity—especially incidental multicollinearity that obscures causal effects—really does hinder a theoretically appropriate analysis. Analysts concerned about partial multicollinearity face numerous options.

Incorporate Additional Information

Multicollinearity becomes problematic when a sample is not adequately informative about differences among two or more variables, resulting in coefficient estimates that are insufficiently precise and coefficient standard errors that are unacceptably large. Because the cause is at root one of poor data, the most obvious way to remove high degrees of multicollinearity is to get better data.

As Eq. (6) indicates, data improvements can lower coefficient standard errors even if they do not address

multicollinearity directly. The analyst could increase the number of observations (n), which would have the additional virtue of making incidental multicollinearity less likely. The analyst also could decrease the number of explanatory variables (k), if some of them are unnecessary, or add other theoretically relevant explanatory variables if they can significantly improve model specification (driving up the numerator). Such changes would compensate for a low $(1 - R_j^2)$.

A researcher also could choose to oversample observations that would increase the independent variation in an explanatory variable, increasing $(1 - R_j^2)$. For example, if a study uses both education and income and these are highly correlated, the researcher could affirmatively select for highly educated poor people or people who are wealthy but uneducated. Selecting on explanatory variables does not induce bias the way that selecting on a dependent variable does. This strategy does entail certain risks, however, because it produces an overall sample that is not representative of the larger population. It may decrease multicollinearity at the expense of inducing bias in other analyses carried out on the data (at least unless those analyses take into account the nonrandom selection through some sort of weighting or similar solution).

These solutions all required pulling new data directly into an ongoing analysis. An alternate way to incorporate additional data is to borrow insights from previous research in the field. The analyst may be able to apportion the joint variance among variables, for example, by assuming a causal order, or otherwise formalize the relationship among multicollinear variables. The analyst may be willing to constrain coefficients for one or more of the partially multicollinear variables, based on previous research. Obviously using prior knowledge is risky; it runs the risk of creating a scholarly literature that is less science and more echo chamber. Nevertheless, researchers trying to exploit imperfect data may decide that their best solution is to take advantage of prior knowledge about the variables being used.

Certain other highly technical solutions also exist. They also incorporate prior information and, therefore, in a sense qualify as Bayesian estimators. Probably the most common example is ridge regression, such as ordinary ridge regression (ORR). This solution relies on the existence of an unmeasured positive constant k that we implicitly can insert into the standard regression equation to derive a new coefficient:

$$** = (X'X + kI)^{-1}X'y \quad (20)$$

where I is the identity matrix, such that k implicitly pumps up the diagonals of Q . This solution depends on the value of k , which is rarely given—the greater that number, the more it reduces variance but the more

it biases coefficient estimates toward zero. Because determining k generally requires rather arbitrary deductions from the data, ridge regression is not used frequently.

Remove Additional Information

Adding data is a great idea, but an analyst may not have that luxury. Instead, researchers often react to a poor information source by using the destructive strategy of throwing out even more information. Analysts occasionally toss out partially multicollinear variables, for example. More commonly, analysts combine multicollinear variables into one composite measure. For example, they might perform a factor analysis to isolate the variance that variables share, using the resulting factor score as a new index variable. Such indices are reported on an arbitrary scale and therefore are not interpretable in any direct substantive way. They also strip out any variation unique to the particular variables used to create the index, which may be substantively important. Finally, they might require questionable assumptions, such as the linearity assumption needed for factor analysis. Such indices do have an important virtue, however, which is that the relative weight of each variable in the index is derived statistically using information contained in the data.

Perhaps the most popular sort of index is the additive kind. Unlike indices derived from factor analysis or other statistical methods, the additive index is driven by assumption. Suppose, for example, that a researcher wishes to include “Trust in other people” as an explanatory concept in a causal model. The researcher has two survey questions representing interpersonal trust, one that asks whether people are “selfish” (variable X_1) and one that asks whether people “try to do the right thing” (variable X_2). Presumably these variables will contain some multicollinearity because they are theoretically related, but they also will exhibit some independent variation because they get at the root explanatory concept of interest in different ways. The population model therefore is:

$$y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + e \quad (21)$$

Recognizing that X_1 and X_2 both represent proxies for the same underlying concept, the analyst may create a new explanatory variable, an additive index $Z = (X_1 + X_2)$. The ostensible purpose of this additive index might be to avoid multicollinearity, or it could be an attempt to simplify the presentation by reducing the overarching concept to a single variable with a single

coefficient estimate and a single hypothesis test. The regression equation actually estimated becomes:

$$\begin{aligned} y &= b_0 + b_z Z + e \\ &= b_0 + b_z(X_1 + X_2) + e \\ &= b_0 + b_z X_1 + b_z X_2 + e \end{aligned} \quad (22)$$

Using an additive index therefore produces coefficient estimates under the assumption that, in the population, $\beta_1 = \beta_2$ (a testable proposition that usually goes untested). If this constraint is inappropriate, the fit of the model will decline (imposing inefficiency) and implicit coefficient estimates will be biased because neither $E(b_z) = \beta_1$ nor $E(b_z) = \beta_2$.

Practitioners sometimes justify additive indices as reasonable under the assumption that each proxy should receive the same weight (which factor analysis and related methods do not guarantee). Unless X_1 and X_2 are scaled so that they have the same variance, however, forcing two variables to receive the same implicit coefficient actually does not ensure that they receive the same weight. The variance of the additive index is:

$$V(Z) = V(X_1 + X_2) = V(X_1) + V(X_2) + 2\text{Cov}(X_1, X_2) \quad (23)$$

Variation in the new variable therefore depends on which component initially contained more variance. The one with greater variance receives greater weight, both in the additive index before estimation and in the predicted values after estimation. Furthermore, as the rightmost term indicates, movement in the new variable will be overbalanced toward the joint variance between the two questions, washing out the independent variation in each proxy question that presumably justified its separate collection in the first place. In other words, a model constrained by use of an additive index assigns variables unequal influence, imposing a functional form both arbitrarily *and* atheoretically.

In sum, additive indices lack the virtue of statistically derived indices, but they possess all of the drawbacks—a meaningless scale and estimation that neglects the independent information provided by each proxy measure. The only real virtue of this solution to partial multicollinearity is simplicity—they are easy to compute and take up less space when reporting results.

Do Nothing

A final solution to the presence of multicollinearity is to do nothing about it at all. It does no real harm to a regression

model aside from making some of the variables less precise, and the standard errors properly report this imprecision. The solution to do nothing may be appropriate when the multicollinearity appears for a theoretically meaningful reason, such as when numerous variables have been computed from the same source. It is also especially tempting in cases when the multicollinearity exists among control variables or within a forecasting model.

However, the option to do nothing is also a viable choice in causal models, as long as the researcher need not parse out the independent effects of the multicollinear variables. The partial F statistic in Eq. (18) allows a test of joint significance for any given package of variables. Although characterizing the effect of a package of variables may be trickier than reporting the effect of only one, it has the virtue of retaining both the scale and the independent variation of the source data.

Multidimensional Item Response Models

Mark D. Reckase

Michigan State University, East Lansing, Michigan, USA

Glossary

computerized adaptive test A computer-administered test that selects test items during the testing process to match the estimated level of performance of the examinee.

dimension A continuum on which individuals vary. The continuum may be directly observable, such as height, or may be a hypothesized continuum, such as verbal ability.

indeterminacy Characteristic of some models that the origin, unit of measurement, or orientation is not determined by the model but has to be arbitrarily set to a value.

item A limited task that is used to assess a person's level on a trait or domain of knowledge.

item response theory (IRT) A theory that hypothesizes a particular mathematical relationship between the levels of a trait and the probability of a response to an item.

latent dimension A dimension that cannot be directly observed but that is hypothesized to exist in at least an abstract sense.

model A mathematical representation of the observed relationships between data.

monotonicity The item response theory assumption that the probability of a response increases as the level on a trait increases.

Multidimensional item response models are probabilistic models for the interaction between persons and measurement tasks, usually called items; these models are based on the assumption that persons vary on numerous latent dimensions and that items are sensitive to differences on multiple dimensions. Item response models can be used to investigate the characteristics of items and to estimate simultaneously a person's location on the dimensions of sensitivity of the items.

Introduction

The Need for Multidimensional Item Response Theory Models

A common approach to measurement in the social sciences is to present persons with a series of tasks (items) and collect their responses to the tasks. For convenience, the responses that a person can give to the task are often limited to a fixed set of choices (such as those given for multiple-choice items), the rating categories for attitude or opinion surveys, or marks on a continuous scale that has been anchored with verbal descriptions to provide meaning to the scale. The observable result from an instrument composed of a set of items is a string of responses for each person that represents the person's interactions with the items. These strings of responses can be aggregated to form a person-by-item matrix of responses for groups of persons. The matrix is usually oriented so that rows correspond to persons and columns correspond to items on the assessment instrument. The goal of much of measurement theory is to determine what can be inferred about persons from their interactions with the items that make up a measurement instrument, when the interactions are summarized as the set of responses included in the person-by-item response matrix.

Much early work in social measurement approached the task of inferring information about the persons from simple models that ordered the persons along a single continuum, often based on a sum of scores given to the responses to the items. For example, achievement items would be scored correct (1) or incorrect (0) and the sum of the item scores would be the number of items answered correctly. This approach implicitly assumes that the major portion of variation in the responses can be accounted for by variation along a single dimension, and that dimension can be approximated by the number-correct score.

However, there is ample evidence in fields of social research that persons have numerous characteristics on which they vary, and the items used in measurement instruments are sensitive to differences in those characteristics. Therefore, to represent the complex information provided in a set of responses to items, multiple characteristics of the respondents need to be taken into account and the complexities of the interactions between the items and the persons need to be modeled. It is the desire to model adequately the complex interactions of persons, using social measurement tasks, that has led to the development of probabilistic models for the person-by-item response matrix; these are collectively called multidimensional item response theory (MIRT) models.

Statistical Rationale for MIRT Models

The need for multidimensional models of the interaction between persons and items can be supported on both statistical and substantive grounds. The statistical support for such models is that it is often the case that the person-by-item response matrix is not well summarized using models based on a single continuum. From a statistical perspective, no further justification beyond lack of fit of a model to data is needed to search for additional parameters to improve the representation of the data.

Substantive Support for MIRT Models

Multidimensional models for the interactions between persons and items can also be supported on substantive grounds. There is a large body of research in most areas of social science that indicates that the number of dimensions needed to describe human behavior is very large, and that even the simplest items are sensitive to differences on multiple dimensions. For example, the variety of cognitive skills found in psychological studies has been catalogued. These results are reinforced by work in cognitive science that shows the wide variety of mental processes that are needed to comprehend and respond to simple tasks. Similar compilations have been done for personality variables and other measures such as attitudes and opinions.

Historical Antecedents to the Current MIRT Models

MIRT models have evolved from two different areas of psychometric theory. The first area is work done throughout the 20th century to relate the performance of persons on items to the location of a person along a continuum. Alfred Binet and Theodore Simon used this concept in 1905 when selecting items for their test of intelligence. The chronological age of students was used as a surrogate for student's location along an ability continuum. Items selected for the test required the level of skill

demonstrated by students at increasing age levels. In 1966, the researcher Paul Lazarsfeld (among others) suggested that a straight line could be used to model the increase in the tendency to give a particular response as a person's level on a trait increased. The use of an increasing mathematical function to model the interaction between persons and items became an accepted method for analysis with the work of Frederic Lord in 1980 under the label of item response theory (IRT). Lord had previously suggested that nonlinear relationships using the logistic and normal ogive functions could be used to model the interaction of persons and items. That work was operationalized in a number of computer programs for identifying the probability functions that represent the relationships in the person-by-item response matrix, which have names such as BILOG (for binary logistics) and BIGSTEPS.

The second area that contributed to the development of MIRT was factor analysis, particularly methods for the analysis of items that are scored 0 or 1. Analysis of these types of response data does not meet the assumptions of continuous normally distributed variables used for much of the development of factor analysis. To properly analyze 0/1 data, relationships are hypothesized between a continuous latent variable and the dichotomized observed variable. The form of the relationships is typically very similar to those used in IRT. Numerous researchers have developed factor analysis procedures that are very similar to the current MIRT methods. The major distinction is that factor analysis procedures often standardize the variables being analyzed to have a common mean and variance, whereas MIRT leaves those variables unstandardized so that item characteristics can be studied.

General Assumptions of the Models

The models that fit under the general heading of MIRT are based on a number of assumptions.

Mathematical Form of the Model

A major assumption of MIRT is that a particular mathematical function will provide a reasonable approximation to the relationship between the characteristics of a person, the characteristics of the items, and the probability of the response to the items. Many different mathematical forms are possible, but most assume that the probability of a correct or desirable response increases with an increase in a person's status on a dimension, or any combination of dimensions. This is called the monotonicity assumption. This assumption is not a necessary requirement, but it seems reasonable for many types of measurement instruments, such as achievement or aptitude tests. The cumulative normal or logistic distribution functions have the monotonicity characteristic and are often used as the basis

for MIRT. These mathematical forms will be described in detail later.

Local (Conditional) Independence

A second major assumption is that if the model contains a sufficient number of dimensions to well represent the relationships between the persons and the items, then the responses for persons with the same location on the full set of dimensions will be independent of each other. This means, in practice, that the information about a person's level on all of the dimensions totally accounts for the non-random components of the responses. However, responses are expected to be dependent when persons vary in their status on the dimensions. Thus, the independence is "local" to a point in the multidimensional space where persons have the same profile of traits, and, equivalently, the independence is "conditional" on persons having the same profile of traits. The local independence assumption is needed for the estimation procedures used to compute the person and item characteristics.

Models

Introduction

MIRT models are often classified into two types, depending on whether high levels on one dimension can compensate for low levels on another dimension. Compensatory models allow the probability of a correct response to approach 1.0, even when the trait level on one or more dimensions is very low, if the trait levels on the remaining dimensions approach positive infinity. Non-compensatory or, more correctly, partially compensatory models do not allow the probability of a correct response to approach 1.0 when there is a low trait level on one dimension, even when the other traits approach positive infinity.

Compensatory Models

The most commonly used compensatory model is given by the following equation for the probability of a score of 1:

$$P(x_{ij} = 1 | \bar{\theta}_j, \bar{a}_i, d_i, c_i) = c_i + (1 - c_i) \frac{e^{\bar{a}'_i \bar{\theta}_j + d_i}}{1 + e^{\bar{a}'_i \bar{\theta}_j + d_i}}, \quad (1)$$

where x_{ij} is the (0 or 1) response by examinee j to item i , \bar{a}_i is a vector of parameters for item i that indicates how well the item discriminates on each trait dimension, d_i is a parameter that is related to the difficulty of the item or the likelihood of endorsing the item, c_i is the probability of obtaining a score of 1 on the item as the level on all of the traits approaches negative infinity, e is the mathematical constant that is the base of the

Figure 1 Compensatory multidimensional item response surface; $a_1 = 1.6$, $a_2 = 0.7$, $c = 0.2$, and $d = -1$.

natural logarithms, and $\bar{\theta}_j$ is a vector of trait levels for examinee j . Note that for a particular vector, \bar{a}_i , if one element of θ_j is large, the exponent will be large, resulting in a high probability of correct response even if other elements of θ_j are small. If there are only two trait dimensions in the model, θ_{1j} and θ_{2j} , as elements of θ_j , then the model can be represented graphically as a three-dimensional surface. An example of the surface for an item that is better at discriminating on Dimension 1 than Dimension 2 is given in Fig. 1.

The model given in Eq. (1) is a multidimensional extension of the three-parameter logistic model that is widely used for the modeling of test data when a single dominant trait can be assumed. If c_i can be assumed to be zero, then a simplified version of the model is an extension of the two-parameter logistic model. A model that is very similar to the model given in Eq. (1) is based on the cumulative normal distribution rather than the cumulative logistic distribution. Using the same notation as that for Eq. (1), the model is given by

$$P(x_{ij} = 1 | \bar{\theta}_j, \bar{a}_i, d_i, c_i) = c_i + (1 - c_i) \Psi(\bar{a}'_i \bar{\theta}_j + d_i), \quad (2)$$

where Ψ is the cumulative normal function. In practice, there is little to distinguish the form of the models in Eqs. (1) and (2), but the logistic form in Eq. (2) is somewhat easier to work with mathematically.

Noncompensatory Models

A number of noncompensatory models have been proposed in the literature; the most commonly referenced model assumes that there is a probability of response to the item related to each dimension, and the overall

Figure 2 Noncompensatory multidimensional item response surface; $a_1 = 1.6$, $a_2 = 0.7$, $b_1 = -1$, $b_2 = 0.5$, and $c = 0.2$.

probability of correct response is the product of the probabilities from the individual dimensions. The equation for the model is

$$P(x_{ij} = 1 | \bar{\theta}_j, \bar{a}_i, \bar{b}_i, c_i) = c_i + (1 - c_i) \prod_{k=1}^m \frac{e^{a_{ik}(\theta_{jk} - b_{ik})}}{1 + e^{a_{ik}(\theta_{jk} - b_{ik})}}, \quad (3)$$

where x_{ij} is the (0 or 1) response by examinee j to item i , \bar{a}_i is a vector of parameters for item i with elements a_{ik} that indicate how well the item discriminates on each trait dimension k , \bar{b}_i is a vector of parameter for item i with elements b_{ik} that indicate the level of difficulty of the item on each trait dimension k or the likelihood of endorsing the item, c_i is the probability of obtaining a score of 1 on the item as the level on all of the traits approaches negative infinity, e is the mathematical constant that is the base of the natural logarithms, and $\bar{\theta}_j$ is a vector of trait levels for examinee j with the individual elements indicated by θ_{jk} , the level of trait on the k th dimension. Note that, for the product term at the right-hand side of the model, the maximum value of the product is controlled by the dimension with the lowest term. When the θ_{jk} -values for the traits go to positive infinity, the corresponding terms go to 1.0. If all but one θ_{jk} goes to positive infinity, the product is equal to the value of the non-infinite term. Some compensation is possible in the model—the probability of correct response increases as each θ_{jk} increases, but the probabilities do not increase to 1.0 unless all θ_{jk} increase to positive infinity. If any one θ_{jk} is less than positive infinity, the value of that term is the limiting factor for the magnitude of the overall probability.

If there are only two trait dimensions in the model, θ_{j1} and θ_{j2} , as elements of $\bar{\theta}_j$, then the model can be represented graphically as a three-dimensional surface. An

example of the surface for an item that is better at discriminating on Dimension 1 than Dimension 2 is given in Fig. 2. The values of the discrimination parameters are the same as those used for Fig. 1, but for this model, values are needed for the difficulty parameters b_{ik} .

Estimation of Model Parameters

For the MIRT models to be used in practice, it must be possible to estimate the parameters of the models. The parameters are the item characteristics and the person trait levels. The parameter estimation procedures are quite different for the compensatory and noncompensatory models, so they will be discussed separately in the following two sections.

Compensatory Models

Two computer programs, NOHARM and TESTFACT, are frequently used for the estimation of the item characteristics of the compensatory models. The name “NOHARM” derives from the normal ogive harmonic analysis robust method. This method approximates the MIRT model using a four-term polynomial series; it determines the coefficients of the terms in the series that minimize the squared difference between the observed frequencies of correctly answering items i and j and the predicted frequency of the joint occurrence of the pair of correct responses. This procedure is not very computationally intensive and the input it requires is the collection of all possible two-by-two tables for pairs of item responses. The program will tally the frequencies for the tables from a person-by-item matrix of item responses. If nonzero c -parameters are assumed for the items, those parameters must be estimated by another program and be input to NOHARM. NOHARM does not estimate the lower asymptote for items. In general, the input data are the same that are needed to compute the correlation matrix for dichotomously scored items.

TESTFACT estimates the parameters of the MIRT model using the marginal maximum-likelihood method. That is, the maximum-likelihood estimate is obtained after integrating out an assumed marginal trait distribution. An iterative method based on the expectation maximization (EM) algorithm is used for estimation. As with NOHARM, TESTFACT does not estimate the lower asymptote parameter. It either accepts values as input or uses $1/(\text{number of item choices})$ as an approximation. TESTFACT is a computationally intensive procedure with limits on the number of dimensions that can be estimated.

Noncompensatory Models

In contrast to the compensatory models, estimation of the parameters for the noncompensatory models is much more challenging. An estimation procedure has been developed for a variation of the model given in Eq. (3), but that estimation procedure requires that data be collected on subtasks within an item as well as performance on the item as a whole. This procedure uses maximum-likelihood estimation. Newer estimation procedures, such as Markov chain Monte Carlo method, are now being applied to this class of models to solve some of the estimation procedures.

Examples of Estimation Results

Estimation software typically provides, at a minimum, estimates of the item parameters for the model. For the compensatory models, the estimates are provided for the a - and d -parameters, often labeled as slope and intercept parameters, respectively. Table I provides the item parameter estimates for the first 10 items from a 40-item tenth-grade mathematics test. The item response data from this test were analyzed using a two-dimensional compensatory model [see Eq. (2)] as implemented in the NOHARM computer program. The a -parameters in the table indicate how well the test items discriminate along the dimension related to that parameter. When the number is large (e.g., $a_1 = 2.37$ for Item 1), it indicates that the item is very discriminating along that dimension. When it is small (e.g., $a_2 = 0.00$ for Item 1), it indicates that the item does not discriminate along the dimension. For this analysis, a_2 was set to 0.0 for Item 1 to remove the rotational indeterminacy of the solution.

When the program estimates the parameters of the items, there are three features of the solution that cannot be determined from the model. They are (1) the location

of the 0-point on each of the dimensions (i.e., the origin of the ability space), (2) the units used to measure along each dimension, and (3) the orientation of the axes in the ability space. The 0-point is usually set at the mean level of performance on each dimension for the sample of examinees being analyzed, the unit is usually set as the standard deviation of that group, and the orientation is set by fixing the a -parameters at 0.0 for $m - 1$ items, where m is the number of dimensions in the solution. For this two-dimensional solution, the a -parameter needs to be fixed for only one item on one dimension. Setting the a -parameter to 0.0 aligns one of the axes of the solution with the skills assessed by that item with the nonzero loading. The indeterminacy of multivariate solutions has been known for some time, and there are many ways to add constraints to allow solutions to be obtained.

Another way of describing the discriminating power of a test item in a multidimensional space is how well the responses to the item divide the space into two parts, i.e., abilities for those who respond correctly to the item and for those who do not. The overall discriminating power of an item, MDISC, is defined by the following equation:

$$\text{MDISC}_i = \sqrt{\sum_{k=1}^m a_{ik}^2}. \quad (4)$$

The discrimination of an item is also best in a particular direction in the multidimensional space. The angle with coordinate axis k that gives the direction of best measurement is given by

$$\alpha_{ik} = \arccos\left(\frac{a_{ik}}{\text{MDISC}_i}\right). \quad (5)$$

The conversion of the discrimination parameter estimates to angle measures allows the items to be represented by vectors in the ability space that point in the direction of best measurement.

The distance of the point of best discrimination from the origin [i.e., the (0, 0) point] is given by the following multidimensional difficulty (MDIFF) equation:

$$\text{MDIFF}_i = -\frac{d_i}{\text{MDISC}_i}. \quad (6)$$

The value of MDIFF can be interpreted much like the b -parameter in unidimensional IRT. Positive values indicate difficult items and negative values indicate easy items. The full description of an item in a multidimensional space is given by the direction of best measurement, the discrimination in that direction, and the distance of the point of best discrimination from the origin of the space.

Table I Item Parameter Estimates for the First 10 Test Items^a

Item number	Item parameter		
	a_1	a_2	d
1	2.37	0.00	2.49
2	0.58	0.38	1.00
3	0.63	0.27	0.66
4	0.99	0.47	0.76
5	0.60	0.18	0.26
6	0.78	0.64	-0.01
7	0.75	0.41	0.57

Applications of the Models

Multidimensional item response theory models have been applied in a number of ways: (1) the analysis of the structure of measurement instruments and the processes involved in responding to the instruments, (2) the evaluation of the parallelism of test forms, and (3) multidimensional computerized adaptive testing. Although these have been the dominant applications to date, this is a new methodology and new applications are being developed as this article is being written.

Analysis of Instrument Structure

The data obtained from a measurement instrument is the set of responses to individual items. One of the challenges to the social sciences is to explain the processes behind the generation of the responses. One of the ways of showing that the responses have been explained is to predict the responses using a model such as the MIRT models described here. When the models are applied to data, the item parameter estimates can be used to determine the composite of dimensions that is best measured by an item. If two items have vectors pointing in the same direction, they measure the same composite of abilities. The angle between two item vectors is a measure of the similarity of the construct measured by the items. If the angle is zero, the items measure the same combination of abilities. The information about the similarity of constructs measured by items with cluster analysis methodology has been used to identify the set of constructs measured by achievement tests. Those constructs align closely with the content dimensions built into the test during the test development process. Thus, MIRT procedures are very powerful for investigating the content validity of a measurement instrument.

Multidimensional Parallelism

When measuring instruments purposely have a multidimensional structure, such as when an achievement domain is being assessed, and when multiple forms of the instrument are desired, interchangeable use of those forms requires that the forms measure the same combination of constructs and that those constructs are assessed with equal accuracy. MIRT provides the tools for determining whether multiple forms of a measuring instrument meet these requirements. For example, there have been comparisons of the multidimensional structure and the accuracy of estimation for multiple forms of a mathematics test that covered a wide range of content. Analysis showed that the forms differed in the emphasis

given to different content dimensions, even though the forms were constructed to be parallel using classical test theory procedures. The results showed that forms needed to be matched on the bivariate distribution of difficulty and discrimination, rather than matching on each characteristic separately.

Multidimensional Adaptive Testing

The MIRT application that is currently of greatest interest is the use of MIRT models as the basis for computerized adaptive tests. When MIRT models are used for computerized adaptive tests, locations of the examinees on multiple traits are determined simultaneously, rather than estimates of the location on each trait by a separate instrument. Items are acknowledged to require multiple trait dimensions for response and the information from those multiple dimensions is used to estimate the location of persons in the multidimensional space. This means that if items require both reading and mathematical skills for correct solution, that a person can be located on both of those dimensions from a single set of complex items, rather than having individual reading and mathematics tests. One type of MIRT methodology for computerized adaptive testing can increase the efficiency of testing because items contribute information to multiple dimensions. A more complex procedure for MIRT-based adaptive testing includes more constraints on the item development process.

Summary and Conclusions

Great progress has been made in the development of multidimensional item response theory since its initial presentation in the 1970s. Estimation procedures have been developed and several applications of the models are being put in practice. MIRT has also been found useful for explaining observed behavior of test items such as differential item functioning and misfit to unidimensional IRT models. Current work on MIRT is emphasizing the practical application of models to computerized adaptive testing and test equating. It is likely that MIRT methodology will also improve the process for constructing measuring instruments that measure complex composites of traits. More important than the individual applications is the conceptual framework provided by MIRT models; this framework, which allows instrument developers to consider the complex interactions of multiple traits with the subtle characteristics of items, should lead to better understandings about the way that measures of social variables function.

Glossary

Euclidean distance The distance, given a representation of objects as points in an R -dimensional space with coordinates for the i th object being $x_{i1}, x_{i2}, \dots, x_{iR}$, between two points i and j , defined as: $d_{ij} = [\sum_{r=1}^R (x_{ir} - x_{jr})^2]^{1/2}$.

INDSCAL (individual differences multidimensional scaling) The most widely used method of three-way or individual differences MDS. INDSCAL is, in addition to being the name of this three-way MDS model, also the name of one particular method for metric fitting of this model to three-way proximity data, as well as a class of more general three-way or higher models. In addition, it is the name of the earliest program for implementing this method.

KYST (Kruskal, Young, Shepard and Torgerson MDS) A family of programs for fitting two-way (metric or nonmetric) MDS implemented by Kruskal and others for two-way MDS.

metric multidimensional scaling Multidimensional scaling in which the function relating distances to proximities is assumed to be linear (or in some cases some specific non-linear function, such as a logarithmic or exponential function). In metric MDS, the scale type of the proximity data is either ratio or interval scale.

multidimensional scaling (MDS) A family of models and methods for representing stimuli or other objects as points in multidimensional space based on proximity (e.g., similarity or dissimilarity) data and relying on the principle that distances (usually, but not necessarily, Euclidean) in that space are related via a simple (usually linear or monotonic) function of the proximities.

nonmetric multidimensional scaling Multidimensional scaling in which the function relating distances to proximities is

assumed to be merely monotonic. The scale type of the proximity data in the case of nonmetric MDS is generally ordinal scale. (In some cases, nominal scale or categorical data can also be used in certain forms of non-metric MDS.)

proximities Measures of similarity (or dissimilarity) or other indices of closeness or proximity of pairs of stimuli or other objects. Proximities are generally assumed to be linearly or monotonically related to distances in an underlying multidimensional space. This function is assumed to have a negative slope (or to be monotonic nonincreasing) if the proximities are similarity-like and to have a positive slope (or to be monotonic nondecreasing) if the proximities are dissimilarity-like.

PROXSCAL (PROXimity multidimensional SCALing) A recently devised program by the Leiden group collaboratively with SPSS, Inc. that allows both metric and nonmetric two-way and three-way MDS, via either the two-way Euclidean model or the three-way INDSCAL model.

three-way multidimensional scaling Three-way MDS is MDS applied to two or more matrices of (usually symmetric) proximity data. Because the overall data array can be represented as a three-way (stimuli by stimuli by subjects or other sources of data) array, as contrasted with a simpler two-way array (or matrix) of stimuli by stimuli proximity data used in ordinary (often called two-way) MDS. Three-way MDS is often referred to as individual differences MDS because the third way of the data very often corresponds to different individual subjects. In three-way MDS, the objective is generally to provide a parsimonious representation of all the proximity data defined by the three-way array of data.

Multidimensional scaling refers to a family of models and methods for representing psychological stimuli of various kinds as points in multidimensional space. These stimuli can range from colors to perceived geometric objects, people, nations, and abstract concepts—in fact, any objects or entities for which judgments of similarity or dissimilarity can be quantified.

Proximity

Proximity is the generic term first introduced by Coombs and later much more fully developed by Shepard. Proximities may result from direct judgments of similarity, dissimilarity, relatedness, friendliness, or other measures of closeness, or proximity, by human subjects or may be derived from other data, such as preferences or rating-scale judgments of the stimuli by human subjects. The goal of multidimensional scaling (MDS) is to produce a representation of the stimuli or other objects as points in a multidimensional space (usually, but not necessarily, Euclidean) in which the distances between distinct pairs of the stimuli or other objects are related by some simple function to the proximity data. For example, if the basic data are similarities, the function relating distances to these similarity data might be, in the metric approaches to MDS, a linear function with a negative slope; in the nonmetric approaches, this function may be a merely monotonic (or order-preserving) function, but a *decreasing* (or, more precisely, a *nonincreasing*) monotonic function (i.e., a weakly monotonic function, in which, as the data values increase in value, the distances either decrease or remain unchanged in value). If the data were dissimilarities (or other proximities expected to be positively related to distances), then the function might be a linear function with a positive slope in the metric case (in which the proximity data are measured on at least an interval scale) or a nondecreasing monotonic function in the nonmetric case (in which the proximity data are measured on a merely ordinal scale). This particular use of the terms “metric” and “nonmetric” to refer to the scale type of the proximity data was first introduced by Coombs and later adopted by Kruskal in his pioneering approach to nonmetric MDS.

Points of View

Tucker and Messick introduced the first computational method for individual differences MDS, which they called the points of view (POV) approach. The POV approach first uses a factor analysis of the extended matrix formed by concatenating all the proximity matrices of all subjects into a single $n \times nm$ matrix (where n is the

number of stimuli, and m is the number of subjects), in which the subjects are represented as points, and then looks for clusters of subjects that are assumed to correspond to different points of view. After this initial factor analysis/clustering step, POV analysis then aggregates the data for each point of view and does a two-way, or non-individual difference, MDS analysis on the aggregate data for each point of view by any one of a number of different metric or nonmetric two-way MDS procedures. Numerous problems have been pointed out concerning this POV approach, including lack of parsimony, a lack of objective criteria for the number or nature of different points of view, and the lack of a strong theoretical justification for this method. These lacunae led eventually to the development of what is now called the INDSCAL (for individual differences multidimensional scaling) model and method for individual differences MDS; this is now, in one form or another, by far the most frequently used approach.

INDSCAL

INDSCAL is the most widely used method of three-way or individual differences MDS. It is based on a model in which different individuals (or other sources of data) use the same (common) set of perceptual dimensions but differ in a profile of dimension weights defining the psychological and/or perceptual salience (or importance) of the various common dimensions (common, that is, to all subjects or other sources of data, who/which are assumed to differ only in the salience or importance weights applied to the different common psychological or perceptual dimensions).

The INDSCAL model assumes a weighted generalization of ordinary Euclidean distances of the form:

$$d_{ijk} = \left[\sum_{r=1}^R w_{kr} (x_{ir} - x_{jr})^2 \right]^{1/2} \quad (1)$$

where d_{ijk} is the distance between stimuli or objects i and j for subject or other data source k , and w_{kr} is a weight for subject k on the r th common dimension defined for the INDSCAL model. As in two-way MDS, x_{ir} and x_{jr} are the r th coordinates of the i th and j th object points, respectively, in a common or group stimulus space. The total INDSCAL model can be expressed as $F_k(\delta_{ijk}) \cong d_{ijk}$ where δ_{ijk} is the i th, j th, and k th entry in the three-way proximity array, F_k is a function (usually linear or monotonic, depending on whether a metric or nonmetric method is used to fit the model), and d_{ijk} is the weighted Euclidean distance between i and j for k , as defined in Eq. (1). INDSCAL is, in addition to being the name of this three-way MDS model, also the name of one particular method for metric fitting of this model

to three-way proximity data, as well as a class of more general three-way or higher-way models. In addition, it is the name of the earliest program for implementing this method.

Among other important properties, the INDSCAL model leads to a unique orientation of the common dimensions. Unlike the representation produced by two-way MDS (with Euclidean distances) the INDSCAL representation can be shown *not* to be subject to an arbitrary orthogonal (or rigid) rotation (even if the subject or source weights are redefined), which leaves ordinary Euclidean distances unchanged or at most multiplies them by a positive constant. The INDSCAL approach assumes basic data that can be viewed as a three-way array. That is, the two-way methods deal with proximity data, defining only a two-way array or matrix of stimuli by stimuli data because either there is only one subject or data source *or*, if there are two or more subjects/sources, these have been averaged or otherwise aggregated to produce a single two-way array or matrix of proximity data. INDSCAL has been shown not only to produce unique (nonrotatable) configurations quite reliably, but also has been demonstrated to result in substantively interpretable dimensions without the need to rotate the stimulus/object configuration to an interpretable set of dimensions (or coordinates)! This need to rotate the stimulus/object configuration often makes two-way MDS methods intractable in practice, especially when the dimensionality of the representation exceeds two or three.

Nonmetric Multidimensional Scaling

A brief history of developments in nonmetric MDS can provide a way to understand the interrelationships among various models and methods as well as guidance in selecting problem-solving methods for social measurement applications.

The earliest description of MDS is the theoretical work published in *Psychometrika* by Gale Young and Alton Householder, which showed how to produce a Euclidean MDS representation with the coordinates' origin placed at any one of the n stimulus points—assuming ratio-scale distance estimates. Marion Richardson followed this with the first paper applying this approach to MDS, a strictly one-dimensional application involving stimuli consisting of various shades of gray (a colorless unidimensional application to the color domain).

The computational intractability of this methodology (no doubt complicated by the onset of World War II) resulted in the field lying fallow until the early 1950s, when, expedited by the emergence of practical digital computer technology, Torgerson and various mentors

and collaborators (Gulliksen, Tucker, Abelson, Messick, Bert Green, and probably others) revived and improved this methodology, enabling the use of interval as well as ratio-scale data. They made the method more robust by devising a solution for positioning the origin at the centroid of all these stimuli instead of at some arbitrary particular stimulus point and, probably most importantly, by adapting the method for use on digital computers. This advance led to what is now usually called the classical two-way metric MDS method most typically associated with Warren Torgerson.

Soon after Torgerson's work, Coombs and some of his students developed an approach to what they called nonmetric MDS (now sometimes called completely nonmetric MDS). The Coombs *et al.* approach was not so much a methodology as a set of vaguely expressed ideas and rules of thumb that constituted more a rough outline of a method than a precise algorithm. It did however provide a theoretical basis for the notion that well-defined MDS solutions could, in principle, be derived from even weaker, ordinal-scale (or nonmetric) data on similarities or dissimilarities—that is, proximities.

In 1962, Roger Shepard devised the first successful computer-implemented algorithm, which he called analysis of proximities, for nonmetric MDS in the modern sense. Shepard was (originally, at least) more interested in the theoretical problem of finding the nature and shape of the nonlinear but monotonic distance function, transmuting observed proximities into distances in an underlying Euclidean space, than in the use of nonmetric MDS to infer the underlying dimensions latent within a specific domain of stimuli. It soon became clear, however, that the power of MDS (metric *or* nonmetric) to find such underlying dimensional structures in proximity data was by far the most important potential application of this powerful new methodology. That nonmetric MDS enabled the use of a much wider variety of data types than the metric methods appeared to allow was perhaps the most exciting aspect of Shepard's seminal work.

In 1964, Joseph Kruskal developed the much more mathematically rigorous approach to what he, following Coombs's earlier terminology, explicitly called nonmetric multidimensional scaling by devising an algorithm that uses the method of steepest descent (or gradient method). The Kruskal algorithm optimizes (minimizes) a nonlinear function of many variables, specifically a measure of badness of fit that Kruskal called STRESS, using this gradient-based optimization technique. This technique was essentially unknown to most psychometricians and mathematical psychologists at that time, although now this and more sophisticated optimization techniques are generally well known in these fields, as well as in marketing and other social and behavioral sciences. A different measure of STRESS, called STRESS2, was later introduced, primarily to handle the case of what

Coombs had dubbed off-diagonal conditional proximity data, most often associated with unfolding analysis—which we prefer to call fitting of an ideal point model to individual differences preferential choice data. Kruskal also introduced the idea of fitting MDS models assuming metrics *other* than Euclidean—specifically the Minkowski- p or L_p metrics, the best known and most widely used of which is the well-known L_1 , or city block, metric, in which distance is the sum of absolute values of coordinate differences instead of the square root of the sum of squared coordinate differences. The most current and flexible version of Kruskal's algorithm is now implemented in the KYST-2A program.

Two-Way and Three-Way Multidimensional Scaling

In 1969 and 1970, Carroll and Chang introduced the model and method now called the INDSCAL model. It assumes a generalized, weighted, Euclidean metric, with a different profile of weights for each subject (or other source of data), so that a wide variety of different private perceptual spaces can be accommodated within the purview of this model, with a common group stimulus space containing dimensions common to all subjects/sources and only the profile of salience weights for these dimensions differing from subject/source to subject/source. As previously mentioned, the INDSCAL model has the additional important property called dimensional uniqueness, which means that, even though INDSCAL is basically a Euclidean distance model, the dimensions or coordinate axes are uniquely identified and *not* subject to rotational indeterminacy. This feature provides a tremendous advantage in substantively interpreting MDS configurations, which may be almost impossible to interpret in higher than two or three dimensions because of the near intractability of finding the “right” or interpretable rotation of a high-dimensional spatial representation. Experience with the INDSCAL methodology demonstrates that this theoretical property in fact works very well in practice, given that INDSCAL representations are almost always interpretable without rotation!

The most user-friendly implementation of the INDSCAL method is provided by Pruzansky's SINDSCAL program, which is specialized to the case of the kind of three-way symmetric data matrices that most often arise in applications of individual differences MDS. The older INDSCAL program, which is based on use of a general method of multiway data analysis called CANDECOMP (for canonical decomposition of N -way tables), is still useful for more general analyses of three-way or higher data, thus providing, among other things, an approach to three-way or higher factor or components

analysis. CANDECOMP is closely related to Harshman and Lundy's PARAFAC approach. The INDSCAL program also allows certain other analyses of more general proximity structures; for example, four-way MDS, in which different subjects, such as consumers, judge the similarity or dissimilarity of pairs of stimuli (products) under different scenarios (e.g., before and after some promotional message has been delivered or after different promotional messages have been delivered).

Other methods of both two-way and three-way (or individual differences) MDS have been devised since then, most notably Takane, Young and de Leeuw's ALSCAL approach, Ramsay's maximum likelihood approach (called MULTISCALE) and Meulman, Heiser, and SPSS, Inc.'s PROXSCAL, a two- and three-way generalization of Heiser and de Leeuw's SMACOF. This recently implemented version of PROXSCAL, now available within the CATEGORIES module for SPSS, includes a three-way nonmetric option (fitting the INDSCAL weighted Euclidean model to ordinal, or nonmetric, data) as well as enabling analysis via two-way metric or nonmetric MDS, with various options for missing data, unfolding analysis, and the like. This program is perhaps the most flexible and dependable for MDS analysis now widely available.

For metric analysis of three-way MDS data, either SINDSCAL or MULTISCALE is the preferred method. For strictly two-way analysis, either the classical two-way MDS method or KYST is probably still the best method for most purposes, although the two-way option in Ramsay's MULTISCALE may be appropriate if a maximum likelihood solution is sought. Various theoretical and methodological problems make ALSCAL less appropriate for most MDS analyses.

Unfolding analysis, which can be implemented by using KYST with appropriate options, appears to be the preferred approach on theoretical grounds for multidimensional analysis of individual differences preference data (using an ideal point model). It is, however, by its very nature, subject to a serious and seemingly intractable degeneracy or quasi-degeneracy problem. In practice, probably the most effective MDS method for the analysis of individual differences preferences is the MDPREF method or some other approach based on the much simpler linear model called the vector model for preferences. Carroll discusses the theoretical basis for this model and the underpinnings of the MDPREF methodology in considerable detail—suffice it to say that the vector model, which MDPREF fits via a straightforward procedure based on the singular value decomposition (SVD), can be viewed as a special (limiting) case of the ideal point model underlying unfolding analysis, with ideal points “infinitely distant” from the stimuli. Apparently, in practice, ideal points for individuals are, if not infinitely distant from the actual stimuli (e.g., products in a marketing application), so far from realistic stimuli (say, products) as to

be, for all practical purposes, *effectively* “infinitely distant.” For example, if not constrained otherwise, many people would describe their “ideal car” as a spacious, luxurious, comfortable, exceedingly safe sports car that gets as close as possible to an infinite number of miles per gallon and is extremely economical in terms of maintenance and other costs, while having a price equal or very nearly equal to zero! In other words, given no constraints at all, most people would have an “ideal product” that simply does not (and *could* not) exist because such ideal points are necessarily infinitely distant from the actual products (or other stimuli) in various directions. It is for this reason, we believe, that a vector model, which corresponds to the special case of an ideal point model with ideal points at infinity, may be so much more robust and useful in practice than the more theoretically elegant ideal point model of which it is a (*very*) special case!

In addition to these standard approaches to MDS, there have been a number of different proposals to extend the definition of the field to include other (nonspatial) geometric models, such as tree or other network structures, or hybrid models combining spatial structure with such discrete or nonspatial structure as tree, network, and clustering models of various kinds.

Glossary

centering Transforming a variable by subtracting the mean. In multilevel data, there are two ways of centering: subtracting the overall mean and subtracting group means. Centering on the overall mean is a straightforward linear transformation, whereas centering on the group mean leads to a radically different model.

cross-level interaction When a regression coefficient of an individual-level variable varies across groups, this variation can be modeled by introducing an interaction term of that variable with one of the group-level variables. Such cross-level interactions are common in multilevel analysis.

cluster sampling A procedure in which data are collected in a two-stage design, starting first with sampling of groups (clusters), followed by sampling of individuals within groups (clusters).

dependence The assumption in cluster sampling and multilevel data that the observations are not sampled independently of one another. The result of this assumption is strongly biased standard errors when standard statistical methods are used.

design effect The amount of bias in the standard errors introduced by having dependent observations.

intraclass correlation The expected correlation between individuals within the same group. When the intraclass correlation is greater than zero, the observations are not independent.

fixed part The part of the model equation that contains the regression coefficients.

generalized linear regression model A regression model that is used when the linearity and distributional assumptions of the linear regression model are not met, for example, when the dependent variable is categorical.

linear regression model A regression model that describes the relationship between one response variable and one or more explanatory variables by calculating the best-fitting linear line (or plane).

logistic regression A generalized linear regression model for response variables that are dichotomous or proportions.

maximum likelihood (ML) The estimation method most commonly used in multilevel analysis. ML estimation produces estimated parameter values that make the probability of observing the data highest.

multilevel analysis of longitudinal data The analysis of longitudinal data or repeated measurements as multilevel data by viewing these as observations nested within individuals. The advantage is that the analysis deals easily with missing measurement occasions.

multilevel data Data that have a hierarchical or nested structure, usually individuals within groups.

random coefficients The regression coefficients of the lowest-level explanatory variables; these coefficients can vary across groups and part of this variation is assumed to be random (stochastic).

random part The part of the model equation that contains the residual error terms.

variance components The variances (and covariances) of the residual errors. In multilevel analysis, there are variance components at each distinct level.

Social research often concerns the relationship between individuals and the groups to which they belong. This leads to hierarchical or multilevel data structures, with individuals nested within the groups. Examples are educational research with pupils nested within classes nested within schools (a three-level data structure), cross-national studies with individuals nested within national units, and family research with members nested within families. Less obvious applications of multilevel modeling are longitudinal studies with measurement occasions nested within individuals and meta-analysis with subjects nested

within studies. More specialized multilevel models have been developed that can incorporate nonnested hierarchical structures and multiple response variables. Multilevel modeling has become popular for the analysis of a variety of problems, going beyond the classical individuals-within-groups applications. This entry gives a brief summary of the reasons for using multilevel models and provides examples why these reasons are indeed valid reasons. Next, the multilevel model is introduced and illustrated with an empirical example. The extension to multilevel logistic regression is briefly discussed.

Introduction

Multilevel modeling is used in the analysis of data that have a hierarchical or clustered structure. Such data arise routinely in various fields, for instance in educational research in which pupils are nested within schools, in family studies in which children are nested within families, in medical research in which patients are nested within physicians or hospitals, and in biomedical research, for instance the analysis of dental anomalies in which teeth are nested within different people's mouths. Clustered data may also arise as a result of the specific research design. For instance, in large-scale survey research the data collection is usually organized in a multistage sampling design that results in clustered or stratified data. Another example is a longitudinal design, in which the data are a series of repeated measurements nested within individual subjects.

A crucial problem in the statistical analysis of hierarchically structured data is the dependence of the observations at the lower levels. Older approaches to the analysis of multilevel data simply ignore this problem and commonly perform the analysis by disaggregating all data to the lowest level and subsequently applying standard analysis methods. The magnitude of the statistical bias introduced by this approach can be illustrated by a simple example from sample surveys. Survey statisticians have long known that the extent to which samples are clustered affects the sampling variance and, hence, causes a bias in statistical significance tests. In his classic 1965 work, Kish defines the design effect (deff) as the ratio of the operating sampling variance to the sampling variance that applies to simple random sampling. Thus, deff is the factor with which the simple random sampling variance must be multiplied to provide the actual operating sampling variance. In simple cluster sampling with equal cluster sizes, deff can be computed by $\text{deff} = [1 + \rho(n_{\text{clus}} - 1)]$, where ρ is the intraclass correlation, and n_{clus} is the common cluster size. (The intraclass correlation ρ indicates the degree of similarity between respondents within the same cluster; the formula is presented in the next section.) It is clear that deff equals 1 only when either the intraclass correlation is zero or the

cluster size is 1. In all other situations, deff is larger than 1, which implies that standard statistical formulas will underestimate the sampling variance and therefore lead to biased significance tests with an inflated Type I error rate.

The impact of cluster sampling on the operating α level is often large. For example, assume that we carry out a t test at a nominal α level of 0.05. If we have a cluster sample, with a small intraclass correlation of $\rho = 0.05$ and a cluster size of 10, the actual operating α level is 0.11. With larger intraclass correlations and larger cluster sizes, the operating α level increases rapidly. Consider the effect of cluster sampling in educational research, in which data are often collected from classes. Assuming a common class size of 25 pupils, and a typical intraclass correlation for school effects of $\rho = 0.10$, the operating α level is 0.29 for tests performed at a nominal α level of 0.05! Clearly, in such situations *not* adjusting for clustered data produces very misleading significance tests. In addition, for nonlinear models such as logistic regression, not only the standard errors, but also the regression coefficients themselves are biased.

If we have clustered data, the standard statistical tests can be adjusted using deff. However, multilevel modeling is more general. In most multilevel problems, we have not only clustering of individuals within groups, but we also have variables measured at all available levels. Combining variables from different levels in one statistical model is a different problem than estimating and correcting for design effects. Multilevel models are designed to analyze variables from different levels simultaneously, using a statistical model that includes the various dependencies. This leads to research into the direct effects and the interactions between variables that describe the individuals and variables that describe the groups, a kind of research that is now often referred to as multilevel research.

Multilevel research requires multilevel theories, an area that seems underdeveloped compared to the statistical and computational advances. If there are effects of the social context on individuals, these effects must be mediated by intervening processes that depend on characteristics of the social context. Multilevel models in general assume that the grouping criterion is clear and that variables can be assigned unambiguously to their appropriate level. In reality, group boundaries may be somewhat arbitrary and the assignment of variables is not always obvious and simple. In addition, if we have many variables at many levels, there is an enormous number of possible interactions between different levels. Ideally, a multilevel theory should specify which variables belong to which level and which direct effects and cross-level interaction effects can be expected. The common denominator in such theories is that they all postulate processes that mediate between individual variables and group variables, such as communication processes, social comparison processes, and the internal structure of groups.

The Multilevel Regression Model

The multilevel regression model is known in the statistical literature under a variety of names: hierarchical linear model, random coefficient model, variance component model, and mixed (linear) model. Most often it assumes hierarchical data, with one response variable measured at the lowest level and explanatory variables at all existing levels. Conceptually, the model is often viewed as a hierarchical system of regression equations. For example, assume we have data in J groups or contexts and a different number of individuals N_j in each group. On the individual (lowest) level we have the dependent variable Y_{ij} and the explanatory variable X_{ij} , and on the group level we have the explanatory variable Z_j . Thus, we have a separate regression equation in each group:

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + e_{ij} \quad (1)$$

In Eq. (1) β_0 is the usual regression intercept, β_1 is the regression slope for the explanatory variable X , and e_{ij} is the residual term. The regression coefficients β carry a subscript j for the groups, which indicates that the regression coefficients may vary across groups. The variation in the regression coefficients β_j is modeled by explanatory variables and random residual terms at the group level:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}Z_j + u_{0j} \quad (2)$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}Z_j + u_{1j} \quad (3)$$

Substitution of Eqs. (2) and (3) into Eq. (1) produces the single-equation version of the multilevel regression model:

$$Y_{ij} = \gamma_{00} + \gamma_{10}X_{ij} + \gamma_{01}Z_j + \gamma_{11}Z_jX_{ij} + u_{1j}X_{ij} + u_{0j} + e_{ij} \quad (4)$$

In general, there will be more than one explanatory variable at the lowest level and also more than one explanatory variable at the highest level. Assume that we have P explanatory variables X at the lowest level, indicated by the subscript p ($p = 1, \dots, P$), and Q explanatory variables Z at the highest level, indicated by the subscript q ($q = 1, \dots, Q$). Then, Eq. (4) becomes the more general equation:

$$Y_{ij} = \gamma_{00} + \sum_p \gamma_{p0}X_{pji} + \sum_q \gamma_{0q}Z_{qj} + \sum_q \sum_p \gamma_{pq}Z_{qj}X_{pji} + \sum_p u_{pj}X_{pji} + u_{0j} + e_{ij} \quad (5)$$

In Eq. (5), the γ are the usual regression coefficients, the u terms are residuals at the group level, and the e term represents the residual at the individual level. The regression coefficients are identified as the fixed part of the model because this part does not change over groups

or individuals. The residual error terms are identified as the random or stochastic part of the model.

The assumptions of the most commonly used multilevel regression model are that the residuals at the lowest level e_{ij} have a normal distribution with a mean of zero and a common variance σ^2 in all groups. The second-level residuals u_{0j} and u_{1j} are assumed to be independent of the lowest level errors e_{ij} and to have a multivariate normal distribution with means of zero. Other assumptions, identical to the common assumptions of a multiple regression analysis, are fixed predictors and linear relationships. Most multilevel software assumes by default that the variance of the residual errors e_{ij} is the same in all groups. However, certain forms of heteroscedasticity can be explicitly modeled.

The estimation of parameters (regression coefficients and variance components) in multilevel modeling is generally done using the maximum likelihood (ML) method. The standard errors (SEs) generated by the ML procedure are asymptotic, meaning we need fairly large samples at all levels. These standard errors can be used to establish a p value for the null hypothesis that in the population a specific regression coefficient is zero. Thus, the significance of a regression coefficient can be tested by referring $Z = \beta/SE(\beta)$ to the standard normal distribution. The ML procedure also generates a value for the deviance that is based on the likelihood (the deviance equals -2 times the log-likelihood). In addition to the standard errors, the deviance can also be used to test parameters for significance. When two models are nested, which means that the smaller model can be obtained by removing terms from the larger model, the difference between the deviances of these two models has a chi-square distribution, with degrees of freedom being the difference in numbers of estimated parameters. This is useful for testing the significance of variance terms. The asymptotic Z test previously described is not optimal for testing variances. First, it assumes normality, and variances do not have a normal distribution. Second, testing the null hypothesis that a variance is zero is a test on the boundary of the parameter space (variances cannot be negative), where standard likelihood theory is no longer valid. The significance of a variance component can be tested by comparing the deviance of a model containing this parameter to the deviance of the same model without this one variance parameter. This value can be treated as a chi-square variate with one degree of freedom, and this can be used to test the significance of that variance component. It should be noted that Raudenbush and Bryk present a different chi-square test for variance components, which is not based on the deviance.

Two different likelihood functions are commonly used in multilevel regression analysis. The first is full maximum likelihood (FML). The second is restricted maximum likelihood (RML). The difference is that

RML maximizes a likelihood function that is invariant for the fixed effects. Because RML is more realistic, it should, in theory, lead to better estimates of the variance components, especially when the number of groups is small. Nevertheless, FML has one advantage over RML—because the likelihood is maximized over both the fixed and the random part, the difference between two deviances can be used to test for differences between two nested models that differ only in the fixed part (the regression coefficients). With RML, only differences in the random part (the variance components) can be tested this way.

The proportion of variance in the population explained by the grouping structure is indicated by the intraclass correlation ρ . The model used to estimate ρ is the model that contains no explanatory variables at all, called the intercept-only model:

$$Y_{ij} = \gamma_{00} + u_{0j} + e_{ij} \quad (6)$$

Using this model, the intraclass correlation ρ is estimated by the equation:

$$\rho = \frac{\sigma_{u_0}^2}{\sigma_{u_0}^2 + \sigma_e^2} \quad (7)$$

where $\sigma_{u_0}^2$ is the variance of the second-level residuals u_{0j} and σ_e^2 is the variance of the lowest level residuals e_{ij} .

Example of Multilevel Regression Analysis

Assume that we have data from school classes. On the pupil level, we have the outcome variable Popularity measured by a self-rating scale that ranges from 0 (very unpopular) to 10 (very popular). We have one explanatory variable Gender (0 = boy, 1 = girl) on the pupil level and

one class level explanatory variable Teacher experience (in years). We have data from 2000 pupils from 100 classes, so the average class size is 20 pupils. The data are described and analyzed in more detail in Hox's 2002 handbook.

Table I presents the parameter estimates and standard errors for a series of models. Model M0 is the null model, the intercept-only model. The intercept-only model estimates the intercept as 5.31, which is simply the weighted average popularity across all schools and pupils. The variance of the pupil-level residuals is estimated as 0.64. The variance of the class-level residuals is estimated as 0.87. The intercept estimate is much larger than the corresponding standard error, and the calculation of the Z test shows that it is significant at $p < 0.005$. As previously mentioned, the Z test is not optimal for testing variances. If the second-level variance term is restricted to zero, the deviance of the model goes up to 6489.5. The difference between the deviances is 1376.8, with one more parameter in the intercept-only model. The chi-square of 1376.8 with one degree of freedom is also significant at $p < 0.005$. The intraclass correlation is $\rho = \sigma_{u_0}^2 / (\sigma_{u_0}^2 + \sigma_e^2) = 0.87 / (0.87 + 0.64) = 0.58$. Thus, 58% of the variance of the popularity scores is at the group level, which is very high. Because the intercept-only model contains no explanatory variables, the variances terms represent unexplained residual variance.

Model M1 predicts the outcome variable Popularity by the explanatory variables Gender and Teacher experience, with a random component for the regression coefficient of gender, and model M2 adds the cross-level interaction term between Gender and Teacher experience. We can view these models as built up in the following sequence of steps:

$$\text{Popularity}_{ij} = \beta_{0j} + \beta_{1j}\text{Gender}_{ij} + e_{ij} \quad (8)$$

Table I Multilevel Models for Pupil Popularity

Model	M0: Intercept-only	M1: +Pupil gender and Teacher experience	M2: +Cross-level interaction
Fixed part			
Predictor	Coefficient (SE)	Coefficient (SE)	Coefficient (SE)
Intercept	5.31 (0.10)	3.34 (0.16)	3.31 (0.16)
Pupil gender		0.84 (0.06)	1.33 (0.13)
Teacher experience		0.11 (0.01)	0.11 (0.01)
Pupil gender Teacher experience			−0.03 (0.01)
Random part			
σ_e^2	0.64 (0.02)	0.39 (0.01)	0.39 (0.01)
$\sigma_{u_0}^2$	0.87 (0.13)	0.40 (0.06)	0.40 (0.06)
$\sigma_{u_1}^2$		0.27 (0.05)	0.22 (0.04)
$\sigma_{u_{01}}$		0.02 (0.04)	0.02 (0.04)
Deviance	5112.7	4261.2	4245.9

In this regression equation, β_{0j} is the usual intercept, β_{1j} is the usual regression coefficient (regression slope) for the explanatory variable gender, and e_{ij} is the usual residual term. The subscript j is for the classes ($j = 1, \dots, J$) and the subscript i is for individual pupils ($i = 1, \dots, N_j$). We assume that the intercepts β_{0j} and the slopes β_{1j} vary across classes.

In our example data, the model corresponding to Eq. (8) results in significant variance components at both levels (as determined by the deviance-difference test). In the next step, we hope to be able to explain at least some of this variation by introducing class-level variables. Generally, we will not be able to explain all the variation of the regression coefficients, and there will be some unexplained residual variation—hence the name random coefficient model, the regression coefficients (intercept and slopes) have some amount of (residual) random variation between groups. Variance component model refers to the statistical problem of estimating the amount of random variation. In our example, the specific value for the intercept and the slope coefficient for the pupil variable Gender are class characteristics. A class with a high intercept is predicted to have more popular pupils than a class with a low value for the intercept. Similarly, differences in the slope coefficient for gender indicate that the relationship between the pupils' gender and their predicted popularity is not the same in all classes. Some classes may have a high value for the slope coefficient of gender; in these classes, the difference between boys and girls is relatively large. Other classes may have a low value for the slope coefficient of gender; in these classes, gender has a small effect on the popularity, which means that the difference between boys and girls is small.

The next step in the hierarchical regression model is to explain the variation of the regression coefficients β_{0j} and β_{1j} by introducing the explanatory variable Teacher experience at the class level. Model M1 models the intercept as follows:

$$\beta_{0j} = \gamma_{00} + \gamma_{01} \text{Teacher experience}_j + u_{0j} \quad (9)$$

and model M2 models the slope as follows:

$$\beta_{1j} = \gamma_{10} + \gamma_{11} \text{Teacher experience}_j + u_{1j} \quad (10)$$

Equation (9) predicts the average popularity in a class (the intercept β_{0j}) by the teacher's experience. Thus, if γ_{01} is positive, the average popularity is higher in classes with a more experienced teacher. Conversely, if γ_{01} is negative, the average popularity is lower in classes with a more experienced teacher. The interpretation of Eq. (10) is more complicated. Equation (10) states that the *relationship*, as expressed by the slope coefficient β_{1j} , between the popularity and the gender of the pupil, depends on the amount of experience of the teacher. If γ_{11} is positive, the gender effect on popularity is larger

with experienced teachers. On the other hand, if γ_{11} is negative, the gender effect on popularity is smaller with experienced teachers. Thus, the amount of experience of the teacher interacts with the relationship between popularity and gender; this relationship varies according to the value of the teacher experience.

The u terms u_{0j} and u_{1j} in Eqs. (9) and (10) are the residual terms at the class level. The variance of the residual u_{0j} is denoted by $\sigma_{u_0}^2$, and the variance of the residual u_{1j} is denoted by $\sigma_{u_1}^2$. The covariance between the residuals u_{0j} and u_{1j} is $\sigma_{u_0 u_1}$, which is generally *not* assumed to be zero.

Our model with one pupil-level and one class-level explanatory variable including the cross-level interaction can be written as a single complex regression equation by substituting Eqs. (9) and (10) into Eq. (8). This produces:

$$\begin{aligned} \text{Popularity}_{ij} = & \gamma_{00} + \gamma_{10} \text{Gender}_{ij} \\ & + \gamma_{01} \text{Teacher experience}_j \\ & + \gamma_{11} \text{Teacher experience}_j \times \text{Gender}_{ij} \\ & + u_{1j} \text{Gender}_{ij} + u_{0j} + e_{ij} \end{aligned} \quad (11)$$

Note that the result of modeling the slopes using the class-level variable implies adding an interaction term and second-level residuals u_{1j} that are related to the pupil-level variable Gender. Model M2 is the most complete, including both available explanatory variables and the cross-level interaction term. The interaction term is significant using the Z test. Because we have used FML estimation, we can also test the interaction term by comparing the deviances of models M1 and M2. The deviance-difference is 15.3, which has a chi-square distribution with one degree of freedom and $p < 0.005$. Using a deviance-difference test on the second-level variance components in model M2, by restricting variance terms to zero and then comparing deviances, leads to the conclusion that all variance terms are significant and that the covariance term is not. This means, that not all residual variation in the intercept and slope can be modeled by the explanatory variables.

The interpretation of model M2 is straightforward. The regression coefficients for both explanatory variables are significant. The regression coefficient for pupil gender is 1.33. Because pupil gender is coded 0 = boy and 1 = girl, this means that on average the girls score 1.33 points higher on the popularity measure. The regression coefficient for teacher experience is 0.11, which means that for each year of experience of the teacher, the average popularity score of the class goes up with 0.11 points. Because there is an interaction term in the model, the effect of 1.33 for pupil gender is the expected effect for teachers with zero experience. The regression coefficient for the cross-level interaction is -0.03 , which is small but significant. The negative value means that with experienced teachers,

the advantage of being a girl is smaller than expected from the direct effects only. Thus, the difference between boys and girls is smaller with more experienced teachers. A comparison of the other results between the two models shows that the variance component for pupil gender goes down from 0.27 in the direct effects model (M1) to 0.22 in the cross-level model (M2). Hence, the cross-level model explains about 19% of the variation of the slopes for pupil gender.

The significant and quite large variance of the regression slopes for pupil gender implies that we should not interpret the estimated value of 1.33 without considering this variation. In an ordinary regression model, without multilevel structure, the value of 1.33 means that girls are expected to differ from boys by 1.33 points, for all pupils in all classes. In our multilevel model, the regression coefficient for pupil gender varies across the classes and the value of 1.33 is just the expected value across all classes (for teachers with zero experience). The variance of the slope is estimated in model M1 as 0.27. Model M2 shows that part of this variation can be explained by variation in teacher experience. The interpretation of the slope variation is easier when we consider their standard deviation, which is the square root of the variance, or 0.52 in our example data. The varying regression coefficients are assumed to follow a normal distribution. Thus, we may expect 95% of the regression slopes to lie between two standard deviations above or below their average. Given the estimated values of 1.33 (in model M2, for inexperienced teachers) or 0.84 (in model M1, average for all teachers) the vast majority of the classes are expected to have positive slopes for the effect of pupil gender. Figure 1 provides a graphical display of the slope variation, which confirms the conclusion that almost all class slopes are expected to be positive.

Figure 1 One hundred class slopes for pupil gender.

Analysis of Proportions and Binary Data

The multilevel regression model discussed so far assumes a continuous dependent variable and normal distributions for the residuals. When the response variable is a dichotomous variable or a proportion, both the assumptions of continuous scores and of normality are not met. In addition, the assumption of homoscedastic errors is violated.

The classical approach to the problem of nonnormally distributed variables and heteroscedastic errors is to apply a transformation to achieve normality and reduce heteroskedasticity, followed by a traditional multiple regression analysis. The modern approach to the problem of nonnormally distributed variables is to include the necessary transformation and the choice of the appropriate error distribution (not necessarily a normal distribution) explicitly in the statistical model. This class of statistical models is called generalized linear models. Generalized linear models are defined by three components: (1) a linear regression equation, (2) a specific error distribution, and (3) a link function which is the transformation that links the predicted values for the dependent variable to the observed values. If the link function is the identity function ($f(x) = x$) and the error distribution is normal, the generalized linear model simplifies to the ordinary multiple linear regression model.

Multilevel generalized linear models are described by Raudenbush and Bryk and by Goldstein. Estimating the parameters (regression coefficients and variance components) for such models is more complicated than ordinary multilevel analysis because the likelihood function used in the ML estimation is nonlinear. One approach to estimating such nonlinear models is to linearize the likelihood function. This results in an approximation to the likelihood, and as a result statistical tests based on the likelihood (such as the deviance-difference test) cannot be used. The second approach is to maximize the nonlinear likelihood itself. This is difficult, and therefore it is implemented only in some of the available software and only for a limited set of models. The link functions presently supported in most software are the logistic link function for binary (dichotomous) and binomial data (proportions), the logarithmic function for Poisson data, and the reciprocal link function for γ -distributed data.

The example presented in what follows concerns data from a meta-analysis of studies that compared face-to-face, telephone, and mail surveys on various indicators of data quality. One of these indicators is the response rate—the number of completed interviews divided by the total number of eligible sample units. Overall, the response rates differ among the three data collection methods. In addition, the response rates also differ across

studies, which makes it interesting to analyze if study characteristics account for these differences.

These data have a multilevel structure. The lowest level is the condition-level, and the higher level is the study-level. There are three variables at the condition level: the number of completed interviews in that specific condition, the number of eligible respondents in that condition, and an explanatory categorical variable indicating the data collection method used. The categorical data collection variable has three categories: face-to-face, telephone, and mail. It is recoded into two dummy variables: a telephone-dummy and a mail-dummy; this makes the face-to-face condition the reference condition. We use one variable at the study level: the saliency of the questionnaire topic. We have 45 studies in which a total of 99 data collection conditions are compared.

The dependent variable is the response rate. This variable is a proportion—the number of completed interviews divided by the number of eligible respondents. Proportions are analyzed using logistic regression, which is a specific generalized linear model. The link function for binomial data and proportions is the logit function, which is defined as $\text{logit}(x) = \ln[x/(1-x)]$. The corresponding error function is the binomial distribution.

Let P_{ij} be the observed proportion respondents in condition i of study j . Although P_{ij} has a binomial distribution, $\text{logit}(P_{ij})$ has a distribution that is approximately normal, and so we use a linear regression equation at the lowest level. The simplest model, corresponding to the intercept-only model in ordinary multilevel regression analysis, is given by:

$$\text{logit}(P_{ij}) = \beta_{0j} \quad (12)$$

Note that the usual lowest level error term e_{ij} is not included in Eq. (12). In the binomial distribution, the variance of the observed proportion depends only on the population proportion π . As a consequence, the lowest level variance is determined completely by the

predicted value for P_{ij} , and it does not enter the model as a separate term.

The model in Eq. (12) can be extended to include an explanatory variable X_{ij} (e.g., the mail or face-to-face condition) at the condition level:

$$\text{logit}(P_{ij}) = \beta_{0j} + \beta_{1j}X_{ij} \quad (13)$$

The regression coefficients β are assumed to vary across studies, and this variation is modeled by the study level variable Z_j in the usual second-level regression equations:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}Z_j + u_{0j} \quad (14)$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}Z_j + u_{1j} \quad (15)$$

By substituting Eqs. (15) and (14) into Eq. (13), we get the single-equation version:

$$\text{logit}(P_{ij}) = \gamma_{00} + \gamma_{10}X_{ij} + \gamma_{01}Z_j + \gamma_{11}Z_jX_{ij} + u_{0j} + u_{1j}X_{ij} \quad (16)$$

It should be kept in mind that the interpretation of the regression parameters is *not* in terms of the response proportions we want to analyze but instead in terms of the underlying variate defined by the logit transformation $\text{logit}(x) = \ln[x/(1-x)]$. The logit link function is nonlinear and transforms the proportions, which are between 0.00 and 1.00 by definition, into values that range from $-\infty$ to $+\infty$. For a quick examination of the analysis results, we can simply inspect the regression parameters. To understand the implications of the regression coefficients for the proportions we are modeling, we must transform the predicted values back to the original scale or transform the regression coefficients to odds ratios. This problem is not specific to multilevel logistic regression.

Table II presents the results for a sequence of three models: the intercept-only model, a model with the two condition dummies, and a model with the two condition dummies and the study-level variable Saliency. In the

Table II Multilevel Logistic Models for Survey Response

Model	M0: intercept-only	M1: +conditions	M2: +saliency
Fixed part			
Predictor	Coefficient (SE)	Coefficient (SE)	Coefficient (SE)
Intercept	1.02 (0.13)	1.29 (0.14)	0.54 (0.22)
Telephone		−0.21 (0.09)	−0.19 (0.10)
Mail		−0.58 (0.16)	−0.56 (0.15)
Saliency			0.68 (0.17)
Random part			
$\sigma_{u_0}^2$	0.84 (0.17)	0.83 (0.19)	0.63 (0.14)
$\sigma_{u_1}^2$		0.26 (0.07)	0.27 (0.08)
$\sigma_{u_2}^2$		0.60 (0.20)	0.56 (0.18)

intercept-only model, the intercept γ_{00} is estimated as 1.02. As noted before, this refers to the underlying distribution established by the logistic link function and *not* to the proportions themselves. To determine the expected proportion, we must use the inverse transformation for the logistic link function, given by:

$$g(x) = \frac{e^x}{1 + e^x}$$

Using this inverse function, the estimated intercept of 1.02 translates back to an expected proportion of 0.73. The study-level variance is considerable and significant by the Z test. Because the estimation method used here is based on the linearization approach, the deviance is approximate and not available for the deviance-difference test. Hence, in this specific case the significance of the variance components is assessed using the Z test.

The next model adds the condition-level variables Telephone-dummy and Mail-dummy, assuming random regression slopes. In this model, the intercept represents the condition in which both explanatory variables are zero, which is the face-to-face condition. Thus, the value for the intercept in model M1 in Table II estimates the expected response in the face-to-face condition, which is 1.29. This corresponds to an expected response proportion of 0.78. The large negative values for the slope coefficients for the Telephone-dummy and Mail-dummy variables indicate that in these conditions the expected response is lower. To find out how much lower, we must use the regression equation to predict the response in the three conditions and transform these values (which refer to the underlying variate) back to proportions. For the telephone condition, which is coded by Telephone = 1 and Mail = 0, the regression equation reads: $Y = 1.29 - 0.21 = 1.08$, which transforms to an expected response proportion of 0.75. For the mail condition, which is coded by Telephone = 0 and Mail = 1, it reads $Y = 1.29 - 0.58 = 0.71$, which transforms to an expected response proportion of 0.67. The variance components for the regression coefficients are significant by the (approximate) Z test.

The final model includes the study-level variable Saliency. Compared to the earlier results, the regression coefficients are about the same, but the value for the intercept is different. This is not informative, because the intercept almost always changes when other variables are added to or deleted from the regression equation. In our case, including the study-level explanatory variable Saliency in the model causes the shift of the intercept value. Saliency is coded as 1 = very salient, 2 = somewhat salient, and 3 = not salient. The coded values for Saliency do not include the value 0. Hence, the estimated value of the intercept has no meaningful interpretation. The regression coefficient for Saliency is positive, indicating that the response rate increases when the study's topic is more salient.

The last logical step is to introduce interaction variables of Saliency with the two condition variables to model the random coefficients. In our example data, it turns out that this interaction variable does not explain any variation of the regression coefficients.

The random coefficient model leads to another interesting conclusion. In general, telephone and mail surveys obtain a lower response rate than face-to-face surveys. For instance, on the underlying scale, the regression coefficient for Telephone is -0.19 in the final model. However, this regression coefficient has a large variance across studies: $\sigma_{11}^2 = 0.27$. The corresponding standard deviation is 0.52. Using the standard normal distribution, we can calculate that in 36% of similarly conducted studies this regression coefficient is expected to be larger than zero! It is instructive to see that, even if there is little doubt that *on the average* the telephone interview has a lower response rate than the face-to-face interview, there is still a chance that in a specific study we will find the opposite relation.

Further Topics

Extensions of the Multilevel Regression Model

The multilevel regression model is one attractive approach to analyzing longitudinal data. In this case, the hierarchical structure is viewed as measurement occasions nested within individuals. Extensions of the multilevel regression model are models for data that are not fully nested, such as cross-classified data, and models in which group membership may not be fully known. The nonlinear regression model discussed in the previous section has been extended to models for ordered or unordered categorical response variables and models for the analysis of counts. Finally, multilevel factor analysis and multilevel structural equation models are becoming available.

Software and Internet Resources

Multilevel analysis modules have appeared in most of the large statistical packages, such as SPSS, SAS, Stata, and SPLUS. Although these modules are quite powerful, specialized software for multilevel tends to have more analysis options and more coverage of the model extensions previously mentioned. The best-known specialized multilevel software are HLM and MlwiN. Don Hedeker provides a set of freeware programs for multilevel regression modeling. A 2001 review of some of these packages was given by De Leeuw and Kreft. The multilevel models project in London maintains a large homepage on multilevel modeling, with emphasis on their own product

MlwiN, but also including much general information. Their website also provides links to other multilevel websites, including one to Don Hedeker's freeware packages. There is also an ongoing review of all software that is able to analyze multilevel data. Finally, there is an active Internet multilevel discussion group.

Music Cognition

Barbara Tillmann

Université Claude Bernard Lyon 1, CNRS-UMR 5020, Lyon, France

Glossary

cognition Processes linked to perception, learning, memory, attention, and the role of the perceiver's (implicit and explicit) knowledge of these processes.

melodic contour Patterns of ups and downs defined by the tones of a melody with changes in pitch heights.

pitch height, pitch class The pitch height is determined by the fundamental frequency of a tone (e.g., the A tone at 440 Hz). A pitch class is defined by a set of pitches at different pitch heights that are separated by octaves (i.e., an interval defined by multiples of the fundamental frequency of a tone); for example, the A tones at 220, 440, and 880 Hz all belong to the pitch class of A.

tonal acculturation Listeners' familiarization with a musical tonal system resulting from exposure to musical pieces obeying the rules and regularities of the system.

tonal stability A concept linked to the musical function of a tone (or a chord) and its perceptual implication: the more stable a tone is, the stronger the induced feeling of tension implying that the melody should not stop at this point.

Music cognition refers to the cognitive activities involved in the perception, memory, performance, and learning of music. It is one example from the more general domain of auditory cognition. Listeners acquire knowledge about the musical system through mere exposure to musical pieces in everyday life. Research on music cognition aims to understand the nature of listeners' musical knowledge, its acquisition, and the influence of this knowledge on encoding, organizing, remembering, and performing musical patterns.

Introduction

Music is a temporal art combining in a highly structured way events that differ in duration, pitch height, timbre,

and dynamics. In order to understand the relations between sounds, listeners have to process the individual events, memorize them, and link them to the preceding events. Listeners who are familiarized with the music of their culture do not perceive a disorganized superposition of sounds, but hear coherent melodic lines and develop expectations and anticipate possible endings of musical pieces. Research in music cognition analyzes how listeners succeed in these processes, and it aims to specify listeners' knowledge about a given musical system and its acquisition, structure, and use in perception and performance.

Interdisciplinary Research on Music

Music cognition represents a growing research domain, bringing together behavioral, neurophysiological, theoretical, and computational perspectives, all adapting an information-processing approach to understand musical knowledge and processing. This article focuses on the cognitive side of music processing and summarizes research that provides evidence for listeners' knowledge of the tonal system and for influence of the tonal system on processing. Other approaches to studies of music perception underline the importance of sensory information, notably psychoacoustical models. Research on music cognition is interdisciplinary and combines music theory with cognitive science (cognitive psychology and neuroscience, neuropsychology, computational modeling, and linguistics). Musicologists describe the different structures and organizational levels in the musical stimulus, and cognitive scientists, beyond this description, are interested in determining which aspects of the structure are relevant for cognition, what is the knowledge acquired by listeners (i.e., acculturation), and how detailed the structural discrimination can be in the perception of this complex, nonverbal material.

Tonal Acculturation

Tonal acculturation is one example of the cognitive capacity to become sensitive to regularities in the environment. Implicit learning processes enable the acquisition of highly complex information, without complete verbalizable knowledge of what has been learned. Music and language are examples of highly structured systems that are learned in an incidental manner: native speakers and nonmusician listeners internalize the regularities underlying linguistic and musical structures with apparent ease merely as a result of exposure. Just by listening to musical pieces in everyday life, listeners become sensitive to regularities of the musical system (e.g., strong regularities on the pitch dimension). Listeners acquire implicit knowledge of the structural patterns used in the musical system, and this knowledge facilitates the processing of music conforming to these patterns. Even nonmusician listeners are “musically expert,” as has been shown in numerous behavioral and neurophysiological studies. Tonal acculturation shapes listeners’ expectations about the continuity of a musical piece. It allows listeners to detect “wrong” notes in a performance and to judge an unfamiliar musical phrase as incomplete when it stops in the middle. Most contemporary research has used Western tonal music, based on its classical foundations, mainly from the 18th and 19th centuries. Regularities between musical elements also exist in other musical systems (e.g., Indian or Arabic music), and cultural learning and familiarity with these systems lead to auditory experiences different from those of a native Western listener.

Music and Language

The comparison between music and language processing is not only interesting because of acculturation, but also because of parallels in cognitive processes and neural correlates. Music, just like speech, is composed of complex auditory information evolving over time. The auditory stream has to be segmented in smaller units (phrases or words) separated by boundaries between these units. Because of the temporality of the information, there are similar constraints on processing, notably memory limitations (i.e., holding information active in short-term memory). The structures in music and language have similar features; for example, both have periodic and repeating rhythmic patterns (longer and shorter durations), which form meter in both music and poetry. A further example is the conceptual similarity between musical contour and prosody in speech. Based on these structural parallels, the question arises as to what extent cognitive processes and underlying neural correlates for music and language are shared or distinct.

Perception and Memory

Four psychological qualities of sound are important in music: pitch (differentiating high and low sounds), duration, loudness, and timbre. Two of these qualities, pitch and time, serve as form-bearing dimensions in Western tonal music. Other dimensions, such as musical timbre or spatial localization, are helpful in perception. For example, more dissimilar timbres (i.e., instrumental sounds) allow different melodic lines in polyphonic music to be more easily separated. The characteristics of spatial position and timbre become particularly important dimensions in contemporary music, but research on these new musical systems is currently only starting.

Organization Based on the Pitch Dimension

The Western tonal system is based on 12 pitches repeated cyclically over octaves (C–C#–D–D#–E–F–F#–G–G#–A–A#–B–C–C#...). Two pitches separated by an octave are functionally equivalent and are perceived as very similar (i.e., voices of men and women singing are often separated by an octave). Strong regularities of co-occurrence and frequencies of occurrence exist among these 12 pitch classes; tones are combined into chords and into keys, forming a three-level organizational system (Fig. 1). Sets of seven tones form scales, which can be either major or minor, depending on the pattern of intervals (i.e., pitch distances) (e.g., C, D, E, F, G, A, B for a C-major scale). Based on the scale, groups of three tones define chords (e.g., C–E–G for a C-major chord). This set of tones and chords defines a tonality, or a key. Inside a key, tones and chords differ in their functional importance. The most referential event (for tones and chords) is the tonic, which gives its name to the key and occurs most frequently in a key context (e.g., it often defines the starting and ending point of simple tonal songs). Keys have more or less close harmonic relations to each other, with keys sharing more tones being more strongly related. A musical piece rarely remains in the same key, but changes key over time. The key changes (i.e., modulations) are often introduced by a pitch that is foreign to the currently instilled key and that primes the new key.

This short description of regularities on the pitch dimension shows that the variety of musical structures is based on a restricted set of events. Consequently, the same musical event fulfills different functions, depending on the key context. The tone C is the most referential tonic tone in a C-major context, but is less stable in a G-major context and out-of-key in an F#-major context (Fig. 2). When the key of the context changes, the functional hierarchies between tones and chords are changing. Understanding this context dependency is crucial for the

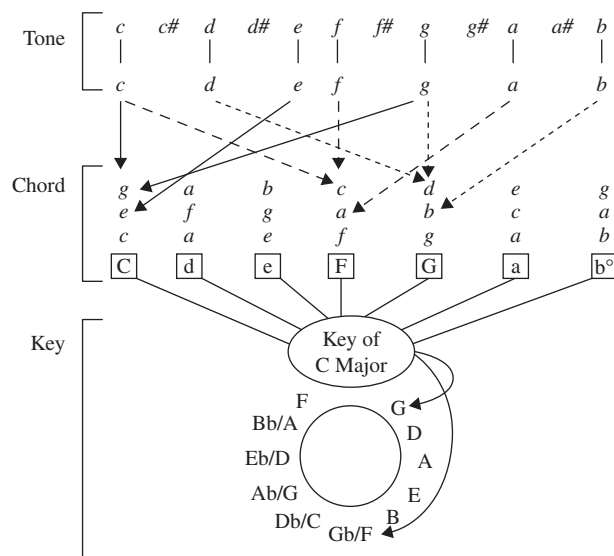

Figure 1 The three organizational levels of the Western tonal system (tones, chords, and keys) illustrated with the example of the C-major key. On the basis of the 12 chromatic tones, a selection of seven tones defines the diatonic scale, which then forms the basis for the construction of seven chords (i.e., associations of three tones, here illustrated with three major chords). At the key level, the C-major key has relationships with other keys, represented here with the “circle of fifths,” which shows the harmonic relationships between major keys. Closely related keys are represented next to each other on the circle (e.g., the C- and G-major keys are more closely related to each than are the C- and F#-major keys). (Adapted from Figure 1 is Tillmann *et al.* (2001), “Implicit Learning of Regularities in Western Tonal Music by Self-Organization” (pp. 175–184), *Proceedings of the Sixth Neural Computation and Psychology Workshop: Evolution, Learning, and Development* (R. M. French and J. P. Sougné, Eds) *Connectionist Modeling of Learning, Development and Evolution Perspectives in Neural Computing Series* © Springer, with permission.)

understanding of musical structures. Context dependency is a characteristic feature of the musical system, and based on listeners’ knowledge, the same physical event will be interpreted differently, depending on the tonal context. Acculturated listeners understand these musical structures and changes in an implicit and tacit way.

Tones

The perception of tones is related to absolute pitch, the ability to recognize a specific tone. This ability is quite rare even among musicians; a person with absolute pitch can rapidly identify, without attentional effort, pitches by their note names, even when the tones are presented in isolation. Different explanations of this phenomenon have been proposed, including an early-learning hypothesis postulating a critical period in the fifth or sixth year of life. However, the most important feature for the understanding of music is the perception of relative pitches and of the relative changes in the functional importance of tones, depending on the currently instilled key context. Numerous studies have shown that listeners are sensitive to the functional differences between tones (i.e., tonal hierarchies) and to the functional changes, depending on the key context. The tonal hierarchy described by music theory has a perceptual equivalence for the listeners. Less referential tones are perceived as unstable and instill a feeling of tension, whereas more referential, stable tones bring relaxation. Listeners judge sequences ending on unstable tones as incomplete. The unstable tones demand resolution to stable tones, which work like perceptual anchors or cognitive reference points. In addition to being functionally important, stable tones are also more stable in memory over time, leading to better recognition performance. When listeners are required to judge how well a tone fits into a preceding tonal context, ratings reflect the tonal hierarchy (e.g., with the tonic tone given the

Figure 2 Probe tone ratings for the 12 pitch classes in three key contexts (■, C major; ○, G major; and △, F# major). Tones receiving higher ratings (e.g., C and G in C major) are perceived as more stable and are situated at the top of the tonal hierarchy. The changes in the tone judgments are stronger between two distant keys (i.e., C and F# major) than between two closely related keys (i.e., C and G major). (Values from Table 2.1, *Cognitive Foundations of Musical Pitch*, by C. L. Krumhansl, © 1990 by Oxford University Press Inc. with permission.)

better fit) and the listeners' sensitivity to the functional changes due to the instilled key context (cf. Fig. 2).

Chords

In parallel to the perception of tones, a set of studies has provided evidence that listeners are also sensitive to the functional differences between chords, as described by harmonic hierarchies. Similar paradigms as used for tones have shown that stable chords induce a stronger feeling of completion, are remembered better, or are processed faster than are less stable or unstable chords. Even subtle differences in harmonic functions are perceived by musically untrained listeners.

Keys

Studies on tone and chord perception provide indirect evidence that listeners understand the changes of tonal functions, depending on the key context. They are sensitive to the tonal and harmonic hierarchies in the currently instilled key. This sensitivity to intrakey hierarchy changes is crucial for understanding modulations during a musical piece. When modulations occur, listeners deal with upcoming changes; the perception of tones and chords is reorganized with the new key and adapts to the new hierarchies. The magnitude of perceived changes reflects the harmonic distances between the keys, with small changes for modulations to harmonically closely related keys and larger changes for modulations to more distant keys. Key distances also affect memory for transposed melodies, with better discrimination between melodies separated by distant keys. The changes in keys and functions of events have been compared to travel through a "tonal pitch space," with longer trajectories for more distant key changes. Modulations and associated changes in tone and chord functions have expressive effects for the listener.

Temporal Organization

Besides pitch, temporal regularities (i.e., how events are organized over time) create a second form-bearing dimension in Western tonal music. Temporal regularities include the organization of event-onset intervals through time, leading to a sensation of meter, i.e., a sensation of a regular succession of strong and weak beats superimposed over an isochronous pulse. Temporal regularities include the temporal patterns of onset intervals, creating rhythms that are perceived against the metrical background. For example, when listening to a waltz, the three-beat meter underlying different rhythmical figures is extracted. The metric structure also contains a hierarchy; for example, the first beat in a waltz is more important than the other two beats. Listeners are sensitive to temporal regularities and develop expectations about the temporal occurrence of future events.

These expectations influence perception and make it possible to synchronize rhythmic productions with precision. Processing advantages for metrical sequences with a hierarchical structure in comparison to nonmetrical sequences have been observed in perception, production, and memory tasks. Additionally, the processing of rhythms with temporal ratios of 2:1 between elements is facilitated in comparison to rhythms with more complex ratios.

Perception of Pitch and Time

In a musical piece, tonal stabilities and temporal organizations (rhythm and meter) are combined in a structural organization. This structure integrates each event and can be described as a structural tree, which is referred to as an event hierarchy (Fig. 3). Currently, research based on behavioral data and on neuropsychological cases has not reached a consensus on the understanding of pitch and time processing: some data suggest that pitch and time dimensions are processed independently and others suggest that they are integrated. Despite this controversy, it has been shown that listeners are sensitive to the underlying organizational structure of musical phrases that are based on both tonal and temporal information.

Musical Structures and Global Organization

A strong characteristic of Western tonal music is its hierarchical nature. The encoding of musical information as a hierarchy of events is attractive for cognitive psychology, because hierarchical structures are economic

Figure 3 Illustration of tonal hierarchy and event hierarchy concepts. The top of the tonal hierarchy of C major is indicated under the musical score, with C being the tonic tone. Above the score, the event hierarchy of this melody is represented: the structural tree is opened and closed by the tonic tone. (Adapted from Figure 1.4, *Percevoir la Musique: une activité cognitive* by M. Pineau and B. Tillmann, © 2001, L'Harmattan, Paris, with permission.)

representations with numerous advantages for processing and storage in memory. In music perception, listeners discover the musical events successively within short temporal windows. The perceptual task consists in discovering the structure that underlies the incoming information and that evolves over time. Over short time periods, listeners are sensitive to the underlying musical structures, as shown in perception, memory, and segmentation tasks. For example, listeners indicate more group boundaries at structurally higher level arches of the structural tree (Fig. 3). They also differentiate between melodies that have similar surface characteristics (i.e., similar melodic lines and rhythmic patterns), but differ in the underlying structural trees. Based on tonal knowledge, the perceived hierarchies render melodies more than just a simple succession of tones. Most research has investigated the perception of structural organization with relatively short musical excerpts. It has not been entirely clear how far and in which form this perceptual capacity extends over longer time periods. Some studies have suggested that global organization has less perceptual impact than predicted by music theory and that listeners seem to base their perception mainly on local units of shorter time scale.

Musical Expectations

Expectations guide perceptual processing to important and relevant aspects of incoming patterns and facilitate the processing of expected events (vs. unexpected events). In music perception, it has been shown that processing is faster and more accurate for an expected event occurring at an expected time point (i.e., expected on the basis of musical relations and temporal regularities). Musical expectations can be based on a number of features, some of them reflecting the perceptual organization of the musical sequence (i.e., melodic contour, with its directions and interval sizes), others reflecting the influence of listeners' knowledge about the musical system or about particular musical exemplars. Schematic and episodic musical knowledge facilitates perception, attention, and memory. For example, memory performance is better for tonal than for atonal melodies, and better for tonally stable events than for unstable ones. When two melodies are played at the same time, knowing what melody to listen for enables listeners to focus attention on specific pitch heights and at specific time points, allowing them to pick out the notes necessary to recognize the melody. Tonal expectations based on listeners' schematic knowledge about the musical system have a role not only in the perception and mental organization of music, but are also important for aesthetic experience of music. Meaningful and expressive moments in music arise from the violation of schematic expectations. Listeners use cognitive schemata of prototypical structures to anticipate music (these anticipations are automatic and irrepressible).

Aiming to evoke emotions, composers and performers play with these schematic expectations by violating them or by fulfilling them later or differently. These sets of subtle surprises make music interesting, exciting, and emotionally involving. Expectations may thus serve as a concept linking music cognition and emotion. Research on music and emotion is an expanding field of study.

Contributions from Computational Models

Computational models based on music theory or on empirical data have been developed to simulate various aspects of music perception, memory, and performance. A subset of these models uses artificial neural networks (i.e., connectionist models). Neural networks provide modeling frameworks that allow understanding of (1) aspects of cognition as a result of neural pattern associations and (2) the acquisition of these representations through repeated exposure to the material. The networks extract statistical structures from musical material with the help of algorithms that are based on plausible and rather domain-general principles of neuroscience. The learned representations are analyzed and used to simulate human listeners' behavior. This approach has been applied to different aspects of music perception, ranging from basic processes (such as pitch height extraction, octave equivalence, or chord classification), to the learning of either schematic tonal knowledge or specific melodic sequences and even to more complex aspects of music learning and perception (such as categorization and memory of musical style). Computational models contribute to our understanding of music cognition—for example, how listeners build up musical knowledge that allows them to develop expectations, which shapes musical processing and subjective experience.

Developmental Perspectives on Musical Abilities

One of the methods used to investigate music perception skills of infants is the head-turn procedure. Musical stimuli are presented via laterally displaced loudspeakers, and the time it takes infants to look at the loudspeakers is interpreted as "listening time" (i.e., how long the sound captures the infants' attention). In some studies, infants are rewarded with a toy for the detection of changes in sound. Research has provided evidence for strong developmental progress, confirming that music-processing skills become more and more sophisticated with age. Infants do not respond progressively to tonal scale structures; the perception and understanding of tonal scale relationships emerge later. Infants are sensitive to

rhythmic groupings of sounds (i.e., perceiving similarity of rhythmic patterns despite tempo changes) and to pitch (i.e., being sensitive to octave equivalence, pitch discrimination, and melodic contour). Melodic contour is a salient feature for infants. For example, melodies with the same melodic contour are processed as the same even when the key is changed. Pitch contour and note duration are important determinants for infants' perception of structural phrases inside musical pieces. Later during childhood, the child's cognitive structure allows having a stable pitch sense while singing. Children at age 5 years are sensitive to stable tonal centers and make the distinction between near- and far-key transpositions. Around the age of 6 years, children distinguish tonal from atonal melodies, allowing them to have better pitch detection performance for tonal melodies than for atonal melodies. With age, the structure of tonal hierarchy becomes more differentiated and pitches are heard more and more in terms of tonal frames of reference: whereas 5-year-old children distinguish only between in-key and out-of-key tones, 7-year-old children additionally distinguish between tones belonging to the triad chord (e.g., CEG) and other in-key tones. Concerning the emotional content of musical excerpts, children are sensitive to the opposition of "happy/sad" at a young age. For example, 3-year-old children attribute smiling faces to positive excerpts in major mode in opposition to negatively connoted excerpts in minor mode. The preference for consonant music over music including dissonant intervals can be observed even for infants.

Musical Performance

Forms of musical abilities include performance of well-learned pieces from memory, sight reading, and improvisation. All of these abilities combine rapid motor skills and elaborated cognitive skills. Analysis of musical performance involves investigating a performer's mental representation of a musical piece, their plan for transforming this representation into sound, and their realization of the movements necessary for this transformation. Studying musical performance is interesting for developing theories on motor behavior and cognition and for understanding the relation between performance and perception. Musical sequences have to be planned and then executed under fine motor control; it is important to control which elements have to be played and the relative timing of these elements. For timing of movements, anticipation and coordination of gestures, and overall motor control, models of internal clocks ("timekeepers") have been proposed. The performer has to coordinate sequences of movements in advance of their execution. Generally, a planned sequence is segmented into smaller units such as phrases. With practice, these units become larger,

future events are more strongly anticipated and expressive features of the performance are enhanced. The performer's task is to highlight the structure of the musical piece and also its emotional content. The main expressive parameters that are modified in a performance are timing, loudness, and timbre. Slowing down in tempo at phrase boundaries helps to underline the structural organization of the musical excerpt. A further example taken from piano performances is the melody lead (i.e., onsets of melody precede onsets of other parallel voices by up to 50 msec), which helps to differentiate among simultaneously occurring voices in polyphonic music. Analyzing performance errors provides insight into underlying cognitive processes, such as memory limits (i.e., how far can performers plan ahead) or the influence of the performers' tonal knowledge (i.e., replaced tones are more likely to be in-key tones than out-of-key tones).

Neural Correlates of Music Cognition

The relation between cerebral structures and music perception has been investigated by neuropsychological case studies involving patients with damaged brain regions and by neurophysiological studies using electrophysiological methods and brain imaging. The two approaches provide converging evidence for a hierarchical organization in the brain reflecting stages in music processing: primary auditory areas process spectrotemporal features of the sound, higher order tonal and sequential patterns involve temporo-frontal networks, and the processing of more complex (or real) musical stimuli involve multimodal, widely distributed neuronal networks in both hemispheres.

Neuropsychological Cases

Neurological disorders related to music can take different forms, including musical hallucinations, musicogenic epilepsy (i.e., seizures triggered by music), synesthesia (i.e., hallucinated colors triggered by music), and cases of amusia. Amusia, the most well-studied disorder, represents a disorder of music processing and recognition abilities that can concern specific parameters (i.e., pitch, rhythm, timbre, and emotion) and can be either receptive or expressive, or both. Neurological deficits can be selective to music, with some patients showing amusia without aphasia, or selective to language (i.e., aphasia without amusia). This double dissociation has been taken as an argument that music and language are processed by separate, independent brain structures. Further insight in understanding neural correlates of music processing

has been based on patients with right and left temporal damage by comparing their respective performance of tasks varying along different features (i.e., timbre, pitch, rhythm, or memory). For example, in tonal working-memory tasks, performance is decreased in patients with right temporal and frontal lesions. The role of right temporal cortex as well as right frontal cortex in pitch memory has been confirmed by brain imaging studies.

Neurophysiological Approaches

In parallel to the left hemisphere asymmetry observed for language processing, a right hemisphere asymmetry has been suggested for music processing. Recent research allows further qualifying this approach and, more generally, has described bilateral activation networks implied in music processing (i.e., becoming more extended, the more complex the musical materials and tasks are). One of the proposed hypotheses concerns the importance of the auditory cortex in low-level perceptual processing, with the right auditory cortex allowing for fine-grained pitch processing (i.e., pitch height, pitch directions) and the left auditory cortex being involved in the processing of rapid temporal changes. Besides temporal regions, frontal regions (i.e., inferior frontal cortex, dorsolateral frontal areas) become involved in the processing of pitch patterns (e.g., melodies) and for tasks with working-memory aspects (e.g., comparing tones or melodies). For more complex tasks or materials, the parietal cortex also becomes activated, creating a network with frontal, temporal, and parietal components that is similar to neural circuits underlying multiple forms of working memory or attention-demanding activities. Musical imagery occurs when music is internally replayed by imagining it. This musical imagery results in activating auditory regions and other cortical regions involved in the perception of externally presented musical stimuli. This outcome replicates in audition previously observed brain activation patterns for visual imagery. Neurophysiological markers have been detected when listeners are exposed to musical sequences containing deviant musical events that violate expectations. Some of these markers (i.e., the evoked potential P600, a positivity starting 600 msec after the violation onset) have also been observed for language processing: the amplitude of the marker increases with increased difficulty of syntactic integration. In contrast to perception and performance of music, much less is known about cortical networks for emotional processing of music. Preliminary results suggest that there are wide networks, including limbic and sensory areas, with some overlapping networks involved in general emotional

processing. Finally, music represents an opportunity to investigate brain plasticity, notably the influence of musical training on brain structures. Extensive practice with an instrument leads to neuroplastic changes in motor cortex. Recent studies have also started to investigate the extent to which increased exposure to particular sounds leads to sensory changes in the auditory cortex.

National Crime Victimization Surveys

Janet L. Lauritsen

University of Missouri, St. Louis, St. Louis, Missouri, USA

Shannan Catalano

Bureau of Justice Statistics, Washington D.C., USA

Glossary

bounding A method for reducing the duplicate reporting of victimizations across repeated interviews. Information from past interviews are used as a reference point or bounding period. If during subsequent interviews a respondent reports a similar victimization experience, the interviewer is able to ascertain whether the current event has been previously reported.

household-based survey A survey in which households are sampled and interviews are conducted with all eligible persons within each household.

nonsampling error The extent to which an estimate of victimization may not represent the true victimization because of errors other than those associated with probability sampling. Examples include question wording, interviewer or coding mistakes, respondent willingness to report crime events, or memory and recall error.

panel rotation A method of implementing the victimization survey to increase efficiency and reliability. The full sample of households consists of six groups, and each group or panel is interviewed once every six months. Interviews are administered to each panel at the beginning of every month. Because interviews are administered continuously on a monthly basis, a panel of newly sampled households is rotated into the full sample each month as an old panel is rotated out of the full sample.

PSU Primary sampling units (PSU) are composed of large metropolitan areas or counties and groups of counties across the United States. PSUs are chosen during the first stage of the sampling process to ensure that selected households are representative of the nation as a whole.

sampling error The extent to which a sample estimate of victimization may not represent the true victimization rate because of error associated with the process of probability sampling.

self-response method A data collection technique in which survey respondents are asked to disclose information regarding their personal victimization experiences.

time in sample bias The error associated with the length of participation in a study. Research has shown that lower victimization rates are associated with increased length of participation (i.e., number of prior interviews).

victimization rate The number of crimes committed against a household or person divided by the total number of households or persons. Household victimization includes crimes of burglary, motor vehicle theft, and other thefts from the household, while personal victimization includes nonlethal violence against persons (i.e., assault, robbery, and rape and sexual assault) and thefts from persons (i.e., purse-snatching and pocket-picking).

“The National Crime Victimization Surveys” describes the methodological features of the nation’s only nationally representative, on-going survey designed to measure the extent, nature, and consequences of crime in the United States.

Introduction

Origin and Purpose of the National Crime Victimization Surveys

The National Crime Victimization Survey (NCVS) and its precursor, the National Crime Survey (NCS) began in 1972 as a result of recommendations from the President’s Commission on Law Enforcement and the Administration

of Justice. The 1967 Commission Report highlighted the importance of having information on crime and its consequences that was independent of police recording practices and available on an on-going basis so that changes in crime rates could be reliably estimated. Prior to the NCS, Uniform Crime Reports (UCR) were the only national source of data on crime and victimization. The NCS was developed to complement the information available in police records by including crimes not reported or recorded by the police. To help inform public policy, greater detail about criminal victimization also was desired, hence the survey contains a wide range of information about crime including weapon use, victim–offender relationships, the extent of injury and property loss, and the reasons for reporting or not reporting crime to the police.

History of the Survey

The Law Enforcement and Administration Association (LEAA) and the Census Bureau developed the methodology for the NCS based on an extensive research program. This research was informed by the Census Bureau's expertise in sampling and survey methodology, a series of reverse record-check studies to test questionnaires and procedures among known crime victims, and supplements to the Quarterly Housing Survey to test procedures among random samples of the population. In July 1972, the National Crime Survey began, consisting of three components: the National Crime Panel, the Commercial Victimization Survey, and an additional 26-city victimization survey. Of these three components, the nationally representative household survey (the NCP) continued and became known as the NCS.

Significant changes to the NCS occurred following an evaluation of the survey by the National Academy of Sciences. The NAS report recommended a series of modifications including better use of screening questions to encourage greater reporting to interviewers as well as additional items to improve understanding of crime and its consequences. The NAS report also advocated a program of on-going methodological research and more timely and user-friendly data and product dissemination.

The evaluations and implementation of these recommendations were performed by a consortium of experts in social science, survey methodology, and statistics and were managed by the Bureau of Social Science Research. Following lengthy review, the consortium proposed that survey modifications be implemented in two phases. In 1986, the first of these changes (known as “near-term” changes) were implemented. Alterations that were unlikely to affect overall crime rates were included at this time so that the continuity of ongoing annual reports could be preserved. The second phase of changes (known as “long-term” changes) were phased

into the survey beginning in 1992. This phase-in of the new questionnaire was developed so that changes associated with instrumentation could be assessed independently from temporal changes in crime.

These long-term changes included a more thorough screening section to better stimulate victim recall of events, improved screening to reduce the effects of subjective interpretations of events, and more detailed questions regarding the characteristics and consequences of victimization. Research suggested that victims were less likely to recall victimization incidents or view events as criminal when either the victim knew the offender or when victimization occurred on a regular basis. To better capture events of this type, the redesigned survey incorporated additional prompts to improve the measurement of nonstranger crimes, rape and sexual assault, and domestic violence. In addition, vandalism victimization was added to the survey.

The redesigned interview procedures resulted in significantly higher victimization rates for simple and aggravated assault, rape, household burglary, and theft, but produced no significant changes for robbery, personal theft, or motor vehicle theft. Increased reporting also was somewhat larger for nonstranger crimes, attempted crimes, and crimes not reported to the police. The redesigned interview increased crime reporting for all socio-demographic groups, although the increases were somewhat greater for whites and other racial groups than for blacks, for higher-income households than for lower-income groups, and for middle-aged persons than for younger or older respondents. The National Crime Survey was officially renamed the National Crime Victimization Survey to indicate changes in the interview.

Article Overview

A complete review of the methodological characteristics of the NCVS and the measurement of crime is beyond the scope of this paper. The remainder of this article describes the most important features of the NCVS, including the sample and rotation design, method of administration and interview form, questionnaire content and special supplements, sources of error, and research uses. Emphasis is placed on the characteristics of the current survey.

Sample and Interview Administration

The NCVS is a household-based survey. A random sample of households is generated through a multistage stratified sampling procedure designed to produce a representative sample of all households and individuals 12 years of age and older in the United States. Households are used as

the unit of analysis in estimations of household crime (e.g., burglary), and persons are used as the unit of analysis in estimations of personal crimes (e.g., assault). The Census Bureau conducts the sampling procedure and administers the survey for the Bureau of Justice Statistics.

Drawing the Sample

The sample is generated in two stages. During the first stage, primary sampling units (PSUs) are designated to reflect metropolitan areas, counties, and groups of counties. Larger PSUs (reflecting metropolitan areas) are termed self-representing (SR) and are automatically included in the sample. Smaller PSUs (non-self-representing or NSR PSUs) are grouped together in similar strata based on known Census geographic and demographic characteristics. From the NSR PSUs, sample PSUs are selected by probability proportionate to population size.

In the second stage of sampling, the SR PSUs and selected NSR PSUs are divided into sampling frames known as unit, area, permit, and group quarters. Clustered subsamples of approximately four housing units are then selected from each frame. The selection of household addresses differs for each frame, but is derived from Census information for each PSU. Addresses for unit and group quarter frames are generated from the most recent census and sample blocks are used to generate address listings for the area frame. Building permit data are used to generate addresses within the permit frame, ensuring that new housing units not included in the prior census are captured in the sample. This sampling procedure is designed to produce reliable national estimates of criminal victimization and not state or local estimates.

The importance of using a household-based sampling procedure becomes apparent when compared to other sampling procedures such as random digit dialing (RDD). Research has shown that up to 20% of poor households are without telephone service and that poverty rates are correlated with crime rates. By using a household-based sampling strategy, the NCVS is less likely to produce biased victimization rates. In addition, the Census Bureau is renowned for producing very high survey participation rates. The household and person participation rates for the NCVS consistently range from 90% to 95%, while RDD surveys and surveys conducted by other organizations tend to produce substantially lower rates.

Reliable estimates of criminal victimization on an annual basis require very large samples. The NCS sample originally included approximately 60,000 households. However, budget constraints have forced declines in sample size. In 2001, the NCVS sample included about 44,000 households. This decline has implications for statistical estimation, especially for the most rare forms

of victimization such as rape. For such crime types, standard errors are larger and thus it is more difficult to detect significant annual changes or subgroup differences.

Interview Procedure

The NCVS uses the self-response method. This means that respondents are asked to disclose information about their victimization experiences. The probability-based sample makes it possible to produce estimates for the population of persons ages 12 and older in the United States. The sample excludes crimes against children younger than age 12, persons without a permanent residence, crew members of merchant vessels, armed forces personnel living in military barracks, institutionalized persons, and businesses or organizations.

Following selection for the sample and notification by mail from the Census Bureau, the NCVS interviewer contacts the household, obtains consent to participate, and conducts the first set of interviews in person. Households selected for the sample are retained for three years, and each person (age 12 and older) in the household is interviewed once every six months about their victimization experiences during the preceding six months. The NAS evaluation suggested a combination of in-person interviews coupled with telephone interviews to balance efficiency, cost and rapport. During early years of the survey, the first, third, fifth, and seventh interview were conducted in person. Currently, only the first interview is conducted in person and the second through seventh interviews are administered by telephone. Exceptions are made if the respondent insists on in-person interviews. The use of Computer-Assisted Telephone Interviewing (CATI) from centralized facilities has increased over time as well.

The NCVS measures experiences with crime in two ways, either as a household or person victimization. One member of the household is surveyed regarding crimes against the household, and all members (age 12 and older) are surveyed regarding personal victimization. The questionnaire uses two components, an initial screening tool administered to all respondents and an incident form designed to collect information and details regarding any events mentioned during the screening portion of the survey. Once household victimization screening is recorded from the head-of-household designate, respondents are screened and interviewed about personal victimization experiences.

Panel Rotation

The NCVS uses a rotating panel design to increase the efficiency of the interviewing process. Sample households are divided into six rotation groups. Each rotation group is interviewed a total of seven times with interviews taking

place at the beginning of each month for households in that month's panel. Within each rotation group there are six panels, thus allowing for one-sixth of the rotation group to be interviewed each month. For instance, households in the first panel are interviewed in January and July, those in the second panel are interviewed in February and August, etc. This framework ensures that the sample is balanced, thus minimizing problems in estimating year-to-year changes by reducing "time in sample bias." This procedure also helps to ensure that victimization estimates are not confounded with seasonal differences in crime found to exist in many areas of the country. Once a household panel has completed seven interviews, a new household panel is selected and rotated into the sample to replace the exiting panel. An exception occurs when respondents move out of the household. In this instance, the new residents become part of the sample and complete the remaining number of interviews assigned to the household.

Bounding

An important feature of the NCVS is that bounding is used to limit recall error. Extensive research on survey methodology has shown that respondents often misplace the occurrence of events in time. To reduce this type of error, data from previous household and person interviews are used to "bound" subsequent reports of victimization. For example, if a respondent reports a robbery in the first interview and again in the second interview, the interviewer verifies that these are indeed two separate events. Because unbounded interviews produce estimates of crime that are significantly higher than bounded interviews, the first household interview is excluded from victimization estimates. Bounding however, is tied to the household rotation. Therefore, first-time interviews with new residents in an ongoing household rotation are not bounded and are included in victimization estimates.

Survey Content

Types of Crime Covered

NCVS crime coverage includes both violent and property crimes associated with households and individual victims. Household property crimes include attempted and completed burglary, motor vehicle theft, and household theft (e.g., theft from the yard). Personal crimes (or crimes against individuals) include attempted and completed violent crimes of rape, sexual assault, robbery, aggravated and simple assault, and personal thefts (such as purse snatching). Homicide is excluded due to the victim-based nature of the survey. Arson is excluded as well.

Crimes against children under age 12 are not measured because the Census Bureau has determined that the instrument is not valid for younger respondents. The NCVS is able to measure crime more broadly than the UCR because incidents not reported to police are included.

The determination of whether an event is a crime and if so, the type of crime, is not made during the interview. Rather, the characteristics of each reported event are detailed during the interview. Final classification of the crime type occurs during data processing and is based on information provided in the incident report. This is done to minimize definitional variations and to ensure that the use of legal terms such as burglary or robbery matches definitions used by the police and the UCR. Additionally, events are classified according to the most serious aspect of the victimization. For example, if a respondent reports that they were hit (assaulted) and had something taken from them by the use of force (robbed) during the same event, a "hierarchy rule" is applied and the event is classified as a robbery. Specific victimization definitions can be found in Bureau of Justice Statistics (BJS) victimization reports.

Household and Person Characteristics

Characteristics of the household are obtained from the interviewer and from the designated household respondent. Prior to beginning the interview, the interviewer fills out a "control card" that contains demographic information on the household and its members. This information is subsequently transcribed onto the questionnaires. The interviewer records information relevant to the conditions of the interview such as type of living quarters, telephone availability, use of proxy respondents (e.g., for those with difficulty communicating), presence of others during the interview, and reasons for any noninterviews with household members. Information on the control card regarding household characteristics obtained from the household respondent include number of persons in the household, changes in composition since the last interview, income, length of residence, number of times moved in the past five years and presence of a home business. Person characteristics for members of the household include age, sex, race, Hispanic origin, marital status, educational attainment, armed forces membership, employment status and type of job, and relationship to head-of-household.

Incident Characteristics

Details about each incident are gathered after the respondent completes the personal screening questions. For each incident, respondents are asked to provide detail on the time and location of the event and whether the incident was reported to the police by the respondent or

some other person. Reasons for reporting or not reporting to police are obtained, as are police actions for events reported. For incidents involving face-to-face contact between the victim and the offender (e.g., most violent crimes), the respondent is asked whether anyone else was present during the incident, the number of offenders involved, actions taken by the offender during the incident, the presence of weapons, the level of injury, whether medical care was received, whether time was lost from work, actions by the victim during the incident and the perceived result of those actions. The respondent also provides the sex, race, and approximate age of the offender, whether the offender appeared to be under the influence of drugs or alcohol, and the victim's relationship to the offender. For property crime incidents (which typically do not involve face-to-face contact), the respondent reports the type and value of property stolen or damaged, whether property was recovered or repaired, and who, if anyone paid for the costs of repair or replacement.

Series Incidents

For some victims, experience with crime is extensive. If the victim is able to describe each incident in sufficient detail, incident characteristics are gathered for each event. However, in cases where the victim reports six or more similar events *and* is unable to distinguish these events, incident data are gathered only for the most recent event. In these cases, the experience is defined as a "series" victimization. Although incident information for the most recent event is gathered, series victimizations are excluded from annual rate estimates because their impact on crime rates is sensitive to counting rule assumptions.

Recent Content Additions

Because of the strength of the NCVS sampling strategy, the survey provides a platform for assessing changing concerns about crime and justice. Various social and political initiatives have resulted in occasional survey supplements as well as additional questions about criminal victimization. Supplements are additional sets of questions that are asked of respondents following completion of the main survey. Recent supplements have addressed school crime experiences among 12- to 18-year-olds, and the nature of public contact with the police outside of crime reporting (e.g., traffic stop information) to persons age 16 and over. Federal crime initiatives have prompted the addition of questions about possible hate crime victimization, personal computer crime victimization, and victimization among the physically and developmentally disabled.

Sources of Error

All sample surveys contain two sources of error—that associated with sampling and that due to other methodological features of the survey, such as nonparticipation, question wording, and the recall tasks that the respondent must accomplish. The former is known as sampling error, while the latter is known as nonsampling error.

Sampling Error

The amount of error associated with random sampling is a function of sample size and the relative rarity of the event under investigation. The amount of this error is estimable and is known as the standard error. In published reports, confidence intervals are included with victimization estimates so that readers can know, for example, whether changes across time or differences across subgroups are statistically significant. The parameters necessary for calculating standard errors can be found in BJS reports.

Nonsampling Error

The error associated with the tasks of the survey is difficult to measure with great precision, but it can be minimized with careful research on the properties of the survey. As noted earlier, the NCS and NCVS items have undergone extensive research to minimize respondent errors, as well as interviewer and data processing errors. When new items or supplements are developed for the survey, they undergo a series of evaluations before they are introduced in the field. These evaluations include cognitive testing and pretesting with specially selected samples and random samples.

Research Uses

Information obtained from the interviews have been used in numerous ways, the most common of which are annual reports on victimization by BJS statisticians that are often cited in the popular press. These reports facilitate and inform public policy debate on a variety of issues such as violence against women, injury and financial costs associated with crime, school crime, and race and contact with the police. The data also have been cited in support of legislation and in various court cases. BJS reports are available at their website (www.ojp.usdoj.gov/bjs). The most commonly produced reports feature estimates of various crime types and the different victimization experiences of selected groups (such as women, teenagers, the elderly). BJS also uses NCVS data to produce reports on special topics such as intimate partner violence, reporting crime to the police, violence at schools, and the costs of crime.

Academic researchers typically use the data to study how victimization risk and reporting to police vary across subgroups and crime types, and how broader changes in society are related to changes in crime. Crime estimates from the NCVS also have been compared to police estimates of crime to understand how police recording practices have changed over time. In addition, the data have been used to study how the outcomes of events (such as the escalation of violence, injury) are related to victim, offender, or third party actions. Public use versions of the NCVS data may be accessed through the National Archive of Criminal Justice Data (NACJD) (www.icpsr.umich.edu/NACJD/index). A link to the NACJD is also accessible through the BJS homepage under the “Dataset and Codebooks” option. As the only source of nationally representative data on victimization, the NCVS data provide an ongoing wealth of information that may be used to inform public policy about crime and its consequences.

National Education Longitudinal Survey of 1988 (NELS:88)

Laurie A. Drapela

Washington State University, Vancouver, Washington, USA

Glossary

base-year ineligible students Students who were excluded from the NELS:88 base-year study participation due to a language barrier or a mental or physical disability.

base-year ineligible study A study of the base-year ineligible students at the first and second follow-ups of NELS:88 (1990 and 1992).

ceiling effect The effect produced when variation on the NELS:88 cognitive tests is artificially constrained among high-ability examinees due to an insufficient number of difficult questions.

cross-sectional survey A survey design in which data are collected at a single point in time from a cross section of respondents representing a larger population.

Data Analysis System (DAS) A Windows software application providing public access to NCES survey data. Users can generate tables of percentages, means, standard errors, and correlation coefficients for survey items in NELS:88.

design effect (DEFF) A measure of sample efficiency; a design effect is the variance of an estimate divided by the variance of the estimate that would have occurred if a sample of the same size had been selected using simple random sampling.

electronic codebook (ECB) A graphical user interface (GUI) tool listing all the variables, weights, and flags for each unit of analysis at each wave of the data for the particular study period.

flags Dichotomous indicators that isolate respondents based on the questionnaire they completed and/or their participation in a particular wave or waves of NELS:88.

floor effect The effect produced when variation on the NELS:88 cognitive tests is artificially constrained among low-ability examinees, due to an abundance of questions that exceed their abilities.

longitudinal panel sample Survey designs in which the same data are collected from the same respondents across multiple time periods.

National Center for Education Statistics (NCES) The federal sponsoring agency for the longitudinal high school studies, including NELS:88.

sample freshening A sampling technique designed to increase the representativeness of NELS:88 by adding out-of-sequence students to the data file.

survey package Software packages, such as SUDAAN, STATA, and HLM, that take into account complex sampling designs when calculating standard errors for parameter estimates.

waves Points in time at which data were collected for the study; also called follow-ups. Currently, NELS:88 contains five waves of data; a base-year sample (1988) and four follow-up periods (1990, 1992, 1994, and 2000).

weights Factors representing the sampling design that parameter estimates are multiplied by. Typically, sampling weights are used to adjust parameter estimates for the oversampling of certain demographic groups and to adjust items for nonresponse. In NELS:88, Asians, Latinos, and private schools are oversampled.

The National Center for Education Statistics (NCES) is mandated by Congress to conduct longitudinal research on educational outcomes in the United States. The National Education Longitudinal Survey of 1988 (NELS:88, or NELS) is one of three panel studies of students conducted by the NCES to fulfill this mandate. To that end, NELS:88 is designed to measure the determinants of education-related outcomes such as academic achievement, successful transition to secondary and postsecondary institutions, participation in the workforce, and dropping out of high school. The survey also collects data on other types of outcomes for adolescents and young adults. For example, NELS:88 has been used to study the predictors of

adolescent deviance (e.g., truancy and teen pregnancy) and delinquency (e.g., fighting, drug use, being arrested, and being detained in a juvenile facility). NELS:88 collects data from students, parents, teachers, and school administrators at several points in time to model these outcomes. This entry describes the structure and analytic populations available in NELS:88 and describes how it has been used to study key constructs in social science research.

Structure of the National Education Longitudinal Survey of 1988

Units of Analysis and Waves of the Data

The National Education Longitudinal Survey of 1988 (NELS:88, or NELS) contains data for four units of analysis: students, parents, teachers, and school administrators (schools). The baseline cohort consisted of 24,599 eighth-graders attending mainstream public and private schools in the United States during 1988. (Bureau of Indian Affairs schools were excluded from the study.) To date, four follow-ups have occurred: 1990, 1992, 1994, and 2000. This set of five waves is typically referred to by NELS:88 users as the base year (BY) and first through fourth follow-ups (F1–F4).

All data collected for teachers, parents, and schools are linked to the students via the students' identification numbers. This enables researchers to model the effects of home, classroom, and/or school environments on the types of student outcomes. These types of analyses typically involve the first three waves of the data (collected in 1988, 1990, and 1992) because most students in the study were attending junior high and high school during this time period. Factors affecting post-secondary school outcomes such as college/university attendance, labor force participation, and marital status typically involve the third and fourth follow-ups of NELS:88 (collected in 1994 and 2000).

The structure of NELS:88 permits both longitudinal and cross-sectional analyses. In terms of its longitudinal capabilities, NELS:88 contains four follow-ups of an initial baseline cohort of 24,599 eighth-graders. These data provide a rich opportunity to model both scholastic and nonscholastic changes among adolescents and young adults over a 12-year period (1988–2000). NELS:88 can also be used to conduct cross-sectional analyses at each wave of the data. In 1990 and 1992, respondents were added to the data file to enhance grade-specific cross-sectional analyses, a process called sample freshening. It increases the representativeness of cross-sectional analyses by adding students to the data file who did not have a chance to be selected into prior rounds of the study. In 1990, the NCES added respondents to NELS:88 who

were in the tenth grade in 1990 but not in the eighth grade in the United States in 1988. Similarly, in 1992, the NCES added respondents who were in the twelfth grade but did not attend tenth grade in the United States in 1990 and did not attend eighth grade in the United States in 1988. The addition of freshened students to the first and second follow-ups also permits grade-specific trend comparisons between NELS:88 respondents and the two other NCES longitudinal high school studies: the National Longitudinal High School Class of 1972 (NLS-72) and High School and Beyond (HS&B).

Articulating Analytic Populations for Study in the National Education Longitudinal Survey of 1988: Samples, Scope of Analyses, Flags, and Weights

NELS:88 contains multiple waves of data for multiple units of analysis measured at five points in time (see [Table 1](#) for a list). Moreover, the time intervals between waves of the data vary from 2 to 6 years, complicating the measurement of longitudinal processes. This section provides a brief description of the types of concepts measured at each wave of the data for each unit of analysis and defines the term analytic population. It further describes the use of questionnaire flags for selecting study participants as well as the use of sampling weights and survey packages to calculate valid parameter estimates.

At the base year, first, and second follow-ups (1988, 1990, and 1992), students were surveyed about their school experiences (e.g., school climate between students and teachers), school activities (extracurricular activities), attitudes concerning pro-conformity and pro-delinquent activities, educational expectations, career aspirations, their family lives, locus-of-control (self-esteem), and language proficiency. There was particular attention devoted to the effect of speaking English as a second language on both the base-year and second follow-up student surveys.

Parent surveys are only available for the base year (1988) and second follow-up (1992) of NELS:88. These questionnaires ask one parent to provide information about his or her relationship to the child, his or her educational expectations for the child, his or her occupation and educational background, the educational tools available in the home for the child, his or her involvement with the school and the child's education (e.g., tutoring), and the family's financial preparation for college.

Teacher surveys are available for the first three waves of the data. Generally speaking, the teacher surveys measure student variables (e.g., whether they have met with the parents of the NELS:88 student in their classes, the quality of the student's work, and the ability grouping of

the student); classroom variables (e.g., the amount of control they have over selecting texts and structuring the curriculum and the topics taught in their subject area); and the teachers' characteristics (e.g., instructor demographics, training, and credentials). No more than two of the students' teachers completed questionnaires for the base year and first follow-up; only one teacher completed a questionnaire at the second follow-up.

Finally, school administrator surveys are also available at the first three waves of data collection. These surveys contain information about the school characteristics, school services for students (e.g., from computer laboratories to birth control classes), school policies on parental notification for student infractions, faculty qualifications, and graduation requirements.

The analytic populations in NELS:88 are those study populations created by using sample weights and questionnaire flags. Generally speaking, weighting is used to compensate for unequal probabilities of selection into the sample and/or to adjust parameter estimates for non-response to survey items. NELS:88 weights are designed to correct for both types of bias. Moreover, the type of weight used determines the scope of an analysis (whether it is cross-sectional or longitudinal). Questionnaire flags isolate those respondents who completed a particular survey (e.g., student, parent, teacher, school administrator, or dropout) at a particular round (or rounds) of the study.

For example, if a researcher wanted to estimate the effects of student reports of school climate on their participation in school-based extracurricular activities (e.g., science club, cheerleading, and sports), such a question could be evaluated with longitudinal and cross-sectional analyses. A cross-sectional investigation of this question at the base year (1988) would require both the use of

a questionnaire flag and a questionnaire weight to select the cases for inclusion into the study. In this case, the eighth-grade cross-sectional questionnaire flag would select the appropriate number of cases for the analysis (e.g., BYQFLG (1) = 24,599). This flag, when used in combination with its respective questionnaire weight (BYQWT > 0), produces the appropriate parameter estimates for the analytic populations under study—a nationally representative sample of 1988 eighth graders in the United States.

If we want to investigate the longitudinal effect of tenth-grade assessments of school climate on twelfth-grade participation in school-based extracurricular activities, the first and second follow-ups can be used to conduct the analysis. In this case, the panel flag for the 1990 tenth-graders in 1992 (F2F1PNFL = 2) should be selected to ensure that all 16,749 respondents who completed both questionnaires at both follow-ups are included in the study. The panel weight (F2F1PNWT) should be used to ensure representative analyses for the analytic population—the panel sample of 1990 tenth-graders in 1992. (A table of study populations, flags, and weights can be found in the 1994 study by Ingels, Dowd, Stipe, Baldridge, Bartot, Frankel, and Quinn.)

The mechanical dimensions of using flags and weights to isolate appropriate populations of interest are discussed at length in the NELS:88 user's manuals. However, they take on an additional significance among researchers who use NELS:88 to measure social scientific processes. With four units of analysis over five waves of data, the number of cases selected from NELS:88 for study varies widely, depending on the research question. The number of respondents isolated by the sample flags serves as a benchmark, communicating to other researchers

that the appropriate flags and weights are being used to conduct the analysis. If the number of respondents in a researcher's working data file differs from that articulated in the user's manual, researchers are encouraged to explain the relationship between their study's N and the sample N generated by NELS:88 sample flags.

Muller's 1995 study of base-year maternal labor force participation on first follow-up student mathematics achievement serves an example. After a brief discussion of the NELS:88 study objectives and sampling strategy, the first follow-up panel sample is articulated as the appropriate sample for the study. According to the data documentation, 17,424 students participated in the first follow-up panel sample. Muller articulates additional criteria for selection into her study, noting that students are included in the analyses only if their mothers' employment status was available and the student's natural mother is present in the home. She restricts her analyses to only those respondents who have panel data, and she further notes that "Native Americans were also excluded, making a sample size of 13,381 from the panel sample of 17,424."

NELS:88 users also should take its multistage cluster sampling design into account when generating parameter estimates. Statistical packages assuming simple random sampling can generate biased parameter estimates when used with NELS:88 or other data collected with complex sampling designs. Variances and standard errors of parameter estimates tend to be smaller under simple random sampling than complex sampling designs; thus, researchers are at increased risk of committing a Type I error when interpreting NELS:88 results with software assuming a simple random sample.

If a statistical package must be used, design effects should be employed to ensure the accurate calculation of sample variances. The NCES computed design effects for a subset of variables in the base year and first through third follow-ups of NELS:88. Analysts may calculate design effects for the remaining variables using the Data Analysis System (DAS). The fourth follow-up of NELS:88 (2000) is the only wave of the data for which the NCES calculated design effects for every variable in the analysis.

Users of statistical packages may employ the design effects and weights to calculate a new case weight that better accommodates complex sampling designs. The new weight is a product of the inverse of the design effect and the rescaled case weight: $NEWWGT = (1/DEFF) * [F2QWT_i / (\sum F2QWT_i / N)]$. This procedure approximates the effect of the sample design, but is not precisely comparable to estimates obtained with survey packages. Nonetheless, it is a more accurate method of using statistical packages with cluster or other less-efficient sampling designs than assuming the data were collected with a simple random sample.

Survey packages such as SUDAAN, STATA, and HLM account for complex sampling designs when calculating

sample variances and standard errors. Although these types of packages may be more expensive to obtain and challenging to learn, the researcher gains greater accuracy of parameter estimates, increased validity of study results, and greater flexibility in the selection of variables for analysis.

What Can the National Education Longitudinal Survey of 1988 Measure? A Brief Discussion of Research on Content Areas in the Survey

Because of its broad scope, multiple units of analysis, and multiple waves of data, NELS:88 is ideal for researching scholastic and nonscholastic outcomes among adolescents and young adults. A comprehensive literature review of all studies using NELS:88 is beyond the scope of this entry; this section provides a brief description of some of the more popular content areas in the data set. It also provides examples of studies measuring such concepts.

Academic Achievement

In light of its congressional mandate to track educational progress among American primary and secondary school students, assessing academic achievement is a critical function of NELS:88. Cognitive tests were developed by the Educational Testing Service (ETS) and covered four subject areas: reading comprehension, mathematics, science, and social studies (history, citizenship, and geography). Cognitive tests were administered at the first three waves of data (1988, 1990, and 1992). These multiple measures of achievement allow researchers to measure gains (or losses) in academic achievement among a cohort of students as they made the transition from junior high school to high school.

The ETS designed one form for each of the four base-year cognitive test areas and six forms per subject area for the 1990 and 1992 testing rounds. The difficulty level of the math and reading tests varied on each of the six follow-up test forms. Respondents' scores from the prior wave of testing determined the difficulty level of the reading and math tests at later waves of the study. Thus, if a base-year student scored in the top 10% of students on the 1988 mathematics achievement test, the level of difficulty on his or her 1990 math test would be higher than for a student who had performed at the mean level on the 1988 test. This approach is a more valid measure of the students' cognitive gains over time than a single test per subject at a fixed level of difficulty. Variation in cognitive tests can be constrained if this level of difficulty is too simple for high-ability respondents (i.e., shows a ceiling

effect) and/or too challenging for low-ability students (i.e., shows a floor effect).

Students' performances in math and science courses tend to sort them into precollege and noncollege tracks. For this reason, many NELS:88 studies focus on both micro- and macro-level processes that affect mathematics and science achievement. For example, the 1995 micro-level analysis by Muller explored the effect of maternal employment and parental involvement on students' gains in tenth-grade mathematics achievement. Parental involvement is measured using items from both the parent survey (e.g., checking homework, restricting television on weekdays, and parental participation in a parent-teacher organization) and the student surveys (e.g., self-reports of discussions about school activities and subjects, planning of high school program, discussion of college plans, and the amount of time left unsupervised after school). Muller found that although certain types of parental involvement increase math test scores between the eighth and tenth grades (e.g., restricting television and parent-teacher organization participation), students whose mothers were not employed showed significantly fewer gains in mathematics achievement than students whose mothers worked full-time (after unsupervised time after school was controlled).

Other researchers have examined the effects of macro-level processes on mathematics achievement. For example, Ainsworth examined in 2002 the effects of neighborhood-level factors affecting mathematics and science achievement. NELS:88 is ideal for this purpose because a supplemental file allows researchers to match students' zip codes to their census tract identifiers. (Note: Users must obtain a restricted user license in order to link the NELS:88 data to the census tract information.) The neighborhood characteristics under study were the proportion of high-status residents, residential stability, levels of economic deprivation, and levels of racial/ethnic heterogeneity. The proportion of high-status residents is the only one of the four neighborhood-level variables affecting math and reading achievement scores. This positive effect is strongly mediated by the amount of time the student spends on homework and the student's educational expectations.

Social Capital

Social capital is a construct frequently used by sociologists to conceptualize "benefits accruing to individuals or families by virtue of their ties with others." Generally speaking, social capital is conceptualized as the level of obligations, expectations, and trustworthiness of social structures. Put another way, the more interconnected individuals are through social ties at the family, church, and community levels, the greater the level of social capital these individuals possess. The closed nature of the

network facilitates both economic and personal interactions among the individuals involved. This is due to the level of trust engendered among the members of a social network, as well as the knowledge that transgressions against any one member of the group has ramifications across critical domains of social life.

NELS:88 can measure several dimensions of social capital because it contains information about the students, their home(s), their school(s), and their neighborhood(s). (Recall from the prior section that respondents' addresses can be linked to their census tracts, allowing for measurements of neighborhood factors such as poverty and the prevalence of female-headed households.) One example is Suet-ling Pong's 1998 analysis of the effect of social capital on the relationship between family structure and academic achievement. The author uses NELS:88 to test the hypothesis that social capital, operationalized as students' reports of their parents' school involvement and social relations with other parents, can mitigate the deleterious effect of high proportions of single-parent families on school academic achievement measures (e.g., tenth-grade math and reading test scores).

These measures of social capital were available on the student surveys, not on the school administrator surveys (school surveys). In order to obtain school-level measures of these indicators of social capital, Pong aggregated them by school and then used them, along with the school administrators' estimates of the proportion of students from single-parent families, to test the mediating and conditioning effects of social capital on family structure and tenth-grade gains in achievement test scores.

She found that school-based social capital (in addition to the school's economic status) mediates the negative effect of moderate proportions of single-parent families on school academic achievement scores. The level of parental acquaintances also conditions the effect of proportions of single-parent families on school achievement test scores. Schools that were one standard deviation below the mean level of parental relations showed a negative effect of high proportions of single-parent families on reading and mathematics achievement. Schools that were one standard deviation above the mean showed that students attending schools with a predominance of students from single-parent families performed as well as or better on achievement tests than schools with a low proportion of students from single-parent homes.

Youth—Early Adult Transitions

The fourth follow-up (2000) is the most recent round of NELS:88. Approximately 12,000 cases of the original 24,599 eighth-grade cohort were retained in this wave of the study; thus, it is a 12-year panel study measuring transitions common to people in early

adulthood—namely, college attendance, career development, and family formation.

Because this follow-up of the study was released in August 2002, analysts have just begun to mine its longitudinal capabilities. However, an initial report produced by the NCES assessed the effects of eighth-grade curriculum choices on postsecondary educational attainment and labor market experiences (Ingels *et al.* 2002). Factors such as high eighth-grade mathematics achievement scores, algebra, private schooling, and participation in extracurricular activities increased the likelihood of both enrolling in and completing university degrees 12 years later. Levels of postsecondary educational attainment were positively associated with job satisfaction, professional/managerial occupation, and median income levels.

The report also evaluated the relationship between eighth-grade risk factors for dropping out of high school and life-course transitions such as labor force participation, marriage, and parenthood. Eighth-grade risk factors for dropping out of high school were measured as living in a single-parent household, having neither parent complete high school, having an older sibling drop out, being home alone after school for more than 3 hours per day, having low English proficiency, and being in a low-income family (less than \$15,000 total family income per year). Cohort members who had no dropout risk factors were more likely to be childless 12 years later (at age 26) than cohort members with one or more risk factors. Eighth-graders at risk for dropping out who eventually did so were more likely to be working in low-skill jobs (e.g., as laborers or mechanics), be single parents, and receive public assistance 12 years later than their counterparts who graduated from high school.

In their 1998 study, Horn, Chen, and Clifford assessed the effects of student, parent, and peer factors on the odds of 1994 college enrollment. Their study was focused on a subgroup of NELS:88 students identified during the eighth grade as being at risk for dropping out of high school. These students were at risk for dropping out if they exhibited two or more of the following: being in a family in the lowest socioeconomic quartile, living in a single-parent home, earning Cs or lower between the sixth and eighth grades, being held back a grade in school, changing schools two or more times outside of grade-appropriate transitions, and having an older sibling who dropped out. They found that students with peers who had college plans and students with parents who frequently discussed school-related matters with them had greater odds of enrolling in postsecondary education than did students without these factors. Participation in college preparation activities (e.g., financial aid and help with entrance exams) and college outreach programs also increased the odds of a student's enrolling in a university degree program.

High School Dropouts

In NELS:88, dropouts are defined two ways: (1) students who had not been in school for 4 or more consecutive weeks and who had not been absent due to accident or illness and (2) students who had been in school for less than 2 weeks after a period in which he or she had missed school for 4 or more consecutive weeks not due to accident or illness. Dropout status was double-confirmed by both the school and household reports. Dropping out of high school is typically measured along three dimensions: the proportion of students who leave school each year without completing a high school program (event rates); all of the young adults in a specified age range who have dropped out of high school (status rates); and the experiences of students who drop out of high school at various points in time (cohort rates). NELS:88 is one of the NCES data sets used to perform cohort-based analyses of high school dropouts.

Generally speaking, NCES analyses of event and status rates for high school dropout in the United States have found that high school dropout rates are highest among low-income groups, people of color (particularly Latinos and African Americans), and older adolescents (e.g., over two-thirds of event dropouts in 1998 were between the ages of 15 and 18 years old). The proportion of people dropping out of high school has fluctuated between approximately 5 and 6% since 1987.

NELS:88 permits cohort analyses of high school dropouts from the eighth to tenth grades and from the tenth to twelfth grades. Many of these studies focus on factors that significantly affect the likelihood of dropping out of high school. For example, in their 2001 analysis of tenth- to twelfth-grade dropouts, Croninger and Lee found that greater amounts of teacher-centered social capital (operationalized as students' perceptions of teacher-based support of their education and teachers' reports of both school and personal guidance given to students) significantly decreases the probability of a student's leaving high school between the tenth and twelfth grades. This was particularly the case for students with high levels of academic risk (poor school performance) and high levels of social risk (e.g., minority status or single-parent household). High levels of teacher-centered social capital reduced the probability of dropping out of high school by one-half for these students.

Finally, because NELS:88 began data collection with eighth graders, it was able to capture people who dropped out of school before the tenth grade (a population not included in the HS&B data set). One NELS:88 analysis of this group found that although both school and family problems affected dropping out of middle school, students attending lower SES middle schools with fair discipline policies and in non-Catholic religious schools had lower odds of dropout than students in the full sample of schools.

Adolescent Delinquency and Deviance

NELS:88 contains several measures of adolescent delinquency and deviance, most of which are concentrated in the first and second follow-ups (1990 and 1992). Base-year measures of law-violating behavior are restricted to one indicator asking the respondent about smoking behavior; the third follow-up (1994) asked the respondents only if they or one of their friends has been arrested in the past year.

First and second follow-up delinquency measures primarily focus on drug use among students and dropouts and school-based misbehavior. For example, students are asked to self-report their use of tobacco, alcohol, marijuana, and cocaine over their lifetime, the previous year, and the previous 30 days. The second follow-up also asks these two groups of adolescents the frequency with which they were under the influence of alcohol, marijuana, or cocaine at while they were at school. There are also measures of fighting, teen pregnancy, cutting classes, being suspended, being transferred for disciplinary reasons, and being arrested. Most of these measures can be found among both student and dropout questionnaires at the 1990 and 1992 waves of NELS:88.

As mentioned earlier, NELS:88 permits contextual analyses of social phenomena because respondents' addresses were linked to their census tract via their zip code. In this case, researchers are able to explore neighborhood-level characteristics affecting delinquency in addition to individual, family, and school characteristics. This is of particular relevance to sociological theories of crime and delinquency, which place a strong emphasis on the role of community characteristics in the etiology of criminal behavior. One example of such a study is John Hoffmann's 2002 contextual analysis of three leading theories of crime and delinquency. This study assesses the effect of delinquent peers, negative emotions (or strain), and social bonds on fighting, school suspension, and being arrested among a sample of 1990 NELS:88 tenth-graders. The study also examines the effects of these variables independently of four tract-level characteristics of each respondent's residence: the level of racial segregation, the percentage of female-headed families, the percentage of jobless males, and the percentage of residents in poverty. Generally speaking, the mediating and conditioning effects of strain and social control theories are strongest for a subset of adolescents living in urban areas (approximately 20% of the study's original sample).

In his 2002 analysis of the contextual effects of family structure on drug use, Hoffmann again uses the NELS:88 data linked to the respondent's census tract. The purpose was to assess whether community-level factors affect the relationship between family structure and juvenile drug use. Drug use is operationalized as a composite measure of the following items: alcohol, marijuana, or cocaine use; having five or more drinks in a row; and attending school

while under the influence of the three drugs listed. The only neighborhood-level characteristic significantly affecting drug use was the percentage of unemployed men living in the neighborhood. Adolescents living in neighborhoods with high percentages of male joblessness are at increased risk for drug use, irrespective of their family structure.

The preceding sections merely scratch the surface concerning the breadth of topic areas available in NELS:88. Although it is essential to briefly describe the relevance of NELS:88 to research topics in the fields of education and the sociology of education, a brief introduction to other research areas pertinent to the lives of youth illustrates the possibilities of the data set.

Cautions When Using the National Education Longitudinal Survey of 1988

As can be surmised from the discussion thus far, NELS:88 is a very complex database that permits a diverse array of analyses. Novice users are *strongly* encouraged to read the data file user's manuals as well as any technical reports that pertain to waves of data used in their analyses. The *Quick Guide to Using the NELS:88/200 Data* is a brief introduction that is a must-read for researchers with little to no experience with this data set. This section describes a few features of NELS:88 of which the novice or casual user should be aware.

Subsampling of Cases at the 1990, 1994, and 2000 Waves of the National Education Longitudinal Survey of 1988

Between 1988 and 1990, many eighth-grade students who participated in the base-year study attended high schools with very few or no other base-year study participants. Following up every base-year student proved to be cost-prohibitive. Consequently, the NCES chose to subsample those students participating in the 1990 longitudinal panel study. The subsampling procedure assigned the probability of being included in the first follow-ups to be proportionate to the number of base-year students attending the first follow-up school. Thus, students attending 1990 high schools with 10 or fewer base-year respondents were less likely than students attending high schools with more than 10 base-year participants to be included in the 1990 longitudinal panel sample. These selection criteria resulted in approximately 6000 base-year participants being sampled out of the second wave of the study. Major subsampling also took place at the third (1994) and fourth (2000) follow-ups of NELS:88 (although

respondents were randomly selected to be dropped from the analysis at these waves). Users are strongly encouraged to weight their analyses in NELS:88 to adjust for the effects of nonresponse attributed to subsampling. Consult the data file user's manual for the respective wave and respondent type to obtain more information about using specific weights to adjust for item nonresponse.

Abbreviated Questionnaires and Intersurvey Analyses

The NCES used an abbreviated questionnaire to collect data from some respondents at the first follow-up. This shorter version of the questionnaire was disproportionately distributed to dropouts, with approximately 25% of them completing this version of the instrument. Items not included on this abbreviated questionnaire have a nonresponse rate that exceeds acceptable standards by the NCES. A questionnaire weight (F1DPAJW) was created to adjust for the high nonresponse rate among these items. However, because it was created specifically for dropouts, it cannot be used in analyses combining both student and dropout questionnaire data. Users wishing to combine the adjusted first follow-up dropout weight with other first follow-up weights should consult the NCES for technical assistance.

Users are strongly encouraged to obtain hard copies of survey questionnaires for each type of respondent in their analyses (e.g., student, dropout, and teacher). Although survey questions may be identical across questionnaire types, the differential use of filter questions may produce high rates of item nonresponse between respondent types. For example, at the second follow-up (1992), both students and dropouts are asked the same questions about the quality of their relationships with their parents. However, a filter question precedes this section of the dropout questionnaire, permitting only those dropouts who are currently living with their parents to complete this section of the survey. Many dropouts were not living with their parents; as a result, the nonresponse rate for these indicators is substantially higher among dropouts than students. Thus, combining these indicators between the dropout and student data files could potentially bias results.

Accessing National Education Longitudinal Survey of 1988 Data, Data Documentation, and Information about the Data Set

Two types of NELS:88 data are available on CD-ROM from the NCES: public-use data files and restricted-use

data files. In public-use data sets, any information that could potentially identify a respondent has been either encrypted or deleted from the data file. Restricted-use data files do not encrypt this information; thus, the NCES only loan the data set to qualified people who complete a thorough application process. Analysts wishing to obtain a restricted-use NELS:88 data file should refer to the NCES application procedures Web site (<http://www.nces.ed.gov/surveys/nels88>).

Each CD-ROM contains data files, the electronic codebook (ECB), and several sets of user's manuals. The ECB is a graphical user interface (GUI) tool listing all the variables, weights, and flags for each unit of analysis at each wave of the data for the particular study period (e.g., 88/92, 88/94, and 88/00). It displays the survey question, frequencies, and percentages of these variables, as well as any other notes or pertinent information about them. The ECB allows users to tag variables of interest for export into SAS, SPSS, or codebook text. This is a very handy feature of NELS:88, allowing the user to create programming code as well as a hardcopy codebook for the variables in an analysis.

In past years, obtaining hard copies of the actual survey instruments used in NELS:88 required contacting the NCES (whose supply could run short, due to demand) or borrowing copies from a colleague. This was also the case for other NELS:88 documentation, from users' manuals to specialty reports. These critical documents were frequently hard to locate and data documentation on the data CD-ROM was often incomplete. Put another way, obtaining the actual NELS:88 data was easy, but obtaining information about using the data was not.

During the past year, the NCES has created digital copies of all surveys used in all waves of NELS:88 and placed it on their Web site. Moreover, most of the data file users' manuals are also available (the first follow-up is the exception), as are many of the technical reports, working papers, and statistical analysis reports. This is a major improvement in accessibility concerning NELS:88. Seasoned users of NELS:88 will happily abandon their quest(s) for various copies of the "big green books" in favor of the Adobe Acrobat files easily downloaded from the Web site.

New users to NELS:88 should take full advantage of two documents available on the Web site. Both are available under the quick guide and example links. The quick guide walks the user through the structure of the database, provides examples of research questions appropriate for NELS:88, gives technical advice on creating working data files, and has a frequently asked questions section. The example link provides step-by-step instructions on how to select variables from the electronic code book, export them to statistical and survey software programs, and use them for basic quantitative analyses.

Network Analysis

Peter V. Marsden

Harvard University, Cambridge, Massachusetts, USA

Glossary

blockmodel A summary of the subgroup structure in a network, consisting of an assignment of social units to positions and images of the relationships among those positions.

centrality The prominence or importance of a given unit within a network as reflected in its relationships to other units.

clique A subgroup of mutually related units.

cohesion The strength of the relationship between units; a criterion for assigning units to subgroups.

egocentric network The partial network surrounding a given unit.

mutuality Reciprocity within a relationship from one unit to another.

one-mode design A design focusing on relationships among social units of a single type, for example, friendships among children in a school classroom.

relational property A property of a unit defined by information on its relationships to other units in a collective or group.

structural equivalence A condition in which two units have identical relationships to and from all other units within a collective or group; a criterion for assigning units to subgroups.

structural property A property of a collective or group defined by information on relationships among the units it includes.

transitivity The presence of a relationship from one unit to another when both are related to a third unit, implying closure or clustering within a network.

two-mode design A design focusing on the relationships between social units of two distinct types, for example, the memberships of directors in corporate boards.

whole-network study The study of relationships among units within a bounded social collective or group.

Network analysis identifies regularities in relationships among social units, thereby measuring both relational properties of individual units and structural properties of collectives. Major subjects of network analysis include

connectedness, centrality, range, and social differentiation. Mathematical, graphical, and statistical techniques are used to study network data.

Introduction

Network studies measure features of social structure by identifying regularities and patterns in relationships among social units. The properties of interest lie at several distinct levels. They include relational properties of individual social units, such as status, social integration, social support, and social capital, as well as structural properties of entire groups or collectives, including vertical and horizontal differentiation, centralization, and social density.

The social units that compose networks are often individuals, but networks are also made up of other units including families, organizations, or countries, among others. Both formally constituted groups (such as workplaces or schools) and informally defined ones (such as scientific communities or policy domains) can be studied using network analysis. Network studies examine diverse relationships among units including interdependence, communication, membership, solidarity, and affect. Network theories assert that social ties serve as channels for the diffusion of cultural ideas and practices, infectious diseases, and information and as pathways offering access to information, opportunity, and resources. Locations in networks can be sources of power and signals of a unit's social standing. Network analyses are found throughout the social sciences, especially in anthropology, epidemiology, management and organization studies, and sociology.

This entry first covers major network study designs. It then introduces graph-theoretic representations of network data and visual representations. Next, it summarizes network approaches to the measurement of

centrality/prominence, network range, and social differentiation. Most of these techniques describe features of the particular networks under study. The entry then introduces some developing statistical approaches to network analysis that seek to draw inferences that extend beyond the available data.

Social Network Data and Research Designs

Beginning in the 1930s, studies of the sociometric measurement of interpersonal affect introduced quantitative methods and tools that were important precursors to network analysis. Ethnographic fieldwork by social anthropologists in the 1950s and 1960s offered a set of concepts, ideas, and methods that informs the study of social networks. Work of both kinds continues, but most contemporary studies use quantitative data. The typical network study uses a nonexperimental design. Common approaches to data collection are surveys, questionnaires, and direct observation. Archival sources also offer rich information on the relationships among certain social units. Designs for network studies are distinguished by whether they assemble data on whole or partial networks and by the number of types (modes) of social units studied.

Whole-network studies examine interrelated units that are analyzed as a bounded social collective; the analytical boundaries of the collective may be based on formal membership criteria, density of interactions, or involvement in a set of events or activities. The most common one-mode whole-network design collects data on relationships linking a set of N social units of a single type. Examples are friendships among students in a school and alliances

among businesses in an industry sector. One-mode network data can be represented as a square matrix $\mathbf{X} = \{x_{ij}\}$, where the element x_{ij} represents the strength of the relationship from unit i to unit j ; relationships x_{ii} from units to themselves are usually undefined. A data matrix for a binary relationship in a 10-unit network appears in Fig. 1A. A 1 indicates that there is a tie from the row unit to the column unit, and a 0 indicates that there is no such tie. One-mode designs can be extended by observing a relationship at multiple time points, by measuring two or more relationships (e.g., antagonisms as well as friendships) linking the social units, or by obtaining measurements on a single relationship from multiple observers or sources. Each extension leads to a three-way data matrix $\mathbf{X} = \{x_{ijk}\}$, where the subscript k indexes time points, types of relationship, or observers/sources.

In a two-mode whole-network design, basic relationships link two distinct types of units. Data are recorded in a rectangular matrix $\mathbf{Y} = \{y_{ij}\}$, where the element y_{ij} refers to the relationship between the i th unit of the first type and the j th unit of the second type. Studies of interlocking boards of directors exemplify the two-mode design: individuals and corporations are the two types of units, and data elements indicate whether person i is a director of corporation j .

Egocentric network studies collect data on partial networks consisting of a focal social unit i and the other units and relationships clustered in its locality. The social support network surrounding a given person is one example. Egocentric networks are often delimited by including other units that lie within the focal unit's first-order zone, those units directly linked with the focal unit. Unit i 's egocentric network, then, consists of those others bearing some criterion relationship to i , and the relationships among them. In Fig. 1B, the egocentric

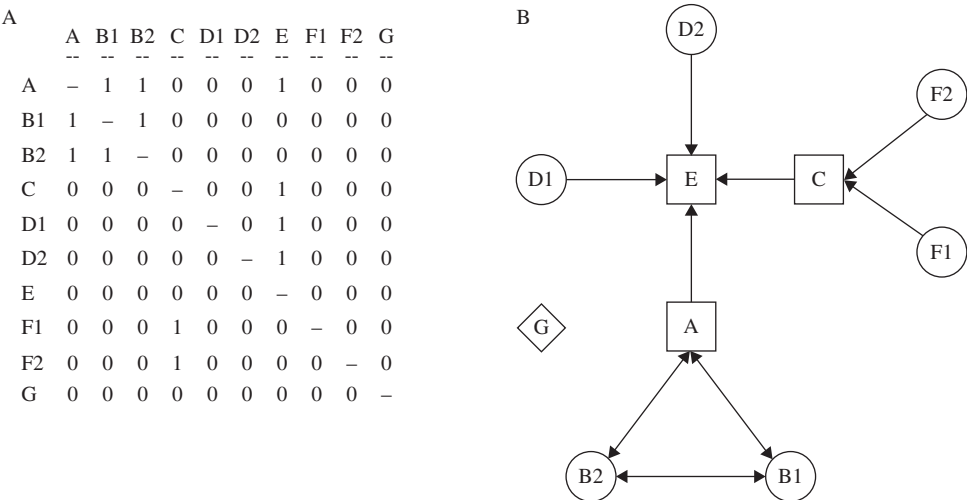

Figure 1 (A) Data matrix and (B) directed graph for a 10-unit, one-mode network.

network for unit A consists of A, B1, B2, and E. Egocentric network data measure relational properties of the social context in which the focal unit is situated. They generally are not well suited to measuring structural properties of collectives.

Most network studies purport to obtain data on a theoretical population of units. Research on network sampling examines the inferences about whole networks that can be drawn using different sampling designs. Node-induced samples observe data on relationships among a sample of social units drawn from a network. Egocentric data are often gathered for a sample of units from a larger population, a design known as sampling of stars.

Graph Theory and Connectedness

Directed graphs (or digraphs) are isomorphic to social networks, providing a fruitful representation for network data. Graph-theoretic concepts provide foundations for many social network measures.

A digraph consists of a set of nodes (corresponding to the units in a network) and a set of (possibly valued) lines linking pairs of nodes. Network analysis makes most use of binary digraphs in which relationships are either present ($x_{ij} = 1$) or absent ($x_{ij} = 0$). The set of such binary relationships $\mathbf{X} = \{x_{ij}\}$ is known as the adjacency matrix of the graph. The matrix in Fig. 1A is an adjacency matrix; the corresponding digraph is shown in Fig. 1B. In the digraph, an arrow denotes the direction of a relationship. There is a one-directional (asymmetric) relationship from unit A to unit E in Fig. 1B, but a mutual relationship linking units B1 and B2. If the relationship under study is not directed, it is represented as a graph rather than a digraph; then $x_{ij} = x_{ji}$ for all pairs of units i and j .

Statistics for the adjacency matrix define elementary structural properties. Probably the most commonly used structural index is network density, the matrix mean:

$$\frac{1}{N(N-1)} \sum_{i=1}^N \sum_{\substack{j=1 \\ (j \neq i)}}^N x_{ij}$$

For binary data, density gives the number of relationships observed as a proportion of those possible. Sparse, loosely knit networks have low density; closely knit networks have high density. A similar local density index can be defined for the egocentric network surrounding each node; this contrasts interlocking (high-density) and radial (low-density) egocentric networks.

Graph theory defines various forms of connectedness between nodes in a network, of which the most important is indirect connectedness via a path. A path consists of a sequence of distinct nodes, each of which is related

to the next. In Fig. 1B, path (B2, B1, A, E) leads from node B2 to node E via intermediary nodes B1 and A. The length of a path is the number of direct relationships included in it; path (B2, B1, A, E) has length 3. If a path exists from one node to another, the second node is reachable from the first. Node E is reachable from B2 in Fig. 1B, but B2 is not reachable from E. A geodesic path is a minimum-length path from one node to another. Path (B2, B1, A, E) is not a geodesic because B2 can also reach E via the length-2 path (B2, A, E). The geodesic (or path) distance d_{ij} from one node to another is the length of the geodesic path between them. The geodesic distance need not be symmetric (i.e., d_{ij} need not equal d_{ji}) and is infinite if one node cannot reach a second.

Two-mode network data can be represented in a bipartite graph including two distinct sets of nodes. All direct relationships in a bipartite graph link nodes in different sets; nodes in one set may be indirectly related to one another via paths involving nodes in the other set. For example, two corporations have an indirect tie of length 2 if their boards include one or more directors in common.

Visualization

Visual images such as the digraph shown in Fig. 1B have long been used to represent and study network data. Such plots capture many intuitions about networks. They depict social distance by placing closely related units near one another while separating weakly related ones. Likewise, they readily identify central and peripheral units.

Network graphics may be enhanced by using symbols of differing shapes or sizes to designate types of units. For example, the different shapes in Fig. 1B could denote differences in rank or social origin. Distinct types of relationships may be illustrated with varying line legends. Solid lines may indicate friendships while dotted lines identify antagonisms, for instance. Variations in the strength of ties can be represented using different line widths. Continuing developments in computer graphics offer many more enhancements, including the use of color and animation.

First termed sociograms, network graphics were long constructed in an *ad hoc* manner dependent on the judgment of the analyst. The emphasis was on presentational clarity, placing units so that few lines crossed one another. More recently, multidimensional scaling and spring embedders have been used to establish locations for units within plots in a standardized fashion and to develop three-dimensional plots. Correspondence analysis and singular value decomposition have proved similarly useful in constructing visual representations of two-mode network data.

Centrality and Centralization

Centrality measures are among the most widely used indices based on network data. They generally reflect a unit's prominence; in different substantive settings, this may be its structural power, status, prestige, or visibility. Studies often use network-based centrality measures in efforts to account for interunit differences in behavior or attitudes.

Distinct centrality measures are sensitive to different aspects of a focal unit's ties to other units. Several important graph-theoretic measures were first defined for binary symmetric graphs. They have since been generalized to include valued and directed ties, but the illustrations in this section assume binary symmetric measurements. A unit's degree centrality $C_D(i)$ reflects its number of relationships:

$$C_D(i) = \sum_{\substack{j=1 \\ (i \neq j)}}^N x_{ij}$$

Separate in- and out-degree measures are suitable for nonsymmetric data. In Fig. 1B, for example, unit E has an in-degree centrality 4, but an out-degree centrality 0.

Other common graph-theoretic measures of centrality are based on indirect connectedness measured using geodesic paths. A widely used measure $C_B(i)$ reflects unit i 's "betweenness:"

$$C_B(i) = \sum_{\substack{j=1 \\ (j \neq i)}}^N \sum_{\substack{k=1 \\ (k \neq i)}}^{j-1} \frac{g_{jk}(i)}{g_{jk}}$$

where g_{jk} is the number of geodesic paths linking units j and k , and $g_{jk}(i)$ is the number of those geodesics on which unit i occupies an intermediary location. Unit C lies between F1 and E in Fig. 1B, for example. Betweenness centrality can reflect a unit's capacity to broker or control social relations involving other units.

A closeness measure conceives of a unit as central to the extent that it is related to other units via short geodesics:

$$C_C(i) = \frac{N-1}{\sum_{j=1}^N d_{ij}}$$

Closeness centrality $C_C(i)$ is defined only for sets of units that are mutually related via finite geodesic distances. Units linked to others via short geodesics have comparatively little need for intermediary (broker) units and thus possess relative independence in managing their relationships.

Another useful centrality index defines a unit's power or prominence p_i on the basis of the strength of its relationships to other powerful or prominent units:

$$p_i = \sum_{j=1}^N p_j r_{ji}$$

where r_{ji} is a normalized measure of the strength of the relationship from unit j to unit i . This index weights ties to powerful units more heavily than those to less powerful ones. The vector of scores $\mathbf{p} = \{p_i\}$ is an eigenvector of the normalized matrix of relationships $\mathbf{R} = \{r_{ij}\}$, so \mathbf{p} is known as an eigenvector measure of centrality.

The foregoing indices of centrality are relational measures defined for individual social units. Corresponding to each one is a structural measure of centralization defined at the level of the group or collective. Centralization is high if relationships are concentrated on a single unit and low if they are distributed evenly across units. A normalized group-level measure of centralization based on degree centrality is:

$$C_D = \sum_{i=1}^N \frac{C_D(\max) - C_D(i)}{(N-1)(N-2)}$$

where $C_D(\max)$ is the maximum degree centrality of any unit within the network under study. Similar centralization measures exist for other unit-level centrality measures.

Range and Composition

Social networks are key constituents of most concepts of social capital. Social actors can gain competitive advantages by making use of resources, information, and opportunities available through their social ties. Such social capital both substitutes for and augments individual capacities or human capital. Social support flowing through networks can improve individual well-being directly and also buffer the impact of stressors on well-being.

The principal network indicators of social capital are indices that measure the range and composition of egocentric networks. Range measures reflect the variety of units with which a focal unit is in direct or indirect contact. The ego units at the center of large, sparse networks are positioned to obtain and synthesize nonredundant information that resides in diverse sectors of a group and thus to be first-movers and early innovators. By virtue of their position as intermediaries bridging structural holes that separate otherwise disconnected alters, such ego units accrue opportunities to profit by exercising entrepreneurial control. In some settings, closely knit, dense egocentric networks also have advantages—they can convey stable social identities and establish well-defined performance expectations.

Basic measures of network range include egocentric network size (degree centrality $C_D(i)$), local density (an inverse indicator of range), and heterogeneity indexes reflecting the level of sociodemographic diversity among those alters tied to a given ego. More refined indicators take simultaneous account of these factors.

Effective network size, for instance, is lower than $C_D(i)$ to the extent that the alter units in unit i 's egocentric network are linked to one another and therefore redundant. A unit's structural autonomy is high to the extent that it has many alternative relationships with other units, whereas its transaction partners have comparatively few.

Most network range indicators capture features of the configuration of relationships surrounding a given unit, positing that these features promote access to information and resources. Network composition indicators measure the accessibility of social resources more directly. The status composition of a focal unit's egocentric network, for example, might be measured by the average status of the other units included in it, often weighted by the strength of their relationships to the focal unit.

Social Differentiation: Network Subgroups

Network approaches to studying social differentiation rest on the postulate that social relationships reflect salient social distinctions. Patterns of relationships, then, point to subgroups and statuses within a group or collectivity. Analyses of differentiation seek to assign units to subgroups and develop models of intersubgroup relationships. Two major principles for assigning units to subgroups are extensively used. One defines subgroups as sets of cohesive, densely interconnected units. The other defines them as sets of units occupying common social positions by virtue of their substitutable equivalent profiles of relationships to other units.

Cohesive Subgroups

Cohesive subgroups consist of strongly interconnected units. Such sets of units are thought to be solidary, having a high capacity for collective action. If units in such a subgroup are also isolated from those in other subgroups, an assignment of units to subgroups partitions the network into disjoint clusters of units. For three subgroups, this image of social structure implies the following binary matrix of intersubgroup relationships:

$$\begin{matrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{matrix}$$

where a row and the corresponding column refer to a subgroup and a 1 indicates that units in the row subgroup tend to have relationships with those in the column subgroup.

Formal mathematical models are often used in assigning units to cohesive subgroups. For binary data, an idealized graph-theoretic model is the sociometric

clique. Cliques are maximal complete subgraphs, subsets of units in which each unit is tied to all others within the subset. That is, $x_{ij} = 1$ for all distinct units i and j within a clique. In Fig. 1B, units A, B1, and B2 constitute a clique. A given unit may be part of more than one clique. Relaxations of the clique concept consider units to be in a cohesive subgroup if they can reach one another indirectly at a short geodesic distance such as 2 or 3, or if a subgraph is nearly complete—that is, if each unit in the subgroup is directly connected to all but a small number (e.g., one or two) of the others. Strong components of a digraph are disjoint sets of units mutually linked to one another by a path.

Other methods for assigning network elements to subgroups are exploratory. One approach is based on dyadic measures of connectedness such as geodesic distance. Clustering techniques are used to identify subsets of highly interconnected units. A direct approach begins by specifying a criterion function that indicates how closely any given partition of units resembles a target image matrix such as the one just shown. It then uses combinatorial optimization techniques to identify a partition of units that best satisfies the criterion.

Positional Analysis, Structural Equivalence, and Blockmodels

The subgroups identified by cohesion-based analyses have a specific common form—in-group solidarity. Positional analysis takes a much more general approach to studying differentiation in networks. The defining features of some social locations are relationships to others rather than relations to peers, and they do not always include within-group density. Superior positions, for example, are defined by having authority relations to subordinate positions; brokers mediate between buyers and sellers, but are not necessarily connected to other brokers. The distinctions and expectations that define some positions, moreover, may involve multiple, differently patterned types of relationships. A nation in the core of the system of international stratification, for instance, may receive raw materials from countries in peripheral locations, send processed goods to peripheral countries, and have economic and political alliances with other core countries. Cohesion-based approaches to examining differentiation lack the flexibility to examine multiple networks of relationships simultaneously.

Positional analyses map units into subgroups using equivalence criteria. Two units are said to be structurally equivalent if their relationships to and from other units in the group are identical. Units D1 and D2 are structurally equivalent in Fig. 1B because both are unilaterally related to E and unrelated to all other units. Likewise, B1 is structurally equivalent to B2, and F1 is structurally equivalent to F2. Note that structurally equivalent units need not

have relationships with one another. Role equivalence is a more general criterion that groups two units together if their profiles of relationships link them to similar, but not necessarily identical, others. The entry-level employees in different bureaucratic organizations are role-equivalent in that they are subject to the authority of first-line supervisors, but they are not structurally equivalent because they are subordinate to different supervisors.

A blockmodel depicts the typical relationships among units grouped into equivalence-based subsets. It consists of an assignment of units to subgroups, together with one or more binary images of intersubgroup ties. The following images for a two-relation, three-subgroup blockmodel might describe a workgroup:

Authority			Friendship		
0	1	1	1	0	1
0	0	0	0	1	0
0	0	0	1	0	0

In the first subgroup (or position) are those who exercise authority over others; they tend to be friendly with one another. The second position includes subordinates who are solidary with one another, whereas the third consists of subordinates who are not friendly with one another, but do maintain friendships with some of the supervisory actors.

The formal mathematical definitions of structural and role equivalence constitute rigorous standards for assigning units to common positions. Empirical studies usually must relax them. Often this begins with a dyadic similarity or dissimilarity measure of the extent to which two relational profiles approach equivalence, such as the Euclidean distance ed_{ij} :

$$ed_{ij} = \sqrt{\sum_{k=1}^N \sum_{m=1}^M [(x_{ikm} - x_{jkm})^2 + (x_{kim} - x_{kjm})^2]}$$

where M is the number of types of relationship studied. Units i and j are structurally equivalent if $ed_{ij} = 0$; to the extent that it exceeds 0, they occupy distinct positions or niches in social structure. Once such a measure of relational dissimilarity has been defined, cluster analysis methods are used to identify subsets of units having relatively homogenous profiles. Rather than using an intermediate dissimilarity measure, optimization methods for the empirical construction of blockmodels take a direct approach by seeking a partition of units into blocks that best satisfies a criterion function.

Statistical Network Analyses

By comparison with most other branches of quantitative social science, network analysis has given limited

attention to statistical issues. Most techniques and measures examine the structure of specific data sets without addressing sampling variation, measurement error, or other uncertainties. Such issues are complex because of the dependencies inherent in network data, but they are now receiving increased study.

The most widely investigated approach to the statistical analysis of networks stresses the detection of formal regularities in local relational structure. Figure 2 illustrates some of the interrelational dependencies commonly found in analyses of social networks. Many relationships exhibit tendencies toward reciprocity or mutuality, as in Fig. 2A. To the degree that units vary in in-degree centrality, relationships will tend to be directed toward common targets, as in the in-star configuration of Fig. 2B; Fig. 2C illustrates a corresponding out-star pattern in which relationships tend to emanate from common sources. In transitive relationships (Fig. 2D), there is a tendency for direct ties (e.g., from A to C) to accompany indirect ones (e.g., from A to C via B). This redundancy leads to local closure and thus a tendency for the units to separate into subgroups. Another typical structural tendency is known as homophily. It is present, for example, when same-sex friendships are more common than between-sex friendships. This involves an interaction between a property of units and the presence of relationships.

To the extent that a given local configuration is an important basis for structuring a network, the likelihood of observing networks including that configuration increases. The following exponential probability density defines a family of random graph models known as p^* :

$$\Pr(\mathbf{X} = \mathbf{X}) = \frac{\exp\{\boldsymbol{\theta}'\mathbf{z}(\mathbf{X})\}}{\kappa(\boldsymbol{\theta})}$$

where an observed network \mathbf{X} is a realization of a random variable \mathbf{X} , $\mathbf{z}(\mathbf{X})$ is a vector of network statistics giving the number of local configurations of particular types found in network \mathbf{X} , $\boldsymbol{\theta}$ is a corresponding vector of parameters

Figure 2 Local configurations commonly found in social networks. (A) Mutuality. (B) Two in-star. (C) Two out-star. (D) Transitivity.

indicating the strength with which different local structural tendencies operate, and $\kappa(\theta)$ is a normalizing constant. The estimation of θ is complicated by the difficulty of evaluating $\kappa(\theta)$; to date most estimates have been obtained via pseudo-likelihood methods.

This modeling framework considers multiple principles underlying social network structure simultaneously and identifies those tendencies that are significant structural patterns. It marks a considerable step beyond previous probability distributions formulated for network data, which included a restrictive specification of dyadic independence. Many extensions and innovations in modeling and estimation methods are underway within this framework.

The p^* density was first formulated by spatial statisticians. Many statistical problems of interest in network analysis have parallels in spatial statistics, although network data are not usually referenced to fixed locations. Network analysts have used spatial regression and spatial autocorrelation techniques when studying processes of influence and diffusion that operate by way of network ties. Other parallels between the analysis of network data and spatial data remain to be explored.

Neutrality in Data Collection

Carmen Diego Gonçalves

Minho University, Braga, Portugal

Glossary

epistemological vigilance The scientific practice of always questioning assumptions, assuring rupture with both externalist and internalist pre-notions about the object of research. As a tool of research, it contributes to scientists' reflexivity, to their being conscious that all empirical research is done within the ambit of a set of theories and accepted technical procedures, within which scientists question what is being observed.

neutrality The scientist's ideological distance from, or non-involvement with, what is being analyzed in social contexts.

objectification The necessary process in empirical research of objectifying all conditions in which the research is done, even research into social processes in which the scientist is developing a role according a *habitus* that has been incorporated into a certain field with theoretical and practical proprieties.

objectivity The scientific position that objective truths are external and independent of the observer's wishes, beliefs, and interests, thus guaranteeing the neutrality of science and scientists.

reflexivity The scientist's capacity to be conscious of the theoretical assumptions and social conditions of research. Therefore, methodological procedures should be explicit, ensuring the objectivity and validity of scientific production.

Neutrality in data collection is always implicit in social science research and is related to two complementary directions of episteme-methodological reflexivity, one orientated toward the assumptions of the scientist and the other toward the object of science, embedded in historical and social contexts.

Introduction

Why Neutrality in Data Collection?

The issue of neutrality in data collection is related to the affirmation of the objective value of scientific truth, which comes from scientific presuppositions about nature joined with a human attempt to produce fixed disciplinary cultures. Therefore, as an important dimension of social science research, neutrality aims to ensure the specific identity of the discipline, in consonance with the independence and impartiality of scientists and the objectivity of their results.

Crucial Debates

In the empirical-positivist tradition, which favors the primacy of observation, science is neutral. By observing the method of neutrality, knowledge will correspond to reality, copying it, and, based on that presupposition, we will have a record of how much of what we are observing is "nature" and how much is "society."

However, there were some writers close to the Vienna Circle who criticized this perspective. Karl Popper, for example, affirmed that observations are impregnated with theory, recognizing, thus, the primacy of theory in opposition to observation. Data that are clearly inconsistent with a hypothesis can show that it is false, as Karl Popper explains in *The Logic of Scientific Discovery*. Lakatos also affirmed that "all propositions of science are theoretical," and that "a factual proposition is only a particular type of theoretical proposition."

Admitting that observing necessarily supposes the category of what is being observed (i.e., dividing the world into data processes according to different scientific visions of the world), the aim of the rationalist perspective is the unity and the integration of the research process, in which

the epistemological vector, as Bachelard said, is oriented from the rational to the real. Giddens, in turn, considered primordial in the production of scientific knowledge the network of overlapping and intersecting states, whether theoretical or observational, that form changeable connections with empirical objects.

Reflexivity within epistemological vigilance, one of the factors stressed in the thinking of Bourdieu, is much more important because it is certain that, although the object (and objective) of all science is to disclose what is hidden, what is hidden in society and what is hidden in nature are not hidden in the same sense—another difference between the two scientific universes. A more systematic kind of reflexivity claims to take up the ultimate consequences of Bourdieu's concern with the self-objectification of the subject of understanding.

The Problem

Accepting the myth of neutrality in an unquestioning way seems to constitute a dogma of faith, which can contribute to the anti-social applications of science. The problem consists, on the one hand, of knowing whether the science produced is recognized as *representing* social reality, that is, knowing the relationship of scientists and their methods, theories, frames of meaning, and finally idiosyncrasies and contingencies in the production of scientific knowledge, and, on the other hand, of knowing what constitutes the social role of the social scientist, in his or her identity as a scientist and as an actor who intervenes in society.

In fact, knowledge is inseparable from the struggle between different theoretical perspectives through which scientists try to construct and reconstruct society and its scientific interpretations. What exist are technical procedures developed by the scientists with the aim of neutrality. These procedures, as instruments, are only functional departures from previous conventions and decisions about what distinctions must be recorded, and because of this they are always impregnated with theory. There are authors who consider the existence of contextual, cultural, and social conditioning in the production of scientific knowledge. In addition, science is always politically implicated, even if only through its unavoidable relations with politics of science in national or transnational contexts.

In short, the problem is related, on the one hand, to the general demarcation between science and nonscience and, on the other, to the demarcations between the natural and social sciences. The ecology of practices, the demarcation of the objects and subjects of the science(s), and accepted procedures such as instruments for collecting data introduce a form of objectification that can contribute to the illusion of neutrality. All of them, in their turn, contribute to the dualities that sociocultural

processes establish between the natural and social, the biological and cultural, the human and nonhuman, and the subject and object. It is clear that the paradigm of modern science is based on an obsession with method, and we can say that never has so much evidence of the illusion of neutrality been seen as in the last decades.

Article Overview

Beginning with questions relating to scientists' and scientific neutrality posed by Max Weber and Robert Merton and the historical contexts that allowed them to reflect on these issues, this entry first presents a (not necessarily chronological) review of authors whose works reflect on neutrality in science, neutrality between science and social contexts, and the distinction between neutrality and objectivity. Whereas as neutrality is shown to be, in fact, an impossible ideal, objectivity may be defended through procedures and the evaluation criteria for these procedures that principally look to make explicit the conditions of knowledge production (cognitive, institutional, cultural, social and political, economic constraints, and the scientists' identifications, including their biographies) in order to permit the identification and criticism of possible bias and other influences on the process of the production of scientific knowledge. From this, we can identify three important essential points. First, science, as a vision of the world based on the values of objectivity and neutrality, imposes itself in opposition to obscurantism and, above all, religion. Second, science has profited from politics, namely in the Second World War, and it is necessary to distance politicians from scientists in terms of ethics and identity. And, finally, in current societies, in which the social implications of the development of science become ethical questions and concerns, what are the conditions under which social scientists must intervene in society. So, considering that ethics seems to be linked to this intervention and the social responsibility of scientists, and if epistemologically it is right, how can scientists guarantee neutrality? The answer seems to lie in the methods and technical tools of research, anchored in the process of the objectification of the presuppositions of the research.

Scientists and Science Neutrality

At the end of the 1930s and the beginning of the 1940s, the belief that science is neutral, objective, and true—the ideology with which science had defined itself as a discipline in opposition to the dogmatic obscurantism of religion in the Middle Ages and that had moved it to the apex of social acceptance in the nineteenth century—received its first significant blows. In Germany, the submission of science to political objectives overthrew the fundamental criteria of scientific validity and the professional competence of scientists.

Max Weber: Axiological Neutrality of Reason

Defending the integrity of scientific activity in the face of political intervention in Germany at the turn of the twentieth century, Max Weber was preoccupied with the demarcation between politicians and scientists. According to Weber, the dimensions that identify the characteristics of politics and of science are, or at least should be, different. Advancing the concept of the “axiological neutrality of Reason,” he defined the ethics that must regulate the position of the scientist in opposition to the politician.

This idea presupposed not only the value of neutrality in science and technology, but also the value of the reflexivity of the scientist. In other words, the universal validity of science demands that scientists do not project their value judgements onto the research process or state their preferences in terms of aesthetics or politics. In this sense, Weber thought to overcome a very well-known contradiction that the scientist who is passionate about the object of his or her investigation can never be impartial or objective.

According to Weber, scientists must separate value judgments from their work in the ambit of Reason. The characteristics of science are to be morally and socially free of values. Weber wanted a neutral science, in which professors never use their prestige to impose ideas. But he also wanted a neutral science that would be useful to people of action and politics. The ethics of conviction and responsibility finds itself, in a way, already complementing political vocation. This being so, although society may use science for good or for evil, scientists are no more socially responsible than any other citizens. Science is a double-edged sword. Current authors writing about the social responsibility of scientists affirm that science is limited to the descriptive study of natural laws and is devoid of moral or ethical qualities. This is as true for social science as it is for biological science.

Robert Merton: Scientific Ethos of Science

Robert Merton, beginning in 1942, wanted to guarantee the role of science in a society facing social problems posed by science, namely the negative impact of the development of controversial scientific and technological advances and the engagement of scientists with politics. This is usually identified with his externalist orientation of the development of science. In fact, the lack of confidence in science and scientists’ neutrality and the results of the application of science that indicated that continued scientific development might not be unconditionally good created conditions that led to questioning the social functions of science and to imposing fundamental tasks

that defined the functional conditions of science that must be practiced.

It is in this historical context that Merton delimited the sociological object of science, which is to study not only the cultural structure itself but also to study the impact on society of the creation of a focus of scientific interest, the selection of research problems, and their development. Merton also enumerated a set of norms, simultaneously moral and technical, that in his understanding constituted the scientific ethos, considered binding by scientists:

- Universalism—not contemplating criteria associated with personal and social attributes, the professional academic position.
- Communalism—openly communicating results as a basic presupposition for the advance of knowledge; because scientific knowledge is a social product, the results of research, as well as the theory that guides it, must be in the public domain.
- Disinterest—maintaining science as independent from other fields and interests, namely economics and politics, that are not related to the normative imperatives of scientific ethos; this is to be understood as an ideal to preserve autonomy.
- Organized skepticism—suspending ideology, controversies, religion, beliefs, and common sense until the facts speak for themselves. This leads us to methodological and institutional questions and to the process of the construction of new scientific knowledge; writers consider that this norm takes form, above all, in institutional appraisals of the validity of scientific knowledge.

Democratic society is the sociopolitical context that permits the maximum realization of these values. Disregarding this set of norms will lead to a situation in which, beyond moral indignation, science begins a process of cumulative dysfunction until it collapses.

Merton, in addition to his analyses of the influence of society on science and of science on society, was concerned with how social factors participate in the construction of scientific facts. He was also dedicated to the analysis of the social relations that constitute scientific institutions, of the processes of scientific production that mediate between theory and analysis in diverse sociocultural contexts, and of the contradictions and conflicts between structures and actors’ motivations and perceptions—in other words, to the analysis of the contextualization of scientific production. Nevertheless, from Merton’s perspective, the criteria of objectivity, validity, and neutrality and the theoretical conditions and methods are objects of the philosophy of science (or of the theory of science), but never of the sociology of science.

Objectivity, Reflexivity, and Neutrality

Positivism and Objectivity

August Comte: The Syntheses of Scientific Knowledge

August Comte, who is commonly identified as the founder of sociology, verified that the rigorous methods of the natural sciences—linked to positivism, which possesses a universal validity, and based in observation, experimentation, and the establishment of laws—must be widened to include the disciplines we now call the social sciences in the ambit of a reform of collective beliefs, which is a consequence of scientific development. The laws established by scientists are, in Comte's vision, comparable to dogmas; they must be accepted once and for all and not be perpetually questioned. Comte was much more conscious of the necessity of faith than in the legitimacy of doubt as a scientific method, thereby guaranteeing objectivity.

Emile Durkheim: Social Fact Theory

Durkheim's objective was to demonstrate that a sociology can exist that is objective, in agreement with the model of natural sciences, and whose object is social fact. To achieve this, two things are necessary: (1) that the object of this science may be specific, distinguishing itself from the objects of all other sciences and (2) that this object be observed and explained in a manner similar to the facts of other sciences. The rules of Durkheim's sociological method are anchored in the basic ideas that social facts are things and that the characteristic of a social fact is that it exercises coercion on individuals.

Durkheim used a deductive approach (coming from natural science) in which social scientists begin with explanatory hypotheses about a research problem and use logical reasoning to deduce its empirical implications. In this framework, theory building requires that the basic concepts be spelled out before they are used in the formulation of hypotheses. For example, Durkheim's basic concepts (egoism, altruism, anomie, and fatalism) were used as key independent variables in his analysis of suicide rates. The hypotheses were then tested using data in the real world.

The Critics of Positivism—Reflexivity

The positivists were criticized for assuming that society could be described and understood according to an ontology and methodology committed to seeing social behavior as empirically evident and quantifiable and the object of investigation according to a process of validation associated with measurement and quantitative data. Therefore, the deductive model was also criticized for assuming that it was possible, via the use of observer

categories and theories, to provide an expert account of the social world superior to the lay accounts of the actors.

The antipositivists discovered or disclosed social reality by being receptive to accepting the actors' own perceptions and interpretations of the world, fashioned through interaction with other actors. Because meaningful human communication depends primarily on language, language is obviously of central interest, according to a validation process based on qualitative data and a comprehension of the way individuals create reality through interactions with others and make sense of it; there is no more to the social world than this. Consequently, they rejected not only the positivist's observational categories, but also any preconceived hypothetical statements about causal relations.

The deductive model was rejected, namely by the critical theorists. They attacked what they called "traditional," or "positivist," theory for suggesting that its deductive arguments could be assessed objectively and for having pure knowledge as a goal. The proponents of critical theory (e.g., Marx Horkheimer) related social phenomena to their notion of historical possibilities that were different from and superior to current reality.

Also, Michael Polanyi, who anticipated some of the ideas of Thomas Kuhn (e.g., conventionism and the importance of scientific community) and of Pierre Bourdieu (e.g., the notion of field), submitted the objectivist and positivist conceptions of the natural sciences to a radical criticism, and the way in which he did this approximated its epistemological status of the one of social sciences. According to him, the knowledge of the natural sciences cannot be distinguished in absolute terms from common sense knowledge; the methods that we use to confirm the facts of daily life logically predate the specific premises of science and must, because of this, be included in a complete description of these premises; also, science is a field of tradition and organized authority, before which only a fiduciary concept of scientific truth seems sustainable. Truth consists of a "scientific consensus" obtained from the scientific community and, because of this, those who speak about science, in the current sense and with the approval of custom, accept that this organized consensus determines what *is* scientific and what is not.

From the moment that the positivism orthodoxy entered this crisis, the concept of reflexivity was extended. The way to attain objectivity was through the subjective reflexivity of scientists, as well as through a profound consideration of the research procedures—the objectivist line of reflexivity, which has less confidence in the self-analysis or introspection of scientists than in the (as far as possible) objective analysis of the scientific theories, methods, and techniques of observation that scientists use—and a consideration of the sociological context in which scientific practice takes place: the institutional organization of science; the types of science financing; and the uses of scientific knowledge.

Max Weber: Methodological Individualism

Max Weber, who at the beginning of twentieth century affirmed that “the belief in value of scientific truth does not proceed from nature but is a product of precise cultures,” placed himself in the ambit of the important precursors of reflexivity in social sciences. We cannot doubt this when trying to define and legitimize patterns of scientific rationality that are adequate to the irreducible specificity of phenomenon.

Weber’s views are related to the idea that objectivity can be applied to social problems only after a distinct value orientation has been established. It follows that political action does not corrupt social scientists’ objectivity as long as the scientists’ perspectives or values are explicitly acknowledged. So the categories through which social phenomena are conceived are, prior to social scientific analysis, derived from priorities that the researcher brings to the work rather than to universal laws discovered through systematic observation. Once established, these categories also entail ends, and the working objectively toward those ends, which allows social scientists to resolve given social problems scientifically.

Weber contributed powerfully to stimulating a sociological tradition more directly dependent on and contributory to the positivist program of Comte. As did Pareto, Weber, considered sociology to be a science of human behavior, to the extent that it is social. The way was open for the development of a comprehensive social approach and an approach to the technology of empirical research that were very diverse in the way that the positivist paradigm suggested. The recourse to the evidence of social actors on its existence, with a goal to refine the subjectively appraised causes (motives) of action, constitutes a methodology of investigation.

Weber’s insistence on referring the motivation and, consequently, the sense of human action, to a set of axiological options defined at the level of the subjective actor, constituted the strategy, which developed into his essential methodological individualism. The self-referential character of reflexivity (subjectivist reflexivity) performs in a way that is very much bound to the personality of the social scientist.

Resisting, however, the extension of the effort of objectification of social processes to the disciplinary internal dynamics of the attribution of the sense that they embody, Weber contributed to the perpetuation of a system of epistemic correspondences (objective-explanation; subjective-comprehension) that today still marks and weakens the scientific analysis of social practices. His own designation of ideology, which Karl Marx substituted, in certain cases for “patterns of conscience,” has imposed itself as an obstacle in the analysis.

C. Wright Mills: Explication of Presumptions

In the style of thought that presupposes reflexivity, there are authors who parted from the presupposition that it is not possible to study society with neutrality, and that, instead, because there is always more than one value option, sociologists have to take a position and have to be conscious of the position they take, which implies a conscious reflexivity over their own research practices. If neutrality is always conditioned by internal and external factors of understanding (the ideal type), an objectivity could be found across the methodological procedures that does not dispense with the inherent explication of the conditions of the production of scientific knowledge.

C. Wright Mills, writing in 1959, was the pioneer in the preoccupation with rendering explicit prejudgments, values, and ideological options—in short, the limits by which subjectivity establishes the objectivity of understanding that we produce. In this sense, he can be considered a pioneer of reflexivity in science and in the theoretical and methodological orientation that gained force at the end of the 1960s with the end of the positivist consensus. To Mills, the public explanation of bias is the precondition that makes objectivity possible in the social sciences because these explications can be made by everyone and integrated into scientific debates. The same preoccupation caused Mills to bring to the public domain his “sociological craft.” Bravely, at the time, he showed his scientific practice as an intimate practice, personal, empirical, complex, and in constant confrontation with the aridity and simplicity of methodological recipes. Mills presented the task of research and objectification as a task of the artisan, reflexive, which came to constitute the basis of “grounded theory,” and identified himself with the use of the inductive perspective.

Scientists using an inductive approach feel that to start an analysis with a clearly defined hypothesis is too rigid and may lead them to ignore important aspects of their subjects. It is far better, they suggest, to get to know a subject and situation well, gradually building up, or inducing, descriptions and explanations of what is really going on. In an inductive approach, the key concepts emerge in the final analysis of the research process. Induction implies an inference from the particular to the general (e.g., Goffman’s intensive observations in a mental hospital led him to create the concept “total institution”).

The Critics of Positivism— Contextualizing Neutrality

Thomas Kuhn: Frames of Meaning

According to Kuhn, neutrality is not possible in the visions of the world associated with any scientific discipline. We are always socialized into a paradigm or, alternatively, we

adhere to a rival paradigm. None of the steps of scientific activity, including the production of information and data, can be neutral.

Kuhn's challenge to logical-positivist philosophy of science was twofold: (1) the development of science is not cumulative and (2) the choice that is made by scientists between alternative paradigms (once the process of rupture has begun in the revolutionary phase) is not founded on scientific theoretical considerations. In such periods of paradigm shift, the question about the direction of transition cannot be based on the requirement of truth precisely because the criteria that legitimize this requirement are, themselves, in question. The fight between paradigms at the moment of transition is more ideological than neutral (Kuhn compared it to a political struggle in which ideologies seek to impose conflicting definitions of the world). Different scientific visions of the world are based on different competing interpretative paradigms and, in this sense, reality offers itself for interpretation like a Picasso painting to the Gestalt dimension.

What is implicit is not a decision about the validity of new discoveries but whether a new perception of reality exists. So, the question will be decided, in the ultimate analysis, by the force of the arguments that the different schools of thought use in defense of their interpretations of the world, which are themselves a consequence of different visions and perceptions of the world.

The process of the imposition of a new paradigm is a process of negotiation among the different groups and among scientists within the groups, defined by relations of authority (scientific and other) and dependence. This leads to psychological and sociological factors of knowledge production. Kuhn stresses that "scientific knowledge as a language is intrinsically the common property of a group or it is nothing. To understand it we must know the special characteristics of the groups that believe and use it."

One of the consequences of Kuhnian epistemology is that rationality and veracity in scientific knowledge can be understandable only inside one paradigm, which provides the frame of meaning for all scientific practice. To explain the reasons for fundamental scientific options, it is necessary to leave the circle of theoretical conditions and internal mechanisms of validation and search for explanations in a vast set of sociological and psychological factors; it is also necessary to study the scientific community in which the different groups are integrated, the process of professional training, the process of socialization into the profession, and the organization of scientific work.

In spite of the fact that his concept of paradigm has a prominent social dimension, Kuhn does not provide evidence of the social causes of scientific knowledge; nor do his works give great importance to events outside the scientific community. Nevertheless, in the sense of reducing the importance of external causes in the

revolution initiated by Copernicus, Kuhn used the dichotomy between internal technical factors and external social factors, concepts that were very much in vogue at that time.

Social Conditioning

The sociology of scientific knowledge (SSK) arose in the 1970s and relied on a critical view of the externalist orientation of Merton. Departing from the general idea that knowledge, in its widest sense, is socially conditioned, SSK, independently from the debate about the problem of relativism, had as its object three principal questions: (1) the definition of social conditioning factors, (2) the types of conditioning factors, and (3) the extension of conditioning according to types of knowledge. The treatment of these questions, and above all of the last one, admitted the effect of social conditioning, not only on the theoretical contents of science such as its theoretical and methodological conditions but also on the criteria for validity inherent in the scientific process. This constituted a frontal clash with the positivistic conception of science, in which science is a system of knowledge endowed with internal mechanisms for the validation of the results and the orientation of development, thus guaranteeing objectivity and neutrality.

One of the central streams of SSK was related to what was called the strong program. Within this scope, Bloor and his colleagues wanted to explain how scientific knowledge was caused by social conditions—although not exclusively so. This, in fact, was the first of four canonical principles that he specified for the strong program; the other three were impartiality, symmetry (these two are now usually combined into the postulate or principle of symmetry), and reflexivity (the requirement that the types of explanation given by SSK be to be applied to itself).

To explore this, those practicing the strong program were obliged to look in other directions. Two strategies were explored. The most important of these was to identify the interests of the individuals or small groups under study and use these to explain their choices and judgments. This was inspired, in part, by work on the constituent interests of knowledge by the German philosopher Jürgen Habermas, but the principal focus was specifically orientated toward the influence of social motives in science.

Many debates took place, which eventually led to the fragmentation of SSK at the end of the 1980s. The crucial question in the debate had to do with the characterization of the social range used to explain scientific practice and the nature of the explanations deriving from this. It is important to note that there were questions that were not only derived from Kuhn but that could not be kept apart from questions about the logic of scientific production and patterns of social life. The most important of

these was, in fact, the interest in the social causes of scientific beliefs.

Subcultures as Conditioners of the Production of Knowledge

Collins To Collins, the social ties that delimit and maintain the union of subcultures are essential conditions for the production of consensually accepted knowledge (as in Kuhn, the relations of authority are basic to normal science). The majority of scientists, the major part of the time, live their lives in the ambit of a matrix of confidence and support. It is only when that confidence is broken that its social mechanism is exposed to view. Controversies, independently of being frequent or prolonged, acquire primacy because they reveal the relations of authority, credit, and lack of confidence that are hidden in any type of knowledge that has become largely accepted.

The scientific practice was characterized as an undetermined process of opening and shutting up, and scientists were characterized as being compelled by neither logical deductions from existent beliefs nor nonambiguous evidence to develop their ideas in any particular direction. Instead, scientists were presented as making practical judgements that were to be related to local subcultures in which their recourses and aptitudes had been invested and in which they pursued their specific objectives. In controversies, the structure of these (normally hidden) compromises is brought to the surface and exposed to view.

Collins also showed that a considerable percentage of tacit knowledge must be drawn upon so that knowledge can be reproduced in another place. In other words, he demonstrated that the universality of scientific knowledge is in fact related to the process of replication, which requires the transference of knowledge from the subculture in which it was originally produced to another subculture. Because they are participants in a subculture, scientists learn to see the objects they observe in a particular way; consequently, the representations of the world, or the (di)visions of the world, that they have are linked as much to the techniques they have acquired as they are to the knowledge shared in the heart of a disciplinary subculture. This is a line of thought that we recognize as coming from Kuhn, Wittgenstein, Hanson, and Fleck.

Ian Hacking Some analysts have defended scientific focus on laboratory work, characterizing scientists as being involved in the creation of an “artificial reality,” which is to say, the creation of a configuration of the material world that is *real* but that is not identified with “nature” (which, we suppose, exists *a priori* and independently of human intervention).

The philosopher Ian Hacking spoke of scientific experiences in the laboratory as if they were activities of the creation (representation and construction) of phenomena, treated, stabilized, and reproduced. The phenomena, suggested Hacking, must not be thought of as summer mulberries that have been treated and are available for picking but as identities that have been made via instrumental involvement with the material world. So, laboratories are places where phenomena are reproduced, or constructed—what the French philosopher Gaston Bachelard designated the “phenomena-techniques,” phenomena embedded in technical practices. The specific laboratorial resources, human as well as material, make laboratories privileged places for the construction of artificial reality, via its representation.

Ludwick Fleck Both fundamental arguments of ethnography of the laboratory—that scientific work is practical reasoning in a specific place and that human and material recourses construct experimental phenomena—receded before the work of Ludwick Fleck (1896–1961), *Genesis and Development of a Scientific Fact*.

Fleck insisted that the production of knowledge, even of hard experimental facts, consists of social activity and, starting from there, constitutes an appropriate object for sociological analysis. In one of his more emblematic affirmations, which identified his style of thought, he declared, “cognition is the human activity more socially conditioned, and knowledge is the supreme social creation.” The social character of knowledge is, in this perspective, revealed by the social circumstances of its production in the heart of an interactive community (a “collective thought”) that sustains a distinct mode of reasoning (its “style of thought”).

Bruno Latour Bruno Latour was the major defender of the vision that an explanation of scientific practice and the extension of its effects on society required a drastic revision of categories that sociologists of scientific knowledge used. What was required, according to Latour, was the recognition of the status of nonhuman identities as social actors. Many of these points were developed, and largely expressed, in his 1987 work *Science in Action*.

Therefore, it is necessary that the social scientist make a double effort, penetrating the “rituals” that characterize scientific life and achieving a reflexive understanding of details of scientific work, following a hybrid vision of intellectual, technical, and social activities (human and non-human) that are mutually dependent and reciprocally influenced. The observer assumes a cautious, but deliberate, position, oscillating between naïve ignorance and the complete acceptance of the pattern as the “natives” see things.

Therefore it is important to incorporate the problem of the consequences or implications (anticipated or

probable) of scientific activity that go beyond the circumscribed laboratory space. This is generally associated with and obliges us to rethink, on the one hand, reflexivity and, on the other, the consequences of redividing, reclassifying, or reorganizing the world as a consequence of collecting data.

John Dewey: American Pragmatism Reflection has long been considered by American pragmatists, especially by John Dewey, and is currently being revived today in the context of discussions about risk societies.

John Dewey, as an American pragmatist, used the term “experience” to denote the broad context of the human organism’s interrelationship with its environment, not just the domain of human thought alone. In addition, Dewey later substituted “transaction” for his earlier “interaction” to denote the relationship between organism and environment because the former better suggested the dynamic interdependence between the two and, in a new introduction to *Experience and Nature*, he offered the term “culture” as an alternative to “experience.” The social dimension and function of belief systems explored by Dewey and other pragmatists have received renewed attention by such writers as Richard Rorty and Jürgen Habermas, particularly Dewey’s claims that the human individual is a social being from the start and that individual satisfaction and achievement can be realized only within the context of the social habits and institutions that promote them.

Rejecting fundamentalism, Dewey accepted the view of scientific fallibility that was characteristic of the school of pragmatism—any proposition that is accepted as an item of knowledge has this status only provisionally, contingent on its adequacy in providing a coherent understanding of the world as the basis for human action. According to Dewey, a democratic order, which requires a “socially generous” attitude of mind and “civic efficiency,” is neither more nor less than the capacity to share in a give-and-take experience.

Rethinking Objectivity

Forms of Objectivity

We can identify patterns of objectivity:

- Weak objectivity, which suspends references to social, cultural, and identity factors, in short the external factors of scientific work, and reduces objectivity to a question of method, which is understood as being internal to this activity.
- Strong objectivity, which demands the explication of all relevant conditions to the production of scientific knowledge, without a distinction between external or internal conditions. In other words, it is wrong to think

that the scientific method requires the elimination of all social values from scientific processes.

Sandra Harding defends the need for a strong objectivity, because, in her perspective, it is necessary to consider the relevance of perspectives other than the dominant one. Thus, democratic values increase objectivity. Harding advocates observer communities (instead of an abstract, individual, or “invisible” observer) in association with the consideration of outside and marginal perspectives to achieve more complete, undistorted accounts in science. She calls attention to the redefinition of political problems as scientific ones; because of this, science can be seen as a contested zone, which means, in her perspective, that we need to reshape objectivity even as we criticize it to prevent dangerous depoliticization in investigating processes, or so-called neutrality.

Disunity of Sciences: Ecology of Practices

According to Galison, the notion of scientific objectivity has changed over time in response to social influences within and outside of specific disciplines. We know much less, however, about the way of constructing alternative visions of the world that are capable of proposing other ways of arranging the world and describing its dynamics, permitting us to face the difficulties that the current dominant “versions of the world” are not capable of resolving.

The reduction of science to a unique epistemological model, such as Newtonian physics, which is based on mathematization as a scientific ideal, gave way to a diversification that created a multiplicity of “ecologies of practices” organized in relation to distinct epistemological models. The principles of legitimating the various practices constituted as sciences began themselves, in this way, to multiply, so that this led not only to different sciences invoking different models of science, but also to tensions between these models of science. Defining the frontiers was a way of autonomizing and legitimizing the distinct ecologies of practices, without their submission to “foreign” epistemological models. Defending the frontiers signified, in many cases, the difference between the consolidation and the fragmentation of new disciplines or scientific dominions.

The demarcation of frontiers comes to mark this period in the history of science. Many more innovative areas of scientific knowledge appear in these territories of “passage” that are the frontiers. We are not speaking about interdisciplinary research but of a collaboration that presupposes a dynamic hybridization, miscegenation, or transgression of boundaries that characterizes modernity as historical process. The work of creating frontiers and the dynamics of transgressing those frontiers will raise the

objects and entities that make up the world in which we live today.

The differences between disciplines and the so-called disunity of sciences led to a rethinking of the division between natural and social sciences. Those in the life sciences, cognitive sciences, and environmental sciences, especially, characterized their differences in terms of ecology of practices (as Isabelle Stengers called them) rather than in terms of the classic divisions between the natural and the social sciences. These ecologies of practices permitted the distinction between “naturalist” observation, modeling, simulation, historical research, and experimentation that crosses, transversely, the natural and social sciences.

This means that the problem of collecting data becomes distinct in each of these types of ecology of practice, as referred to by Galison and Stump in *Disunity of Science*. In this sense, the frontiers not only demarcate “science and its others,” they determine the diversification or “disunity” inside the sciences.

Social Sciences Specificity

Each science not only describes reality, it also interprets it according to its frames of reference. In sociology, these are essentially related to its social dimension. And, because the preconstructed is everywhere, the breach with common sense (that is, with the representations shared by all) implies a radical doubt according to a reflexive and self-reflexive intention.

The object of social sciences is not “nature”; it is, above all, the systems of historical and social relations that create specific epistemological obstacles (such as the problem of language) and that compel a more accurate epistemological vigilance (to use the terms of Bourdieu, Chamboredon, and Passeron in *Le Métier de Sociologue*). The safeguard of this rationalist construction of social science is, nevertheless, always precarious. The apparent contradiction between the precariousness of this rationalist construction and the “belief,” to which Bourdieu subscribes in *Leçon sur la Leçon*, in the transforming character of sociological knowledge, fighting against the “monopoly of legitimate representation of the social world” is resolved in the epistemological plane through reflexivity or perhaps by submitting sociological practice to sociological analysis, using for this the theories and methods that sociology uses to analyze social reality (as pointed out already by the defenders of the strong program).

For Bourdieu, scientific practice that forgets to question itself does not know what it is doing; it may discover something about the object, but it is not truly objectified. It is in this sense that the rupture with both externalist and internalist prenotions is equally important. That is, erudite discourse is not enough; it is also necessary to be aware of the scientific ideology—perhaps better termed “significant representations”—which is inevitably part of

the frame of meanings of any scientist. Not taking this into account causes a nonrecognition effect. From there, science reinforces itself while reinforcing scientific criticism, which means that social scientists should take themselves as the object of the instruments that they develop and that the sociology of sociology is an indispensable instrument in the sociological method.

Contrary to what was intended by social physics, it therefore becomes necessary to bear in mind that the object of study does not exist in social life in the direct sense; it is not there, as the positivists thought. Instead, it is a product of our mental exercise; it is constructed by the individual who is going to study it according to the theoretical reference matrix and all the extrinsic and intrinsic constraints of knowledge production, itself the product of the human spirit’s capacity of rational elaboration.

This is fundamentally different from a naturalistic descriptive perspective, which assumes that the objects of study already exist and that the scientist only has to describe them. As Bourdieu would say, it is only in accordance with a set of hypotheses derived from a set of theoretical assumptions that any empirical data can work as proof or as evidence. Thus, it becomes necessary to avoid at all costs the basic inclination to think of the social, natural, or physical world in a “realist” instead of a “relational” way, in so far as “real is relational” (as Hegel put it).

In short, we must assume that even in the exact sciences the object of study is not completely independent of (in the sense of being exterior to) the researcher because, even if the perspective is merely descriptive, it becomes necessary to take the analytical instruments used by the researcher into account. This assumption when applied to the social and human sciences leads to an exponential increase in the uncertainties from the outset because the object of study itself interacts with the scientist and can influence the course of the experiment. Therefore, the deterministic characteristics of social and human analyses also decrease exponentially and, in turn, call on the scientists’ reflexive capacity to explain the conditions of the research process, with the aim of eliminating what we call the object effect.

Rethinking Neutrality

Once the empiricist innocence had been lost, accessing true knowledge became a sinuous road, full of difficulties. The more neutrality appeared to be an illusion, the more scientific truth became precarious and temporary and the more difficult and risky it became to obtain it.

This consciousness of complexity translated into the idea that if there is no *one* real way to access to the truth, *all* possible ways must be used. The basic idea of Feyerabend, in *Against Method*, is that if there is one

methodological rule of absolute value that all other rules are frequently put aside and that this must be if we intend to promote scientific development.

Understanding therefore is a special technique of the social sciences. Social researchers, however, use the same kind of resources as laypeople to give meaning to the conduct that is their object of analysis or explanation, in addition to the fact that the concepts they use are not exterior to the phenomenon observed but are, rather, linked to or dependent on a previous understanding of the concepts used by the laypeople to maintain an intelligible social world. Social scientists, like laypeople in fact, take advantage of the socially available interpretative resources. The difference between scientists and laypeople is that the former take advantage of these resources through the mediation of scientific categories, under the integrated form of a scientific paradigm or frame of meaning; this enables them to have a more developed, but specific, kind of reflexivity, oriented toward scientific presuppositions in order to establish a search for the meaning in itself and whose concepts are dominated as a kind of practical activity that creates specific kinds of description.

As a result of this double relationship between the lay and scientific ways of constructing a universe of meaning, one of the fundamental concepts of Giddens's theory of sociological analysis, called double hermeneutics, is explained, as "the hermeneutic explanation and the mediation of diverging life forms between the descriptive metalanguages of social sciences." This concept should be put into perspective. We start with the assumption that knowledge in itself is part of a production process, which is also the production of facts, data, and actual empirical information. Therefore, we intend to distance ourselves from the perspective of the "unlimited sovereignty" of the subject in an attempt to avoid ending up in an excessive idealism in which it is not very clear where the obstacles of common sense end and where the construction of theoretical prepositions and the perception of the validity of these prepositions by using empirical confirmation starts.

Actually, it defends methodological pluralism, a combination of quantitative and qualitative methods and, consequently, the articulated use of several research techniques. But methodological pluralism should not be confused with methodological anarchy or with methodological eclecticism—the first departs from a logic of research that prescribes norms for the selection and use of methods and the second limits the diversity of the methods used and establishes a hierarchy among them. The idea is to leave behind the Weberian tradition of dividing epistemological problems of the production of sociological knowledge between methodology (essentially intensive and qualitative) and philosophical logic and, instead, to carry out a deep exploration of sociological production from the perspective of applied rationalism. Therefore, the meaning of the "epistemological vector"

goes from mental elaboration to empirical verification—"from reason to reality"—and in this sense no observation can be made without theoretical assumptions and hypotheses, all data are already results, and no technique can be used except with reference to theoretical options and choices. In addition, theoretical proposals should be informed by appropriate substantive research. The scientific subject is shown to be fragmentary and at the same time equipped with this "technical materialism" (more precisely, the empirical research procedures) of which Bachelard wrote.

Modus Operandus

Assuming a scientific and, presumably, neutral (as conventionally defined) attitude involves choosing to put the acquired theoretical knowledge into action, investing it in new kind of research. This leads to a *modus operandus* that orientates and organizes scientific practice without, however, shaping it solely and definitively into an "ideal" method of a positivist (or other) kind.

This refers to a relational attitude and a reflexive and self-reflexive capacity to *make* science, a fundamental characteristic of the social sciences and of social scientists. This takes time to incorporate; however, it is essential to break with dogmatic elitist attitudes that in the name of orthodox methodologies that cause researchers to end up being unable to notice, see, and question the fundamentals on which the construction of their objects of study, experiments, confirmations, and conclusions are based. Hence, the same reflexivity should be used to create radical diversity between scientific knowledge and common sense.

On this basis, Bourdieu defines *Le Métier de Sociologue* as the capacity to convert abstract problems into practical scientific operations, which is always a relational process between theory and practice in which knowledge is transmitted through modes of transmission, namely between the teacher and the learner. Thus, an operating plan, a scientific *habitus*, is progressively incorporated.

Constructing the object of study, questioning the preconstructed objects, mobilizing all the techniques that, given the definition of the object and practical conditions, always follow a critical and watchful epistemological attitude—these are the assumptions that shape a reflexive methodological proposal that considers research something too serious and too difficult to take the liberty of confusing *rigidity* (which is the opposite of intelligence and invention) with *rigor*. Obviously, the other side of extreme methodological freedom, which seems to be merely good sense, is the use of extreme caution in applying techniques, paying attention to their adequacy to the problem posed and to the conditions of their use.

This methodological position, on the one hand, exceeds the epistemomethodological assumptions of the pioneering masters, but, on the other, it is also rooted in them even though in differentiated substantive-theoretical bases. Thus, just as in the Durkheimian perspective, the break with common sense is important for the construction of the object of study, together with a critical attitude linked not only to the construction of the object but also to the actual research, in the sense of objectification; scientific knowledge is presented to us as constructed knowledge. And just as in the Marxist perspective, the critical vision is extremely important in the research process, in terms of objectification; there is a dialectic relationship between the individual and society that justifies and is justified in social transformation; the positioning in the social structure is an objective condition that interferes with the subjective condition of the individual; social reality is not independent on the mind's construction processes; it is necessary to make the implicit explicit; and historical knowledge is important.

But in addition it is important to stress that this methodological proposal is distinct from those of the classics and that it points out some of their limitations. Although it is clear that the proposal distances itself from the unitary, positivist methodological position, just as the Durkheimian perspective does, it also distances itself in the use of quantitative methods *versus* qualitative methods and in following a course away from mechanical and reductionist materialism. The aim is, in fact, to overcome the radical position between positivism and antipositivism, between the structuralist or phenomenological perspective. An attempt is made, therefore, to pursue a perspective that is articulated and that contributes to the explanation of the construction and comprehension of the social in the action of individuals, they themselves being structured and structuring the actors in social structures, which refers to another fundamental concept of Giddens, the duality of structure. Hence, the individual's position in the structure is important for the explanation of social reality; on the one hand, social reality exists alongside the individual and, on the other, it is the individual who constructs and reconstructs social reality using a dialectic interaction between structures and practices. In addition, social reality must be explained bearing in mind the subjective dimension of the individual him- or herself in so far as he or she contributes to its meaning.

In short, the goal is to account for the subjective dimension of the objective action, objectifying the subjective. Therefore, the construction of the object of study is considered a very important step as is the whole process of choosing research techniques and conducting research, keeping in mind that the attitude that should be adopted is one of epistemological caution so that the research conditions are objectified. Thus, the object of study in social sciences has very specific peculiarities that interact with

the researcher, namely with regard to the reflexive-relational capacity of the object, in that at the moment of interaction a situation is generated that is specific in itself and should not be ignored when explaining the actual process of research and the production of results.

Diversity should not be reduced by adopting common dimensions; that is, although it is possible to create an interface among the various scientific perspectives, erasing their diversity, the theoretical-substantive specificities should always be considered in addition to the actual nature of the object of study. Therefore, just as it is completely impossible to accede to intra-individuality, it is completely impossible to reduce to zero the effects on the observed agents of the application of research instruments. The actual discourse of the researcher leads to answers that fall within the range of what is considered desirable or expected as the ideal answer, according to an idealized relationship with the person or entity who analyzes the answers; this in turn unleashes an increase in the reflexive capacity of the observed agents, with more or less observable and lasting effects on the social fabric observed, during the actual research process.

Because it is not possible to research in a vacuum in social sciences, the object is not even there in the direct sense, the objectification of the theoretical priorities and methodological principles becomes important; this not only directs the researcher's way of looking at the object of study, but also controls the actual production of information, in articulation with the researcher's own individualized capacities. Hence, it is understood that different objects of study will be constructed around the same phenomenon in the name of creativity, which is very important to the scientist but which is very specific to each individual. In this way, an attempt is made to explain not only the differences but also the overlap among the various ways of producing scientific knowledge.

It therefore becomes necessary to break with common sense, that is, to be cautious about the preconstructed objects of spontaneous sociology. This, to a certain extent, is rooted in the cardinal rule of the Durkheimian method that social facts should be treated as things and that the main focus should be on dealing with how ("the thing"), on defining a mental attitude, and *not* on conferring an ontological status on the object itself.

The methodological position that is defended here implies not only an epistemological break with preconstructed objects and an attitude of epistemological caution, but also an attitude that systematically questions aspects of reality posed in relation to the questioning to which they are submitted in accordance with theoretical issue. Thus, the whole well-constructed experience results in the intensification of the dialectics between reason and experience and between theory and confirmation, but on the condition that the researcher knows how to think suitably about the results produced, even the

negative ones, questioning and specifying the reasons that lead to the results.

Generally speaking, this epistemological and methodological proposal leads to a cautious dialectical position between the theory and the facts observed and between objective and subjective conditions, in a cumulative process marked by breaks and discontinuities through which knowledge is constructed, which is itself in constant change. This position is removed not only from the holistic objectivist perspective of Durkheimian positivism, emptied of the social action meaning, but also removed from the individualist/subjectivist perspective of phenomenology and other forms of antipositivism, which inhibit comparative and causal analyses. Thus, in both a break from and a continuation of the classics, a theoretical-methodological perspective is adopted in the social sciences that overcomes the naïve radical position between positivism and anti-positivism. It gives structure to a tendency to stop the reduction of polarization around alternative paradigms, and orients research on the social toward the agents' self-reflexive capacity in the various fields, leading to the individual's role as structurer through interaction and as reflected in the various structuring dimensions of society.

Therefore, the emerging logic is one of syncretism, following a path of reducing the excesses of the micro/macro dichotomy. That is, neither methodological individualism nor methodological holism leads an open research process along the line of applied rationalism; but methodological situationalism, we believe, does. In short, the art of sociology is objectification, that is, trying to objectify all the research conditions in the actual empirical experience, without forgetting that it, in itself, is a social relationship in which actors (the scientists) find themselves playing a role in accordance with a specific *habitus*, an incorporated *hexis* that they included in a specific framework of objective properties and that influence and are influenced by the subjective expectations of the researchers in a specific field themselves.

Acknowledgments

The author thanks those colleagues and friends who read and commented on initial drafts of this entry, João Arriscado Nunes and Ruth Chadwick. He also thanks Cecil Williams for his translation of the Portuguese version into English and Kirsten Funk for all her support and for her editing work on the manuscript.

This work is based on the 1994 epistemological reflections in C. Diego's *Divulgação Científica um Sistema de Comunicação e Cultura. Entre Reprodução e Diferenciação*, which is awaiting publication by Cosmos Editora, Lisbon.

Glossary

confidence interval estimate The determination, with a specified probability, of a random interval that contains an unknown constant parameter value.

test of significance (Fisher) A test of the evidential relation of a sample to a hypothesis, based on the probability, conditional on the hypothesis, that the deviation of the sample or more extreme cases from an expected value will occur. If the probability is small (e.g., 5% or 0.1%), the hypothesis is deemed false or we judge that an improbable event has occurred.

test of significance (Neyman–Pearson) A test of whether a sample warrants a rule of behavior, assuming a given hypothesis as a basis for action, in terms of permissible likely long-term frequencies of Type I and Type II errors in repeated trials.

Type I error The rejection of a hypothesis in favor of an alternative, when the hypothesis is true.

Type II error The acceptance of a hypothesis in favor of an alternative, when the alternative is true.

Jerzy Neyman was one of the magisterial figures of statistical theory and application of the twentieth century. With a taste for foundational studies in mathematics, he brought to statistical theory a demand for clear logical grounding. In a remarkable collaboration with Egon Pearson, he contributed fundamentally to the development of hypothesis testing. He developed influential accounts of confidence interval estimation. He established the core theory of randomized stratified sampling. Throughout his career he was concerned, too, with many applied problems and he made influential contributions in agriculture, meteorology, sidereal astronomy, biomedical research and demography, fastidiously immersing himself in the fundamentals of each field.

Early Years

Neyman was born, Jerzy Splawa-Neyman, on April 16, 1894, in Bendery, Moldavia, then part of Russia. His father, Czeslaw Neyman, was a lawyer. Neyman's family had moved or been removed from what had been Poland, then under Russian, Austrian, and German occupation. After several moves and after the premature death of his father, when Neyman was 12 years old he and his mother settled in Kharkov in the Ukraine. Later, he took up studies at the university there.

Early Career

Neyman was particularly attracted to the foundations of mathematics, including set theory, measure theory, and the theory of integration, possibly stimulated by a deep impression made on him by the work of Lebesgue. He was sufficiently motivated to submit a 500-page essay on Lebesgue integration while at the University of Kharkhov. The essay earned him a Gold Medal.

He was influenced on a number of fronts by the prominent Sorbonne-trained mathematician Sergi Bernstein. Bernstein lectured on probability and statistics and was interested in their application to genetics and agriculture. In addition, he introduced Neyman to the philosophy of science of the British polymath Karl Pearson, arguably the doyen of the nascent field of statistical theory. Neyman later reported that for himself and other students at the time Pearson's uncompromising critiques of a variety of authorities seemed almost unbelievably bold. Pearson became a secular source for a group of young men whose orthodox beliefs had dissipated but whose need for authority had not. It seemed to Neyman's wife, Olga, that he talked of nothing but Karl Pearson. Whether by nature, impressed by this early influence, or both, Neyman was to

maintain a philosophical vision of his own work throughout his life, remarkably combining a profound commitment to logical clarity in the conceptual grounding of statistical devices with a prudent sense of the value of applied problems. Concrete problems not only had their intrinsic interest, but also their value as a spur to the development of good theory.

In 1921, Neyman found himself in the newly reconstituted Poland, having been included in an exchange of Polish for Russian prisoners at the conclusion of World War I. But it was not really repatriation for Neyman; it was his first time in the country. He was able to find a position at the National Agricultural Institute in Bydgoszcz; no matter the appeal of measure theory, it was his preparation in statistics that made him employable.

At the end of 1922 he moved to Warsaw and took up employment at the State Meteorological Institute. After that he became an assistant at the University of Warsaw and lectured in mathematics and statistics at the Central College of Agriculture. He also gave lectures at the University of Krakow. He finished his doctorate at Warsaw in 1924. By then Neyman was unique in Poland in his expertise and interests, and, in recognition of this, he was awarded a government fellowship which permitted him to work at the Galton Laboratory at University College London under the direction of Karl Pearson himself.

Neyman and Pearson on Hypothesis Testing

In London, in 1925–1926, Neyman was able to publish several papers in *Biometrika*, employing material that had been published in Poland with little chance of finding an international audience. He was disappointed to find that Pearson's laboratory was not up to date and that Pearson's mathematics was insufficiently modern. Indeed, it seemed to Neyman that Pearson was unwilling to comprehend the difference between independence and absence of correlation, and some strain developed between them, aggravated by Neyman's explanations in impoverished English.

With London now seeming less appealing, he opportunely won a Rockefeller fellowship that permitted him to move to Paris for a year. There, he was able to attend lectures by his revered Borel and Lebesgue and a seminar with Hadamard. Later Neyman remarked that, had it not been for the intervention of Egon Pearson, Karl Pearson's son, he would in all likelihood have returned to work on set theory, measure theory, and the theory of integration.

Researchers in hypothesis testing in the mid-1920s faced a scene that had been remarkably transformed in the previous decade, with new paradigms of statistical appraisal at hand, for the most part introduced by Ronald

Fisher between 1915 and 1925 in an almost single-handed revolution. There were new statistical devices and new criteria for their appraisal. Of particular interest were the new results on small-sample distribution theory developed by Student (W. S. Gosset) and Fisher, reflecting a shift in emphasis from the analysis of natural populations to controlled experimentation. Finding a principled basis for choosing between criteria of appraisal in, say, evaluating whether two samples had been drawn from the same population became important because different, equally intuitively plausible criteria yielded different significances from the same data. The stringency of test, in the sense of minimizing the tail-area p value, became a central preoccupation of a number of researchers, including Karl Pearson.

Addressing these issues, Egon Pearson initiated a correspondence with Neyman about the news of Student's suggestive observation that "if there is any alternative hypothesis which will explain the occurrence of the sample with a more reasonable probability . . . you will be very much more inclined to consider that the original hypothesis is not true." This was a not unambiguous proposal, and Neyman did not immediately recognize its import. Although Neyman endorsed Student's insight, he initially read it as implicating Bayesian-style *a priori* probabilities, to which he was at that time still sympathetic. Pearson, however, had a reasonably clear idea that the crucial element was the introduction of an uneliminable role for the alternative hypotheses in tests of significance. This was to be, of course, a central innovation in the Neyman–Pearson accounts of hypothesis testing. It was also an important departure from the model of significance testing that had been advocated by Fisher and, indeed, Fisher would resist the innovation throughout his lengthy career. Pearson did, however, maintain Fisher's central role of the concept of likelihood. Neyman found the viewpoint compelling, although at the same time he was more skeptical than Pearson and looked for a deeper rationalization of the likelihood principle. He was more guarded about embracing its universal applicability in the adjudication of test statistics.

Pearson visited Neyman in Paris in spring 1927, and it is likely that they then set out the plan of their first joint paper, "On the Use and Interpretation of Certain Test Criteria for Purposes of Statistical Inference. Part I," which was accepted by Karl Pearson for *Biometrika*. Already Pearson was opposed to Bayesian inverse probabilities, they flexibly formulated a range of different approaches, direct and inverse, to the problem of determining whether a single sample may plausibly be taken to be drawn randomly from an assumed population. Having introduced a role for an alternative hypothesis to the hypothesis being tested, the authors noted that two sources of error become clearly identifiable: (1) rejecting the test hypothesis when it is true and (2) retaining the test

hypothesis when the alternative hypothesis is true. The authors noted the essential role of likelihood to which Fisher had drawn attention in the early 1920s.

In part II of their paper, also published in *Biometrika*, Neyman and Pearson brought the likelihood ratio approach to bear on the grounding of Karl Pearson's χ^2 test, the merits of which had been hotly debated in the early 1920s. The second paper made the distinction between simple and composite hypotheses even more explicit than part I had. Neyman, alone, followed part II with what might have been part III were it not that Pearson felt unable to put his name to it. The paper was published as Neyman's "Contribution to the Theory of Certain Test Criteria" and it offered interesting results, showing convergence in the results of direct and inverse methods. Pearson was not happy about the seemingly sympathetic application of Bayesian methods and possibly found the mathematical character of the paper too extreme. It is likely that his interest in the convergence of results from distinct approaches, and possibly the continued attention of Bayesians such as Harold Jeffreys, motivated Neyman to pursue these parallel approaches.

Despite Pearson's withdrawal from that paper, their collaboration was far from over; in fact, the best was yet to come. The next steps included extending the application of the likelihood principle to the problem of drawing two samples from given normal population, building on the appraisal of several proposed criteria by V. Romanovsky. The result vindicated applications of the *t* and *F* tests. The resulting paper, which extended the likelihood principle to the case of an arbitrary number of samples, concluded by commending the principle for its capacity to "deliver the goods" in important problems, validating previously intuitively sound tests and discovering new ones.

Despite his preoccupation at this time with establishing a Biometric Laboratory at the Nencki Institute for Experimental Biology in Warsaw, Neyman was able to start a new initiative—applying the calculus of variations to optimizing the avoidance of error. He intended to find a firm foundation for the likelihood principle. The result was the benchmark joint paper of 1933, "On the Problem of the Most Efficient Tests of Statistical Hypotheses," published in the *Philosophical Transactions of the Royal Society*. Representing the choice of a criterion for testing a hypothesis against an alternative hypothesis as the choice of a critical region in the sample hyperspace, Neyman and Pearson proved the Neyman–Pearson lemma that, for a simple hypothesis and alternative, the "best" critical region, which minimized Type II error at a given risk of Type I error, is picked out by the likelihood ratio principle. Under supplementary constraints, they successfully applied the same strategy to the case of composite hypotheses. In addition, the concepts associated with the uniformly most powerful (UMP) test appeared.

In their *Royal Society* paper, Neyman and Pearson offered a new methodological viewpoint, conceiving of tests as guides to rules governing behavior rather than as inference devices that determine the truth or falsity of hypotheses. Initially, the decisions in question were those of acceptance and rejection, so that a less than prescient reader might take the new viewpoint to be rather innocuous, although serving as a convenient vehicle for linking the costs of acceptance and rejection to the statistician's not being wrong too often. The authors more overtly alluded to Laplace's problem of determining the number of votes of a jury sufficient for conviction, and clear economic and even ethical values are acknowledged to influence the cost of error.

Some of the same ambiguity between epistemological and practical decisions is preserved in their paper "Statistical Hypotheses in Relation to Probabilities A Priori," which applied their strategy to frameworks that appeal to *a priori* probabilities. The paper examined what could be derived from data independently of variation in priors. Notably, they wrote of the different viewpoints possible expressly within the context of scientific inquiry rather than in merely practical and commercial contexts. On the one hand, the researcher may take a hypothesis to be novel and important in scientific terms and not wish to give it up lightly, thus setting the rejection level particularly low. On the other hand, investigating deviations from a standard law, the researcher sets the level high in order to lower the risk of Type II error. However, in "Contributions to the Theory of Testing Statistical Hypotheses," which explored the means for bypassing the difficulty that many problems were not tractable in terms of UMP tests, their exposition of their general approach gave clear priority at the outset to two cases from commercial batch appraisal—one concerning electrical goods, the other pharmacological.

Later, in his *Lectures and Conferences on Mathematical Statistics and Probability* in 1937, Neyman made more explicit his preference for the notion of "inductive behavior" over "inductive reasoning." There he emphasized a more voluntarist notion than hitherto—the crucial phase of deliberation was not reasoning at all but rather an act of will. Problems such as batch acquisition in commercial contexts were easier to solve for definite quantitative costs and benefits than were problems in narrowly scientific work. In such problems, it was often a relatively straightforward matter to adjudicate the particular balance between the permissible risks of Type I and Type II errors. The association of statistical procedures with decision rather than inference and Neyman's denial that belief and conclusion were the appropriate conceptions of the outputs of the procedures received stiff opposition, most notably from Fisher. Although Fisher commended the economically sound methods that might assist the Royal Navy in prudently buying batches of shells for

naval guns on the basis of limited sampling of the product, he felt that establishing a reliable scientific body of information, even in as practical a field as agriculture, needed inference, properly speaking. It is no secret that, for him, the disdainful expression “statistics for shopkeepers” was aimed at Neyman’s and Pearson’s conceptions, together with their generalization to Abraham Wald’s statistical decision theory, which had an overtly game-theoretic stance. (There is some evidence that Egon Pearson did not really share Neyman’s inductive behaviorist viewpoint.)

Neyman on Confidence Interval Estimation

Neyman had started on the problem of confidence interval estimation in 1930 in Warsaw, spurred by a request from Pytkowski for a measure of the uncertainty of an estimate. At that time he had been aware of neither Fisher’s formulation of fiducial probability and fiducial limits nor Hotelling’s application of confidence intervals to Student’s t test. He lectured on his approach for several years in Warsaw and then in London, where Egon Pearson was able to find an appointment for him in the Department of Applied Statistics, which had been split off from the Galton Laboratory when Karl Pearson retired and was replaced by Ronald Fisher.

Neyman applied his approach in his paper “On the Two Different Aspects of the Representative Method.” This contribution may be thought to be doubly revolutionary. First, it offered a decisive repudiation of the purposive selection form of sampling and established a theoretical base vindicating random sampling. This work provided a valuable and original platform for much work in sampling theory. In his discussion, Fisher declared Neyman’s account to be “luminous.” Second, it was the first English-language application of Neyman’s method of confidence intervals, giving prominence to its rejection of inverse inference methods. In the face of Neyman’s relating his confidence intervals to Fisher’s fiducial intervals, Fisher voiced the compliment that it was a “handsome” generalization, although he had reservations about the assumptions that made it possible. Unfortunately, Fisher’s goodwill evaporated after Neyman’s presentation of arguments that Fisher’s z test displayed bias in Latin square and randomized block designs in March 1935, results that, according to Fisher, demonstrated that Neyman did not properly appreciate the intent of such tests.

Neyman came to judge that the underlying intuitions of Fisher’s fiducial conception defied consistent expression in mathematical terms. Fisher’s restriction of the scope of application of fiducial distributions and limits to cases in

which there existed sufficient statistics seemed to Neyman to be in itself undesirable and to provide a motivation for finding a more general and explicitly articulated statistical theory. This debate has continued since that time, and there are still widely divergent opinions on the merits of the respective camps, with some authors identifying the Fisher and Neyman approaches, others insisting on the merits and intelligibility of a unique concept of fiducial probability, and yet others identifying the fiducial approach with that of the Bayesian school.

It was only in 1937 that Neyman’s systematic treatment of the interval estimation material appeared in “Outline of a Theory of Statistical Estimation Based on the Classical Theory of Probability.” Here the method of confidence intervals was scrupulously based on a frequentist interpretation of probability, and Neyman emphasized the crucial point that interval limits were the random variables, not the estimated population parameter, which was in effect an unknown constant. Although Neyman had long given up his early preference for a Bayesian approach, thinking that the Bayesians confused real mathematical probability with a certain psychological feeling, he cheerfully credited the urgings of his student, Churchill Eisenhart as the last straw. It is plain that Neyman was profoundly influenced by the advocacy of the frequentist approach of Richard von Mises.

Neyman in the United States

In July 1935, Neyman was appointed Reader at University College. In time, he became increasingly convinced that his chances of being appointed to a professorial chair were slender. He assumed that Fisher would attempt to obstruct such an appointment—he had voted against Neyman for Reader. Further, he felt that there was little chance of being appointed to a chair in Poland, to which he felt drawn out of gratitude for the support of colleagues and a particular loyalty to his students, to whom he often referred as “my pups.” Neyman had been aware of his Russian wife’s discomfort at the hostility from some Poles, remembering the Russian occupation. In addition, he was aware that his marshalling of data that indicated the extent of the Polish Catholic Church’s holdings of the nation’s wealth had earned him the enmity of prominent figures there. He had been informed that there was no chance that he would ever hold a chair in Poland. In addition, the political tensions in Europe were becoming dangerously threatening.

In 1937 he gave some lectures in the United States, having been invited to make presentations at the U.S. Department of Agriculture. His lecture notes were compiled into a celebrated and influential mimeographed edition of *Lectures and Conferences on Mathematical Statistics and Probability*, already mentioned.

A substantially revised edition was published in 1952 and became the canonical statement of the Neyman's statistical theory.

In 1938 he accepted a professorship in the Department of Mathematics at the University of California at Berkeley. There was a lack of statisticians there; the department was a blank slate on which Neyman could write. He moved rapidly to establish a Statistical Laboratory with himself as director.

After the end of the Second World War, Neyman established a symposium on probability and statistics that attracted the participation of preeminent figures in statistical theory, probability theory, and applied statistics. The striking success of the symposium was confirmation of Neyman's stature and of University of California at Berkeley's standing as one of the great centers for the field. A series of Berkeley symposia followed, another five over the next quarter century, and their publication is an invaluable resource for statisticians of all stripes—their influence can scarcely be overstated.

Neyman's revolutionary achievement of the 1920s and 1930s could scarcely be duplicated; inevitably that very achievement required its own elaboration and generalization. Neyman's work did, however, retain its quality, inventiveness, and commitment to grounding in first principles. One widely regarded achievement was the delineation of best asymptotically normal estimators. These have asymptotically normal distributions and, in addition, satisfy other appealing constraints, such as consistency and asymptotic efficiency, while not falling prey to the complexity of computation associated with maximum likelihood estimators. Neyman, with Elizabeth Scott, who became a frequent collaborator, discovered cases of inefficiency and inconsistency of the maximum likelihood estimator.

Lucien LeCam neatly captured Neyman's strategy for addressing problems in applied fields. Neyman's preference was to build and use stochastic models

from Astronomy to Zoology following a consistent philosophy throughout: Given a question about a particular phenomenon, Neyman tried to visualize the "mechanism" underlying the phenomenon. He then translated this vision into mathematical assumptions and formulas. After devising the stochastic model to his satisfaction, he would derive the statistical methods appropriate to the case at hand.

Neyman's outlook was somewhat at odds with his early sympathy with Karl Pearson's philosophy of science, which treated scientific models as mental constructs and which provides little principled basis for the view that, as LeCam put it, "it is better to catch a bit of the mechanism than to use sundry 'interpolation' formulas."

With Scott, Neyman developed a model for epidemics based in part on work he had done in the late 1930s on

contagious distributions that had been aimed at evaluating the effects of insecticides on larvae. In the earlier work too, his priority had been to guess "the actual machinery" of movements of larvae rather than simply to model the data. Remarkably, he and Scott discovered that the probability of an epidemic becoming uncontrollable in small community was the same as in the population at large.

Some of the same models were applied by Neyman and Scott, who had migrated from astronomy to statistics, to questions about the clustering of galaxies. Their work on these problems continued for many years and has considerable intrinsic interest, although it has been outflanked by new developments in cosmology. Other areas to which Neyman and his collaborators applied themselves included multistage models of carcinogenesis, natural selection or the struggle for existence, and the interaction of radiation on cells. In 1955, as a result of Neyman's great determination and intense efforts, Berkeley agreed to the establishment of a Department of Statistics distinct from the Mathematics Department.

At his retirement, a move was made to keep Neyman on as director of the Statistical Laboratory, an office he had kept after stepping down as chair of the Statistics Department. It was recognized that it would be an enormous blow to the stature of the admittedly distinguished group to lose his official presence and the administration agreed. Amusingly Neyman began signing his letters as Director of the Laboratory "Recalled to Active Duty."

Conclusion

Neyman lived through times of considerable turmoil. Polish by descent, he was born in Russia. He did live in Poland for a time but did not form, as he put it, "a geographic attachment," although he was deeply committed to his Polish colleagues and students. He was also particularly aware of Poland's intellectual heritage and took great satisfaction in editing *The Heritage of Copernicus: Theories More Pleasing to the Mind*. He was observed reading Copernicus fluently in the Latin he had learned as a youth. He lived in England for some years, but crucial parts of his collaboration with Egon Pearson seem to have taken place as much in brief meetings on the continent as in England. However, he spent half his intellectual life in the United States and seemed genuinely to have felt at home, no longer a stranger in a strange land. As he put it: "In 1921, I finished my studies in Russia, and I was an alien. I came to Poland, and found myself an alien. I went to Britain, and found myself an alien. By 1938, I was feeling, all around, like a professional veteran alien. And then I came to California, and here I stopped being an alien." Jerzy Neyman died in Berkeley on August 5, 1981 at the age of 87.

Nightingale, Florence

Gabriel K. Wolfenstein

University of California, Los Angeles, Los Angeles, California, USA

Glossary

Adolphe Quetelet Belgian statistician and astronomer (1796–1874), whose application of statistics to social phenomena was central to the practice of statistics in the 19th century.

Crimean War Conflict (1853–1856) between Russia on one side, and Britain, France, and the Ottoman Turks on the other, over control in the region.

miasmatic Theory of disease popular in the 19th century that suggests that poisonous atmosphere emanating from unsanitary conditions causes illness, as opposed to a contagionist theory.

probationers Florence Nightingale's technical term for nurses.

William Farr British statistician (1807–1883), in charge of the statistical section of the General Register Office and a leading authority on vital statistics. He had a significant impact on Nightingale.

zymotic Term created by William Farr to identify infectious and epidemic diseases, specifically caused by a ferment-like process.

The history of modern nursing has become linked with the name of Florence Nightingale (1829–1910), the Lady with the Lamp as she was widely known in the 19th and early 20th centuries. Yet like all historical figures, the history her life reveals is multifaceted. Often portrayed as a sainted hero, she was a shrewd political player who made effective use of her (perhaps psychologically provoked) invalidism to push her reforms. Though her impact has been considerable, her innovations in health care and in the use of statistics must be understood as emerging out of her historical milieu. The story of nursing as a profession does not begin with Nightingale, and we

need to be careful not to be directed by her still powerful manipulative skills. But while nursing had a history before Nightingale, she remains central to understanding the changes that took place in both nursing and in health care during her lifetime.

Introduction

Even before her death, Florence Nightingale was known not only as a founder of modern nursing but also as one of the major figures in hospital reform in the 19th century. Though *The London Times* proclaimed her heroism for the saving of British casualties during the Crimean War (she was perhaps the only British hero to emerge from that conflict), it was her work subsequent to the war that secured the historical legacy that we still contend with today. In some ways the popular story of Nightingale as creating the first modern nurses—if not fashioned certainly encouraged by Nightingale and her supporters—has changed little over the course of the century. Though Lytton Strachey exposed the world to a Nightingale different from the admired heroine, demonizing her in his 1918 *Eminent Victorians*, her public persona survives mostly unscathed.

The Metropolitan Life Insurance Company, for example, placed her in their “Health Heroes” series, preserving her image intact, though some influence can be detected from Strachey's work. “In the popular imagination,” wrote Grace Hallock and C. E. Turner, “she was the Lady of the Lamp, the Angel of the Crimea, the tender woman whose shadow the soldiers kissed as it fell on their pillows.” But, they said, there was another side to her; she was also “an angel with a flaming sword. Her mind was the sword . . . Ruthlessly she bared the easy-going inefficiency which hitherto had made a disgrace of sanitation and nursing, both in military and civil life.” She was both nurse and

reformer. The recent online edition of the Encyclopedia Britannica defines her primarily as a “nurse and the founder of trained nursing as a profession for women,” placing less emphasis on the other important aspects of her life.

However, both Florence Nightingale and the changes in health care which she spearheaded and inspired are far more complex, as recent scholarship has made clear. To this end, the body of this article will proceed in three parts. It will first examine her life to the point when she returned to England from the Crimea. The second section will contextualize her reforms in hospitals and nursing. The third section will discuss her use of statistics, especially as a tool of persuasion.

Florence Nightingale: Early Life and the Crimean War

Florence Nightingale was born May 15, 1820, in Florence, Italy and was named for that city, though she spent much of her childhood in the family house in Derbyshire. Her family was well-to-do. Her father, William Edward Nightingale, was wealthy, and her mother Fanny Nightingale, née Smith, came from a well-known and affluent family. This provided her with political connections, such as a friendship with the future prime minister Lord Palmerston, and the future cabinet minister Sidney Herbert.

She had no formal schooling—as was the norm for women at her time—but was well educated, taught at home at the insistence of, and primarily by, her father. William was a Cambridge-taught man, and perhaps more importantly, a Unitarian. As such, he felt that it was not only young boys who should be educated and cultured, and young Florence benefited from that belief. Her lessons included the standard fare for a young woman: music and drawing taught by the governess. But her father supplemented this with a rigorous, though somewhat superficial, course of study, which included: Latin, Greek, German, French, Italian, philosophy, and history. In addition, she discovered an interest in mathematics and was able to persuade her family to provide her with a tutor for some weeks on the subject. Although it is impossible to know her level of ability, we do know that she had a real fascination with the subject, and sought out a number of the leading mathematicians, statisticians, and men of science of her day. She met Charles Babbage and was a guest of Ada, Countess of Lovelace. She knew Edwin Chadwick, had heard Faraday speak, corresponded with Adolphe Quetelet, and was a close friend of William Farr.

Though she apparently evinced concern about her fellow creatures from a young age—from “her earliest years her strong love of nature and animals manifested itself. Her games, too, were characteristic, for her great delight

was to nurse and bandage her dolls”—nursing was initially closed to her. Her parents had forbidden her to take up that mission (she had heard God call her to work in hospitals in 1844), as her father saw nurses as among the most dissolute members of society. William Nightingale would have recognized Sarah Gamp, whose face was “somewhat red and swollen,” and whose society “it was difficult to enjoy . . . without becoming conscious of a smell of spirits,” as more than just a literary creation of Charles Dickens in *Martin Chuzzlewit*.

This vocation denied to her, she turned to the study of medicine and health care. She was self-motivated, studying by herself many mornings. It was at this time, when the rest of the family was still asleep, that she studied the governmental blue books and other statistical documents relating to the state and health of the nation. She researched in the field as well, examining some London hospitals. Thus before even leaving the confines of her family, she already had some degree of expertise and interest in the subjects of public health and hospital administration.

In 1851 she was finally able to escape her family, and she spent three months working near Düsseldorf at Pastor Theodore Fliedner’s Kaiserwerth hospital and orphanage. The stay at Kaiserwerth was particularly important, as it provided her with a model for a dedicated nursing sisterhood. Fliedner had created deaconesses—peasant women whose faith helped shield them from the stigma of poverty—to care for the indigent. Though critical of the conditions at the hospital, Nightingale would later draw from this configuration. After this she served as an apprentice at a hospital near Paris, operated by the Sisters of Mercy. Following this experience of the nursing profession first hand, she was able to obtain a position as a Superintendent of a Harley Street facility in London for the “Sick Gentlewoman in Distressed Circumstances” in 1853. Though unable to formalize any nursing training program, which was her great desire, she was able to put her administrative ideas into practice, and brought the accounts into order. She also began to demonstrate an awareness that reliable statistics were vital in effecting improvements.

Her life was soon to undergo a drastic change. In 1854 the British and French invaded the Crimea, supporting their ally Turkey against Russia. After an early victory, a long siege set in at the naval base at Sevastopol. The death rates among the sick and wounded were high, but this made the military hospitals in the Crimea no different from their counterparts anywhere else at the time. What was different, was the fact that for the first time there were regular newspaper updates, as *The Times* had correspondent William Howard Russell on the scene. When his reports reached London (and the rest of Britain) stating that British soldiers were dying for want of medical attention, and that there were no trained nurses at the

British military hospital at Scutari, there was public outrage and uproar.

Nightingale, though deploring the situation, also saw in it an opportunity to implement her ideas about trained nurses, sober women who could effectively help doctors even in the horrors of the hospital. She wrote to her friend Sidney Herbert, at that time Secretary of State for War, to volunteer her services. She was not to be disappointed. In fact, Herbert had already sent her a letter asking her to gather a group of trained nurses to serve in the Crimea in a manner which agreed with her aims. "If this succeeds," said Herbert, "an enormous amount of good will be done now . . . and a prejudice will be broken through . . ." When news of her planned service became public, *The Times* raised a significant fund, which she controlled, to aid in her efforts. So less than a year after she had taken her Superintendent position on Harley Street, she left for the Scutari Hospital near Constantinople, where the casualties from the Crimean War were being taken for "treatment."

She soon discovered that the newspaper reports had not exaggerated; the conditions were dreadful. The troops who made it to the hospital—that is, those who had not died from exposure or starvation—had at best a 40% survival rate within its walls. The hospital itself was infested with all sorts of vermin and insects. In addition, it was built on a sewer, which discharged air into the hospital itself. Both surgical and medical equipment were in short supply. Most British soldiers in the Crimea died not from their wounds, but from frostbite, lack of food, or due to post-operative infection with cholera, dysentery, or typhus.

Nightingale's time in London served her well, for the most important changes she was able to effect were administrative. Despite being hindered by the military, who resented her independence from their chain of command and the fact that she was a woman, she was able to make major progress in terms of patient cleanliness and supplies, significantly aided by the funds at her disposal. Thus she was able to cause specific improvements, such as the creation of a laundry, complete with boilers for the heating of water. Most importantly, though, her monetary resources allowed her to supply the entire hospital. This, she initially felt, was the key to higher survival rates which began to appear approximately four months after she arrived. "The men sent down to Scutari in the winter died because they were not sent down till half dead—the men sent down now live and recover because they are sent in time," she told Lord Panmure in August of 1855.

She was not only an administrator. Her nightly rounds comforting the sick and wounded created the legend of the lady with the lamp. She had banned the other nurses from the wards at night, as a way of enforcing good conduct and maintaining order: such were the central tenets of her ideas about nursing. Some nurses had been sent

home for "delinquent behaviour," although much of that may have been for disobeying Nightingale as for "dissoluteness." This word covered activities ranging from drinking to fraternization. In the end she felt her time in Scutari had been a great success. It demonstrated the viability of nurses and the care of the soldiers, though the latter probably had to do more with the end of winter and the changes instituted by the Sanitary Commission than with her reforms. Whatever the case, she was credited with the improvements, and when she returned to London from Scutari in 1856 she was a national hero. Though for reasons that remain unclear, she became an invalid from 1857 and remained one (though she regained some mobility after about 10 years) to the end of her life, this did not hinder her impact. Indeed, she became an even more active force for change and reform.

Nightingale and Changes in Nursing and Hospitals

She had already been well known by the time she reached the Crimea, but it was her work, and the reports of it, that made her a household name. This provided her with the political power to push through reforms in health care in the military, as well as to establish nursing training programs that helped to raise the respectability of nursing as a profession. She claimed not to enjoy the publicity, but she used it very effectively to her advantage. Nightingale was able to use her illness in a similar manner. Soon after her return from Scutari she became ill, and would spend the rest of her life often confined to bed. Yet she made excellent use of her confinement, diagnosing her illness to suit correspondents, and making herself more or less available as political situations warranted. "She conscripted her very body to her cause." She was able to parlay her fame, through her authoritative personality and political persuasion, into official support for the sanitary reforms that Scutari had convinced her were necessary.

Upon Nightingale's return, Sidney Herbert set up a committee to raise funds for the training of nurses in a teaching hospital in London. The response was overwhelming, raising nearly 45,000 pounds, and she was able to move forward with her plans. The first issue was one of location. The school was set up at St. Thomas's, though she was less than pleased when it later moved to Lambeth (she wanted a facility in the suburbs). It was not immediately successful, as there was attrition due to ill-health and dismissals for misconduct. Gradually, though, it became more productive, and effective publicity served to support its revolutionary image, and export its ideas.

Nightingale required her nurses, probationers to use the official title, to be "sober, honest, trustworthy,

punctual, quiet and orderly, cleanly and neat.” There were, of course, specific tasks and certain sets of knowledge required, but the core of her system was one of control and discipline. It was a hierarchical system, with the matron of the hospital having absolute control of all matters related to nursing. Such an arrangement, was not new. The idea that nurses should be clean, presentable, and well behaved predates Nightingale. This should not be surprising, as it was the religious orders that made up an active nursing population whose history goes back to the middle ages. In France, for example, the Sisters of Charity or the Augustinians of the Hôtel-Dieu de Paris were devoted, organized, and professional nurses who would have satisfied Nightingale’s regulations for her probationers.

Even in the English case nursing reform has a longer trajectory than the Nightingale legend suggests. Religious sisterhoods, a number of which were founded in the 1830s and 1840s, provided nursing care both in and out of the hospital (Nightingale herself drew upon this resource in her work in the Crimea). It is important to remember that Mrs. Gamp was a Dickensian type—not all nurses behaved like she did. Why does the story retain such power? Part of the reason for the equation of Nightingale with modern nursing is due to Nightingale herself. Nurses in hospitals, she said, “were generally those who were too old, too weak, too drunken, too dirty, too stolid, or too bad to do anything else.” Such a story was an effective political device to make a strong case for the necessity of reform among a middle class that had no problem seeing the working class as dissolute. Nightingale’s belief, and her tactics, became entrenched in the history of nursing.

This is not to suggest that Nightingale offered nothing new. What was different was the systematization and professionalization of nursing outside a religious framework, which pushed beyond class boundaries. This gave career and status to the women who pursued the occupation. As changes in hospitals over the second half the 19th century led to better hygiene, the Nightingale system was gradually adopted, in whole or in part, as an effective way to encourage that end.

But while some facets of the system still survive, and the popular image of the comforting nurse has not lost its power, nursing as envisaged by Nightingale is very different from the modern form. Nightingale’s nurses were not to be educated, technically capable individuals, a central part of a health care unit. Nightingale wanted her nurses to be obedient, to conform to a general pattern as her directives for probationers indicate. The people she envisaged as nurses came from a variety of classes, often with little education, and she sought to instill a type of behavior, rather than an education. Their role was at base a moral one, as her 1860 *Notes on Nursing: What it is, and What it is Not* makes clear. “The everyday management of a large ward, let alone of a hospital . . . [does] not come

by inspiration to the lady disappointed in love, nor to the poor workhouse drudge hard up for livelihood.” For Nightingale, to take up nursing is to take up a vow no less serious than a religious one.

We can see a similar complexity in her hospital reforms. As suggested at the outset, the rise of the modern hospital seems inextricably linked to Florence Nightingale. The popular story suggests that her experience in the Crimea, and her subsequent calls for reforms appear to lead directly to the present-day hospital. Indeed, its three central components—the trained nurse, the hygienic design of the hospital itself, and its orderly administration—all seem to have their origins with her in this narrative.

But, similar to her ideas about nursing, Nightingale’s understandings of hospitals and medicine had their basis in far older ideas. Indeed, Charles Rosenberg has convincingly argued that it was the very knowledge of those ideas that made her so successful, that “much of their power lay not in novelty but in their familiarity.” Nor were they all the grim places of legend. Nineteenth century voluntary hospitals, for example, had a mortality rate as low as 10% of admissions, though patients with acute conditions would not have been admitted.

Her idea that hospitals should be clean, well-ventilated places was tied directly to the dominant idea of disease causation, a variation of which she learned from Farr; the miasmatic theory that ran well through the 19th century. If the atmosphere was the primary spreader of infection, then logic dictated that hospitals should be as well ventilated as possible. The bulk of Nightingale’s teachings “were no more than applications of these well-worn speculations—underwritten by the new-style plausibility of statistical analysis.” Yet the social and political power she wielded allowed her to make effective use of these well-worn ideas. Her emphasis on the centrality of nurses to the functioning of the hospital, combined with an efficient administration and the physical space itself made her ideas seem original and powerful.

It is, therefore, important to remember that Nightingale was not a convert to the new ideas of disease causation that were emerging in the 1870s. Her ideas “reflected a vision of the world in which volition and disease, environment and regimen, body and mind were woven together so as to create a meaningful structure into which health, healing, and disease could be placed.” The ferment model readily explained how atmosphere served as a medium for the transmission of disease, and therefore also fit into Victorian social conceptions. That disease should run rampant in the crowded hospital, no less than in the squalid and cramped tenement house, was no surprise. This also fit into Nightingale’s socially reforming mindset. Much as in the hospital, she suggested, if the atmosphere were monitored in the homes and schoolrooms and factories, scarlet fever, and other ills would vanish. “If infection exists,” she argued, “it is

preventable. If it exists, it is the result of carelessness, or of ignorance.” Hospitals, then, were not a place for cure, but were rather a place where the body would be encouraged to heal itself, to regain its natural balance. Her strong belief in the power of fresh air to fight all manner of contagion—physical and moral—is based firmly in this manner of seeing the world.

Just because her ideas were not new should not imply that her reforms were unneeded, that hospitals were bastions of health prior to the reforms inspired by Nightingale, or that the role for women in hospitals was unproblematic; far from it. Though perhaps not always the “sinks of human life in an army” that Benjamin Rush proclaimed them to be, if seriously ill, one undoubtedly had a better chance of survival at home than in the ward. Yet the basis of her reforms are to be found in her time, and we should not mistake similarities in form for similarities in worldview.

Nightingale and the Importance of Statistics

As her modern reputation demonstrates, both in terms of the emergence of the professional nurse, and their role in the functioning of the hospital, Nightingale and the reforms attributed to her were quite successful. Much of that success was based upon her changing ideas about disease after her return from Scutari, and her ability to convince a wider audience that the changes she envisioned were necessary. It was at this point that she turned to statistics, for she saw in them the best way of convincing people of the necessity of her reforms. Though Nightingale certainly had an interest in statistics and hospital administration prior to, and during her, stint in the Crimea, in order to understand her use of statistics it is important to examine her relationship with Dr. William Farr, head of the Statistical section of the General Register Office (GRO), and probably the most famous, if not the leading, British statistician of his day.

Though trained as a doctor, Farr made his name in the collection and publication of statistics, primarily vital statistics, in the over 40 years he spent in the GRO. Farr’s statistical work was not primarily mathematical in nature. Rather, he used the information collected by the GRO to produce practical recommendations, based largely upon his “zymotic” theory of diseases, illnesses spread by air or water, rather than direct contact. The tables he produced were primarily data presentation. There was little in the way of mathematics. Nightingale’s statistics and medical understandings were of a similar nature. Indeed, it was thanks to her work with Farr in analyzing mortality rates in different areas in the Crimea that she came to believe

that bad hygiene, rather than entangled supplies, were responsible for the high death rates at her hospital. This realization perhaps contributed to her invalidism, as it has been suggested that her (self-serving) illnesses were a psychological response to her recent belief regarding her own ineffectiveness at Scutari.

Whatever the case, from the time of her return from the Crimea she and Farr had become close associates. When the commission to study the state of sanitation in the British Army was formed (in response to Nightingale’s prodding), Farr presented statistical evidence to the committee and testified before it. He also was appointed to a position that looked into the sanitary state of India thanks in large part to Nightingale’s patronage. They worked closely on many of her most statistical publications, including the influential *Notes on Hospitals* (1859) and her *Introductory Notes on Lying-in Institutions* (1871).

She was not a clone of Farr. Though she believed in the value of statistics, especially as a tool for convincing people of the need for change, Nightingale recognized the difficulty even educated people had with the pages and pages of statistics produced by the government. To this end, she was the pioneer in the use of diagrams to convey statistical information.

In 1857 she reported to the politician Sydney Herbert: “I have written to Dr Farr for the diagram which is to affect thro’ the Eyes what we may fail to convey to the brains of the public through their word-proof ears.” She was referring here to her now famous “coxcombs,” which were a type of piechart that showed the mortality rate of the British Army. Prepared under Farr’s supervision, they were Nightingale’s creation. She knew that only “scientific men” look at the statistics that accompany official reports, but felt that her diagrams would make the statistics more effective and persuasive. She created and utilized polar-area charts, and made effective use of line diagrams as well as pictorial representations to make her statistical arguments more effective.

We should not, however, forget that her belief in statistics was predicated on her social and religious conceptions. For all her practical interest in the use of statistics she also felt that through numbers the laws of society could be discovered. It was here that she diverged from Farr, who felt that statistics should be “the driest of all reading” and she turned to Adolphe Quetelet. Nightingale met Quetelet in 1860 when the International Statistical Congress was held in London. She was an active participant after a fashion (she was bedridden as always for most of the decade). But a paper of hers, wherein she proposed to create uniform medical statistics for hospitals to aid national and international comparisons, was one of three that were discussed at the Sanitary section of the Congress. There were practical difficulties with her suggestions, as there was no generally accepted theory of communicable disease at the time—there were probably

more people who still held the miasmatic or anticontagionist rather than the contagionist theory of disease. Nevertheless, her proposals were generally accepted.

In Quetelet's work she found resonances with her own search for the divine in social laws. "I never read Quetelet's *Physique Sociale* (which I have done over and over again) without being astounded at the force of genius and accurate observation which has produced such a work." It fascinated her on multiple levels. On the one hand, she was quite interested in the practical applications for statistics, as seen in Quetelet's work on mortality rates. In addition, his search for the average man, *l'homme moyen*, gave voice to her own spirituality and belief in improvement, as the average man represented the state of humanity. For her, Quetelet's study of moral statistics were to be understood very much in religious terms. "[H]is was the very highest kind of religion: the seeking in the Laws of the Moral World which he has done so much to discover the action of plan of Supreme Wisdom and Goodness" she told Farr.

Though these interests did not manifest themselves in her use and manipulation of statistics, they lie at the heart of her belief in their truth value, and their utility in her mission of social reform and improvement. She should, thus, be remembered as one of the earliest, and most successful, promoters of the practical application of statistics, rather than a modern statistician. Her ability to bring her own and others' data to the attention, interest, and comprehension of a general public through charts and graphs represented something new in the history of statistics and social measurement. The clear connection she drew between reliable data and policy decisions also should be noted.

Conclusion

The year 1872 marked a change in her life, as she gradually withdrew from political life, "went out of office," as she put it. Though she continued to take an interest in sanitary reform, her activities were much more peripheral for a variety of reasons. One, of course, was her continued ill-health. Another was the fact that a variety of her political friends and allies had begun to leave office or die. Sydney Herbert had died in 1861, and Palmerston in 1865. Farr would die in 1881. Simultaneously, she had begun to pursue friendships of a more philosophical, rather than political, nature, as her relationship with Benjamin Jowett, the Oxford classical scholar, shows. Moreover, she was forced to take a more active role in family affairs, especially caring for her parents.

Florence Nightingale died on August 13, 1910. In 1857 Henry Wadsworth Longfellow had written "Santa Filomena." It read, in part: "Lo! in that house of misery/A lady with a lamp I see/Pass through the

glimmering gloom/And flit from room to room." Florence Nightingale's work and exploits during the Crimean War had made her a hero, and poems like Longfellow's combined with her own tactical prowess served to solidify her status and her legend, which survives to this day. Indeed, the history of modern nursing has become virtually synonymous with the name of Florence Nightingale, the Lady with the Lamp. Yet like all historical figures, the history her life reveals is complex and contradictory. She invented neither nursing, nor the changes in health care that she called for. But while nursing had a history before Nightingale, one cannot discuss the changes in both nursing and in health care without discussing her. She was not ahead of her time, rather, she was preeminently of it. In her ideas about medicine and administration, in her use of statistics and her push for sanitation, she reflected the beliefs and advances, and made use of the intellectual tools, of her age. However, it was in implementation that she had the greatest impact. She brought all these advances together in her skillful manipulation of the governmental bureaucracies and utilization of her own renown. In this way, she had a significant influence on her own time and ours.

Glossary

Fisher information A measure of the precision of maximum-likelihood estimation as a function of the estimate value.

Fisher scoring An iterative numerical method for nonlinear maximum-likelihood estimation.

latent dimension A measurement dimension that cannot be observed but can be inferred from the internal consistency of responses to multiple items.

location The origin (zero) of a measurement dimension.

logit A mathematical function for mapping points in the interval zero to one (for example, probabilities) onto a real number continuum of infinite extent.

maximum-likelihood estimation A principle of statistical estimation based on maximizing the probability of a sample observation, the distribution function of which is known, given a putative value of the estimate.

nominal categories Arbitrary categories to which observed responses are assigned, in contrast to ordered categories that represent a coarse grading of quantitative observations.

partial credit model A model based on a logistic response function for responses in ordered categories.

quadrature A numerical method of evaluating integrals that have no explicit solution.

response function A mathematical expression of the probability of an observed qualitative response as a function of a continuous latent or manifest variable.

scale The unit of measurement on a latent or manifest dimension.

unfolding model A mathematical model for rank ordering of objects, whereby order is determined by the distance of each object from the ideal point.

The nominal categories model makes the widely used logit-linear (or log-linear) models for analyzing qualitative frequency data available in the measurement of

quantitative attributes. It has been applied mainly to measurement of individual differences among respondents to educational and psychological tests based on multiple-choice items and to measurement of individual attitudes toward public issues or preferences among consumer products. The theory of the nominal model and related estimation methods are reviewed here and illustrated with examples from these fields.

Introduction

The nominal categories model provides a link between the value of an assumed latent variable and the probabilities of a respondent's observed first choice among a number of discrete alternatives. It is one of a larger group of item response models serving the same purpose when the alternatives are dichotomous or form an ordered scale. In the context of modern test theory, several versions of the nominal categories model have appeared in the literature: (1) the initial presentation by R. D. Bock in 1972 applied to the recovery information in responses to wrong alternatives of multiple-choice tests, (2) an extension by F. Samejima in 1972 allowing for possible random choices on the part of the respondents, and (3) a further elaboration by D. Thissen and L. Steinberg in 1984 that included an estimated probability of the respondents' choosing randomly. In connection with his MULTILOG program, Thissen has also shown that the nominal model, when suitably parameterized, specializes to G. N. Masters' partial-credit model for ordinal categories. Takane presented in 1996 a multidimensional model for first choices based on C. H. Coombs'

unfolding model for rankings by individual respondents. In the context of modeling individual differences in complete preference rankings, U. Böckenholt introduced in 2001 a multidimensional version of the nominal model that includes Takane's model as a special case.

The nominal model is a particular application of a more general approach to statistical prediction of first choices among competing alternatives. Suppose there are m such alternatives; then the probability that a given respondent will select alternative k as first choice is

$$p_k = \frac{\pi_k}{\pi_1 + \pi_2 + \cdots + \pi_m},$$

where the π values are positive quantities and $\sum_k^m \pi_k = 1$. In this model, the scale of the parameters is obviously indeterminate. To avoid the necessity of estimation under the constraint $\pi > 0$, reparameterize by setting $\pi_h = e^{z_h}$, $h = 1, 2, \dots, m$. Then

$$p_k = \frac{e^{z_k}}{\sum_h^m e^{z_h}}.$$

In this form of the model, the indeterminacy is one of location and may be fixed by setting $\sum_h^m z_h = 0$ or by reparameterizing the z values in $m - 1$ linearly independent contrasts; for example, $z'_h = z_h - z_1$. In either case, the z values are referred to as multinomial logits, or just logits.

Measurement of Individual Differences

In psychometric applications, where the object is to measure individual differences among respondents with respect to a single latent variable, the logit corresponding to category k of item j may be expressed in terms of the variable, θ , attributed to the respondent, and two parameters, α and γ , attributed to the item category:

$$z_{jk} = \alpha_{jk}\theta + \gamma_{jk}.$$

The unidimensional version of the model may be used in the analysis scoring of standardized tests and psychological scales. In the context of educational achievement testing, the latent variable is typically referred to as "ability" or "proficiency." In psychological testing, the attribute may be any construct descriptive of behavior—"intelligence," "conservatism," "neuroticism," etc. Multiple-choice items may differ in their number of alternatives, m_j . Moreover, the tests or scales do not need to consist of multiple-choice items exclusively: they may be mixed with dichotomous items or with open-ended items, the responses of which are rated in ordered categories.

For purposes of discussing the properties of nominal category items generally, including multiple-choice items, it is useful to define the category response function,

$$P_{jk}(\theta) = \frac{e^{z_{jk}(\theta)}}{\sum_h^{m_j} e^{z_{jh}(\theta)}},$$

which assigns probabilities to the alternatives for any value of θ . The corresponding category information function (Fisher information) is

$$I_{jk}(\theta) = \frac{1}{P_{jk}(\theta)} \left[\frac{\partial P_{jk}(\theta)}{\partial \theta} \right]^2.$$

The following example illustrates the use of these functions in characterizing the operating characteristics of a multiple-choice item.

Example: A Vocabulary Test Item

Figure 1 shows plots of these functions for a multiple-choice item, the word "artifice," appearing in a secondary school vocabulary test. The response alternatives are listed in Table I; number 1 is the correct alternative. The test was administered with the instruction "Do not guess! If you do not know the correct answer, omit the item." This instruction led to an appreciable incidence of omits, which were assigned to a "No response" category in addition to the categories for the alternatives. Two infrequently selected alternatives have been assigned to the same category. The estimated category parameters for this item are shown in Table I. Plots of the corresponding response functions and information curves are shown in Fig. 1.

The information curve for alternative 2 shows that a response to the wrong alternative, "Imitation" is an indication of some vocabulary ability, presumably

Figure 1 Category response and information functions for the vocabulary test item "artifice."

Table I Category Parameter Estimates for the Vocabulary Word “Artifice”

Alternative	α	γ
1. Clever device	0.565	0.828
2. Imitation	0.865	0.375
3. Careless error	-1.186	-0.357
4. Flavor, accident	-1.199	-0.079
5. No response	0.933	-0.817

because a certain amount of word knowledge is required even to confuse “artifice” and “artificial.” Test scoring based on the nominal model would automatically assign full credit to an alternative-1 response and partial credit to an alternative-2 response. It would also make optimal use of the information contained in an omitted response to this item. There is very little information in responses to alternatives 3 and 4.

Item Parameter Estimation and Test Scoring

Data analysis for the nominal model or any of the various item response models is carried out in two steps. In the calibration step, the item parameters are estimated from the responses of a large sample of respondents drawn from the population for which the test is intended. Given these estimates, the attribute values for particular respondents from the population—who are not restricted to the calibration sample—are estimated in a subsequent scoring step. This two-step approach is necessary for maximum-likelihood estimation because the item parameters and respondent attributes cannot be estimated jointly: the number of parameters increases with the sample size and no determinate maximum is obtainable.

The problem of indefinitely many parameters can be avoided by integrating over an assumed or estimated population distribution of θ . This is the so-called method of maximum marginal likelihood. On the assumption that the responses to the n -item test or scale are statistically independent, conditional on θ , the probability of the response pattern $[x_{ijk}]$, $j = 1, 2, \dots, n$, is, say,

$$L_i(\theta) = \prod_j \prod_{h=1}^{m_j} [P_{jh}(\theta)]^{x_{ijhk}},$$

where $P_{jh}(\theta)$ is the response function of category h of item j and $x_{ijhk} = 1$ if the respondent i chooses category k , and zero otherwise.

Assuming that the respondent is drawn from a population with a proper probability density function

$g(\theta)$, the marginal probability of the response pattern may be expressed as the definite integral,

$$\bar{P}_i = \int_{-\infty}^{\infty} L_i(\theta) g(\theta) d\theta.$$

The marginal likelihood of a general item parameter v_{jk} , given the responses of a sample of N respondents, is then

$$L(v_{jk}) = \prod_i^N \bar{P}_i.$$

The corresponding likelihood equations for m_j -category item response models in general are

$$\sum_i^N \frac{1}{\bar{P}_i} \int_{-\infty}^{\infty} \sum_h^{m_j} \frac{x_{ijhk}}{P_{jh}(\theta)} \cdot \frac{\partial P_{jk}(\theta)}{\partial v_{jk}} L_i(\theta) g(\theta) d\theta = 0.$$

Specializing to the nominal model, there are the derivatives

$$\frac{\partial P_{jh}(\theta)}{\partial v_{jk}} = P_{jh}(\theta)[1 - P_{jh}(\theta)] \frac{\partial z_{jh}(\theta)}{\partial v_{jk}}, \quad h = k;$$

$$\frac{\partial P_{jh}(\theta)}{\partial v_{jk}} = -P_{jh}(\theta) \frac{\partial z_{jh}(\theta)}{\partial v_{jk}}, \quad h \neq k.$$

The integrals in these equations may be evaluated numerically with sufficient accuracy by Gaussian quadrature formulas—specifically, Gauss–Hermite quadrature when the normal density is assumed for $g(\theta)$. In view of the indeterminacy of location and scale in item response models, the mean and standard deviation of the θ distribution may be set, respectively, to 0 and 1, or other arbitrary values.

Although a direct numerical solution of the likelihood equations is possible in principle, it becomes unwieldy computationally when the number of items, and thus the number of parameters, becomes large in long tests or scales. In that case an expectation–maximization (EM) solution is the best recourse. With quadratures replacing the integrals, the expectations of the E step are the quantities, say,

$$\bar{r}_{jkq} = \sum_i^N \sum_h^{m_j} \frac{x_{ijhk} L_i(X_q)}{\bar{P}_i} A(X_q),$$

and

$$\bar{N}_q = \sum_i^N \frac{L_i(X_q)}{\bar{P}_i} A(X_q),$$

where X_q is a quadrature point, $q = 1, 2, \dots, Q$, and $A(X_q)$, $\sum_q^Q A(X_q) = 1$, is the corresponding quadrature weight. The quantities \bar{r}_{jkq} and \bar{N}_q , $\sum_q^Q \bar{N}_q = N$, comprise the so-called complete data statistics for the M step, which is just the standard procedure for fixed-effects logit-linear analysis of frequency data.

In the present application, procedures can be simplified by provisionally setting the parameters of one of the

categories to zero. After all other parameters have been estimated, the locations of the parameters can be moved so that the conventional scaling is recovered. Suppose the parameters of the last category, m_j , are set to zero; then the implicit equations for estimating the parameters of category k and item j are

$$G \begin{bmatrix} \alpha_{jk} \\ \gamma_{jk} \end{bmatrix} = \sum_q \{ \bar{r}_{jkq} - \bar{N}_q P_{jk}(X_q) - [\bar{r}_{jm_q} - \bar{N}_q P_{jm_q}(X_q)] \} \cdot \begin{bmatrix} \theta \\ 1 \end{bmatrix} = 0.$$

These equations may be solved by the Fisher scoring (Gauss–Newton) method using the corresponding Fisher information function:

$$I \begin{bmatrix} \alpha_{jk} \\ \gamma_{jk} \end{bmatrix} = NP_{jk}(\theta) [1 - P_{jk}(\theta)] \cdot \begin{bmatrix} \theta^2 & \theta \\ \theta & 1 \end{bmatrix}.$$

The provisional estimates can then be put in standard form by imposing the constraints $\sum_h^{m_j} \alpha_{jh} = 0$ and $\sum_h^{m_j} \gamma_{jh} = 0$.

Once the estimated item parameters of the test or scale are in hand, maximum-likelihood estimation of θ scores for the respondents is straightforward. The likelihood equation for respondent i ,

$$\sum_j^n \sum_h^{m_j} x_{ijhk} [1 - P_{jh}(\hat{\theta})] \alpha_{jh} = 0,$$

may be solved iteratively starting from $\theta = 0$.

The Fisher information with respect to θ contributed by category h of item j is

$$I_{jh}(\theta) = P_{jh}(\theta) [1 - P_{jh}(\theta)] \alpha_{jh}^2,$$

the item information is $I_j(\theta) = \sum_h^{m_j} I_{jh}(\theta)$, and the test information is $I(\theta) = \sum_j^n I_j(\theta)$. The error-variance function is $1/I(\theta)$, and the average error variance in the population is given by, say,

$$\bar{\sigma}_e^2 = \int_{-\infty}^{\infty} [1/I(\theta)] g(\theta) d\theta.$$

If the population variance is set to 1, the reliability of the test is $1 - \bar{\sigma}_e^2$.

The Fisher scoring solution for $\hat{\theta}_i$ converges quickly except in cases where choices of respondent i all fall in the alternative that has the largest algebraic value of α_{jk} or in the alternative with the smallest algebraic value. In those cases $\hat{\theta}_i$ is indefinitely large or indefinitely small, respectively, and cannot be evaluated. Assuming respondent i belongs to a population with proper probability density function, $g(\theta)$, these indeterminate values can be avoided by estimating the Bayes mode, say,

$$\tilde{\theta}_i = \max_{\theta} [L_i(\theta) g(\theta) d\theta],$$

with corresponding posterior information function, $I(\theta)g(\theta)$, or the Bayes mean,

$$\bar{\theta}_i = \int_{-\infty}^{\infty} \theta L_i(\theta) g(\theta) d\theta,$$

with posterior variance,

$$\sigma_{\theta_i}^2 = \int_{-\infty}^{\infty} (\theta - \bar{\theta})^2 L_i(\theta) g(\theta) d\theta,$$

when $\int_{-\infty}^{\infty} L_i(\theta) g(\theta) d\theta$ is set to 1. Again, the integrals may be evaluated numerically by Gaussian quadrature. If the test is used, for example, to qualify students for advancement or to select the most promising job applicants, the Bayes mean will yield the smallest number of misclassifications in the population in question.

Wainer and co-workers have shown that, if the alternatives of an item are ordered in the sense that a response to an alternative higher in the ordering implies a larger value of θ , then the α parameters must be ordered. The algebraic values of the α parameters may therefore be used to assign an empirical order to the alternatives or to verify a prior ordering. Inspection of the category parameters, category response curves, and category information curves of a multiple-choice item is valuable in any effort to improve the measurement properties of the item by revising some or all of its alternatives.

For any testing program with the necessary computing resources and large sample sizes, these various good properties, including the recovery of information in wrong alternatives and omitted item responses, show nominal-model-based item analysis and test scoring to be superior to any method of right–wrong scoring of multiple-choice items.

Measurement of Group Differences

In research studies in which respondents are identified only by their group membership, the data serve only to describe the distributions of θ within the groups. At minimum, the investigator would like to estimate the group means and standard deviations of θ . If the within-group distributions of θ are assumed normal, the marginal-likelihood equations for μ_u , the mean for group u , and for σ_u^2 , the corresponding variance, are

$$\sum_i^{N_u} \int_{-\infty}^{\infty} (\theta - \hat{\mu}_u) L_{ui}(\theta) g_u(\theta) d\theta = 0$$

and

$$\sum_i^{N_u} \int_{-\infty}^{\infty} [\hat{\sigma}_u^2 - (\theta - \hat{\mu}_u)^2] L_{ui}(\theta) g_u(\theta) d\theta = 0,$$

where N_u is the number of respondents in the sample from group u and

$$g_u(\theta) = \frac{1}{\hat{\sigma}_u \sqrt{2\pi}} \exp \left[\frac{-(\theta - \hat{\mu}_u)^2}{2\hat{\sigma}_u^2} \right].$$

Expressed in terms of the Bayes mean and posterior variance for respondent i in group u , these equations become

$$\hat{\mu}_u = \frac{1}{N_u} \sum_i^{N_u} \bar{\theta}_{ui}$$

and

$$\hat{\sigma}_u^2 = \frac{1}{N_u} \sum_i^{N_u} [(\bar{\theta}_{ui} - \hat{\mu}_u)^2 + \sigma_{\bar{\theta}_{ui}}^2].$$

These latter equations are in a form suitable for iterative solution simultaneous with EM estimation of the item parameters. To resolve the indeterminacy of location and scale, the mean and variance of one of the groups may be set arbitrarily.

These results apply to all of the conventional item response models, including the nominal model. They are useful in studies of group differences generally (for example, in educational assessment) when the objective is to measure differences in the effectiveness of school programs.

Analysis of Preference Rankings

Ranking is of particular interest in measurement of preferences for objects of choice, such as political candidates, proposed public policies, occupational choices, or competing consumer goods. When studying preferences, there is an important advantage to asking the respondents to rank rather than rate the objects: ranking avoids undesirable effects of respondents' idiosyncratic interpretations of category labels such as "agree moderately," "agree strongly," etc., found in rating forms. In applying the nominal model to preference studies, the objects take the place of categories. The model can be used to estimate preference functions—that is, the probability that a given object will be first, second, or any lower choice in a preference ranking. The nominal categories model is well suited for this type of analysis because of its computational simplicity and its consistency with other treatments of rankings and ratings, in particular the unfolding representation introduced by Coombs.

In some applications of rankings, the respondents may specify only a certain number of top choices among the objects, as opposed to a complete ranking or ranking of selected subsets of a larger number of objects. The first of these tasks is referred to as incomplete ranking; the second, as partial ranking. In both of these special cases, the

additional information provided by making use of all of the rank positions, not just the first choices, can result in gains in efficiency of estimation and improved identifiability of the model parameters.

Using Luce's principle of independence of first choices from irrelevant alternatives, a rank-ordering of objects may be decomposed into a succession of first choices among successively smaller sets of objects. The principle implies that the probabilities of the first choices are independent and that the probability of the ranking as a whole is the continued product of those probabilities. Inasmuch as probabilities of first (or last) choices are given by the nominal model, which is based on an extremal distribution, the conditional probability of a respondent's ranking, given the respondent's location, θ_i , on the latent preference continuum, may be expressed as follows: Let H be a set containing integers $h = 1, 2, \dots, m$ indexing the objects in the preference study. Let K_i be an ordered subset of elements of H corresponding to the q objects ranked by respondent i , $q = 1, 2, \dots, m-1$. Let $k_i^{(\ell)}$, $\ell = 1, 2, \dots, q$, be an element in K_i corresponding to the object in position ℓ in the rank ordering. Then, let \bar{H}_i^ℓ be the subset of $1 + m - \ell$ elements of H excluding elements corresponding to objects above $k_i^{(\ell)}$ in the rank ordering (note that elements of \bar{H}_i^ℓ not among the elements of K_i need not be ordered). Then the probability of K_i , given θ_i , is

$$P(K_i | \theta_i) = \prod_{\ell=1}^q \frac{\exp[z(k_i^{(\ell)} | \theta_i)]}{\sum_{h \in \bar{H}_i^{(\ell)}} \exp(z(h | \theta_i))}, \quad (1)$$

where

$$z(h \in \bar{H}_i^{(\ell)} | \theta_i) = \alpha_h \theta_i + \gamma_h \quad (2)$$

is the logit of the nominal model for the probability of each successive first choice. When $q = 1$, this probability as a function of θ specializes to the category response function, and $\bar{H}_i^{(1)} = H$.

The multistage structure of Eq. (1) imposes constraints on the collection of ranking data. Ideally, rankings should be obtained in the form of successive first choices by requiring respondents to rank the objects from most to least preferred. Deviations from this format that are not consistent with the model's multistage structure may lead to systematic misfits. It is worth noting that Eq. (1) has the same form as the partial likelihood representation of a stratum in a Cox regression, with "surviving" objects corresponding to risk sets and choices corresponding to failures.

Example: A Partial Ranking

Suppose respondent i is presented five objects, A, B, C, D, and E, indexed $h = [1, 2, 3, 4, 5]$. If the respondent reports

only the top three ranks, $K_i = \text{DAC}$, the conditional probability of the partial ranking, given θ_i , is

$$P(K_i | \theta_i) = \frac{\exp(\alpha_4 \theta_i + \gamma_4)}{\sum_{h \in [4,1,3,2,5]} \exp(\alpha_h \theta_i + \gamma_h)} \times \frac{\exp(\alpha_1 \theta_i + \gamma_1)}{\sum_{h \in [1,3,2,5]} \exp(\alpha_h \theta_i + \gamma_h)} \times \frac{\exp(\alpha_3 \theta_i + \gamma_3)}{\sum_{h \in [3,2,5]} \exp(\alpha_h \theta_i + \gamma_h)}.$$

The role of the logit in an unfolding representation of preference can be shown by reparameterizing Eq. (2) to yield an ideal-point model. In this model, both the object and the respondent have positions on the latent continuum. The unfolding of the preferences follows from setting the origin and unit of scale of θ to 0 and 1, respectively, and writing Eq. (2) as

$$z_h = \kappa_h - (\omega_h - \theta_i)^2, \quad (3)$$

where the θ_i and ω_h represent, respectively, the respondents' so-called ideal point and the object's position on the latent continuum. The equivalence between Eqs. (2) and (3) can be seen by setting $\alpha_h = 2\omega_h$ and $\gamma_h = \kappa_h - \omega_h^2$. The remaining terms may be set to zero because the nominal model is invariant with respect to translation of the logit.

When the position of an object h , ω_h , coincides with the ideal-point position of person i , the corresponding logit reaches its maximum value of κ_h . The interpretation of Eq. (3) is simplified when these maximum values are equal for all alternatives, leading to the additional constraint that $\kappa_1 = \dots = \kappa_m = 0$. This constraint yields Takane's model for first choices. The unfolding structure of the nominal model was noted by Samejima, who showed that the category response functions of the nominal model with the smallest and largest γ values are decreasing from 1 (at $\theta = -\infty$) and monotonically increasing to 1 (at $\theta = \infty$), respectively. In contrast, the object preference probabilities with an intermediate value of γ have unique maxima at finite θ values.

When multiple rankings of the same objects are available, it is useful to consider extensions of the unfolding model, including a multidimensional version of the nominal model. Though in educational applications, ability or proficiency measurements are typically based on multiple items with different alternatives, in studies of choice behavior, it is more common to consider rankings of the same objects on either (1) multiple criteria or (2) on the same criterion but at multiple time points. An example of the first ranking is an election study in which respondents are asked to rank political candidates on the criteria integrity, leadership, and expertise; an example of the second ranking is a panel study in which the same respondents are asked to express their preferences for

political candidates before and after an election campaign. In these settings, the multiple ratings would be treated as if they were items and an index j , $j = 1, 2, \dots, n$, would be inserted in the subscript of the logit. This extension is especially important in the multiple-criteria setting, in which the assumption that a one-dimensional latent variable can describe individual taste differences is too restrictive. Although preference functions can be estimated for any rank position, the focus of interest is most often on the first rank. This is the case in the remainder of this discussion including the next example; the subset K_i then contains only one element, k_i^1 , and the unnecessary superscript may be omitted.

In the multidimensional case, let the logit of the nominal model be a function of a d latent dimensions indexed by $v = 1, 2, \dots, d$. Then the d -factor version of the nominal model logit for object k may be expressed as

$$z(k_{ij} | \theta_{ij}) = \sum_{v=1}^d \alpha_{jv} \theta_{ijv} + \gamma_{jk}, \quad (4)$$

which describes the individual difference in preference for object k with respect to the j th criterion. The assumption in Eq. (4) of a different θ for each item results in a very heavy parameterization, however, and a more tractable approach is to assume a logistic factor-analysis model in which dependencies among the multiple attributes are attributed to a small number of latent variables that are not specific to each criterion. Equation (4) can then be simplified to

$$z(k_{ij} | \theta_i) = \sum_{v=1}^d \alpha_{jv} \theta_{iv} + \gamma_{jk}, \quad (5)$$

where the θ_i vary from person to person according to the multivariate standard normal distribution

$$g(\theta) = \frac{1}{2\pi^{d/2}} \exp \left[\frac{(-\sum_v \theta^2)}{2} \right]. \quad (6)$$

In applications involving repeated measurements of a single criterion, Eq. (4) may be simplified to

$$z(k_{it} | \theta_{it}) = \alpha_{tk} \theta_{it} + \gamma_{tk}, \quad (7)$$

where subscript j is replaced by t to emphasize the time dimension of the measurements. A parsimonious representation of time-specific effect is obtained by decomposing θ_{it} into a person-specific, time-dependent effect and a random time effect, v_t ,

$$\theta_{it} = \phi_{it} + v_t, \quad (8)$$

where ϕ_{it} may vary over time according to an autoregressive process.

Example: Ranking of Political Candidates

In a survey conducted shortly before the 1992 U.S. presidential election, a sample of 81 undergraduate students was asked to order the candidates George H. W. Bush (B), Bill Clinton (C), and Ross Perot (P) according to how well each of them represented their views on education (ED) and economy (EC) issues. The data are reproduced in Table II. For example, 11 respondents ranked the candidates in the order C, B, P on both criteria. Can a common latent trait, reflecting the political orientation of the respondents, account for the observed associations between the rankings? To test this hypothesis the one-dimensional nominal categories model was fitted to the data based on Eqs. (1) and (2) under a normal latent distribution with mean 0 and variance 1. This model yielded a likelihood ratio chi-square of $G^2 = 26.0$ with 27 degrees of freedom (df) and thus provides a superior fit, compared to a multinomial model without a latent trait ($G^2 = 62.2$, $df = 31$). Although a further fit improvement is obtained by a two-dimensional model with $G^2 = 14.9$ ($df = 23$), in view of the small sample size, the one-dimensional nominal categories model seems adequate in capturing the important features of the data set.

The response functions estimated under the one-dimensional model are depicted in Fig. 2. For both ranking criteria, economy (EC) and education (ED), individual differences in the rankings reflect the political orientation of the candidates. Table III shows the estimated item parameters under the ideal-point parameterization. As a consequence of the small number of respondents, the item standard errors are relatively large. With the exception of the κ parameter estimated for Clinton under the education criterion, the remaining κ parameters can be set equal to 0. This result indicates that the respondents favored Clinton's position on this issue regardless of their political views. Yielding a likelihood ratio chi-square of $G^2 = 29.5$ ($df = 30$), this simplified nominal model provides a parsimonious description of the bivariate ranking data.

Non-Probability Sampling

Alison Galloway

Queen Margaret University College, Edinburgh, United Kingdom

Glossary

population The group of people/items/units under investigation, about which the researcher wishes to draw conclusions.

probability sample A sample in which each member of the population has a quantifiable or calculable equal chance of selection.

sampling frame A list of the names and/or addresses of the population under investigation; the data should be comprehensive and up-to-date.

simple random sample A sample in which each element of the population is allocated its own number or identifier, and then random number tables or computer-generated random numbers are used to select a sample; often used as a standard against which other sampling methods are evaluated.

stratified sample A sample whereby the final selection is made to represent the same proportion with which the selected strata (or stratum) occur in the population as a whole.

stratum/strata Group/groups, often demographic, that are identifiable within a sampling frame; may be categorized by age, gender, socioeconomic grouping, income, etc.

systematic sample A form of random sampling whereby, instead of random numbers being selected, the researcher moves through the sampling frame, picking every n th entry.

When undertaking any survey, it is essential to obtain data from people who are as representative as possible for the group being studied. Even with the perfect questionnaire (if such a thing exists), survey data will be regarded as useful only if it can be demonstrated that the respondents used are as representative as possible. As with probability methods, non-probability sampling encompasses a range of techniques. The choice of method will depend on

the nature of the research problem, the availability (or otherwise) of a good sampling frame, money, time, required level of accuracy in the sample, and data collection methods. Each form has its advantages, each its disadvantages.

Introduction

Definition

In a non-probability sample, some members of the population, compared to other members, have a greater but unknown chance of selection. There are five main types of non-probability sample: convenience, purposive, quota, snowball, and self-selection.

Comparison with Probability Samples

The main feature present in a probability sample, but generally absent in a non-probability sample, is a sampling frame. Probability samples are possible only when there is a complete and up-to-date list of the members (names and/or addresses) of the population under investigation. There are, of course, many situations in which it is not possible to obtain a sampling frame. For example, when researching football supporters, it is not feasible to obtain a list of names or addresses of people who attend games. It should be possible to obtain a list of people who are official members of the team, but this is unlikely to comprise all supporters. Similarly, there is not a sampling frame easily available to researchers of all the elderly in a population. Non-probability techniques therefore have to be used whenever there is no readily available and complete list of the population under investigation.

Advantages and Disadvantages of Non-Probability Sampling

The most obvious advantage in non-probability sampling is clearly the ability to target particular groups of the population. Non-probability methods are often dismissed or criticized because they do not have the statistical foundations of probability methods. However, a survey using, for example, random, systematic, or stratified sampling may adopt methods such as postal delivery, which characteristically has extremely poor response rates. It could certainly be argued that as many valid conclusions can be drawn from a well-constructed study using non-probability methods, compared with a probability survey to which only 10% of the sample responded. Researchers would need to be confident that those 10% were truly representative of the population as a whole.

Non-probability methods also have the advantage in typically being less expensive to conduct. Savings, in terms of both money and time, can be achieved not so much by the sampling method per se, but rather by the forms of delivery that are available for these methods. For example, face-to-face delivery can be cheaper than postal approaches, particularly where oversampling has had to be used to compensate for the typically poor response rates of a mailed survey.

Convenience Sampling

Definition

Convenience sampling involves using respondents who are “convenient” to the researcher. There is no pattern whatsoever in acquiring these respondents—they may be recruited merely asking people who are present in the street, in a public building, or in a workplace, for example. The concept is often confused with “random sampling” because of the notion that people are being stopped “at random” (in other words, haphazardly). However, whereas the correct definition of random sampling (using random numbers to pick potential respondents or participants from a sampling frame) generally results in a statistically balanced selection of the population, a convenience sample has an extremely high degree of bias.

Application

Typically, somebody undertaking a convenience sample will simply ask friends, relatives, colleagues in the workplace, or people in the street to take part in their research. One of the best ways of considering the pitfalls of this form of sampling is to look at this last approach—stopping people in the street. On a typical weekday morning in the

shopping area of an average town, the people on the street at that time are likely to result in an overrepresentation of the views of, for example, the unemployed and the elderly retired population. There will be a corresponding underrepresentation of those working in traditional “9-to-5” jobs. This can, of course, be counterbalanced to some extent by careful selection of different times and days of the week to ensure a slightly more balanced sample.

Despite the enormous disadvantage of convenience sampling that stems from an inability to draw statistically significant conclusions from findings obtained, convenience sampling does still have some uses. For example, it can be helpful in obtaining a range of attitudes and opinions and in identifying tentative hypotheses that can be tested more rigorously in further research. Nevertheless, it is perhaps the weakest of all of the non-probability sampling strategies, and it is usually possible to obtain a more effective sample without a dramatic increase in effort by adopting one of the other non-probability methods. The following examples of convenience sampling from published research represent the wide range of applications in the social sciences and in business research:

- A convenience sample of 1117 undergraduate students in American universities explored associations between perceptions of unethical consumer behavior and demographic factors. Instructors on two campuses were contacted to obtain permission to administer the surveys during scheduled classes.
- Questionnaires were distributed using convenience methods in a study of the motives and behaviors of backpackers in Australia. The 475 surveys were delivered in cafes and hostels in areas popular with backpackers.
- Differences in bargaining behavior of 100 American and 100 Chinese respondents were explored using the Fishbein behavioral intention model.

Purposive Sampling

Definition

Purposive sampling is sometimes also referred to as a judgment sample. Whereas convenience sampling involves asking people who happen to be convenient to the researcher (on the street, or using friends and family), those using a purposive sample will endeavor to direct their survey at a range of respondents who are ultimately representative of at least the extremes of variables under consideration. For example, a researcher using purposive methods may strive to ensure that older age groups as well as younger ones are contained within the sample selected. This can be done as a “topping-up” procedure, whereby the researcher can start with what is more or less

a convenience sample and may decide that there are insufficient respondents in a particular age category. Some respondents who will fit into the category are then deliberately sought. A number of criteria may be pertinent in accessing a purposive sample. Researchers may, for example, wish to obtain a balanced range of socioeconomic groupings or even incomes, although these are clearly more difficult variables to predict when looking at potential respondents on the street or in another public place.

Application

Purposive samples do not have to be undertaken in public places or even face to face. Potential respondents can be contacted in a variety of ways and it is perfectly feasible to use several of these methods to select a range of characteristics. For example, a researcher wishing to contact a good sample of the elderly to determine any problems they were experiencing with their housing would want to ensure that a range of demographic factors could be encompassed; this can be achieved with a purposive sample. It would clearly be important to include both male and female respondents in such a sample. It could also be considered critical that both the “young old” (the newly retired) and the “old old” (over 80, say) were included. It might also be important to ensure that all housing tenure forms were encompassed when selecting respondents. Accessing such a broad range of variables might require more than one sampling strategy. For example, access may be given to age/sex registers of medical practices, whereby a range of ages of males and females could be located. Renters could be accessed through housing associations or similar organizations, and owners could be located in private housing developments for the elderly. Social clubs for the elderly could also be used as an access point, but this would generally lead to those elderly who might be considered more gregarious.

Another example of the useful application of purposive sampling would be in a study of healthy eating. If the researcher were to resort to convenience sampling, respondents might be of a fairly narrow age band and a limited range of socioeconomic groupings. A purposive sample would ensure that people falling within a good range of ages (e.g., from 18 to 80 years) were contacted and that the group included professionals as well as manual workers. It might even be considered useful to make sure that the sample included people who take plenty of exercise (by delivering some surveys in a health club, for example), as well as those who do not, by contacting social organizations with a more sedentary focus. The following examples of purposive sampling have been reported in research literature:

- A study of nonsmoking parents of adolescents who smoke. A purposive sample of 25 respondents

encompassed different ages, levels of education, and genders, and whether the parents had smoked in the past.

- Research into the effectiveness of drama in primary schools in the introduction of sensitive concepts such as child protection and personal safety. Participants who were recruited into focus group research included teachers, actors, and health promotion staff.

- A purposive sample of respondents from different levels of service staff. Persons from senior management, the supervisory level, and front-line operations were used in semistructured interviews with local authority employees to explore the implications and perceived benefits of achieving the “Investors in People” standard (a national quality standard of business practices in the United Kingdom).

Quota Sampling

Definition

There are a number of commonalities between quota and purposive sampling, but a critical difference lies in the fact that the former is invariably undertaken by groups of researchers, whereas the latter can be undertaken by an individual researcher. Quota sampling tries to replicate proportions of demographic factors whereas, in purposive sampling, researchers may be satisfied merely to include a reasonable range of the variables being examined.

Quota sampling is an extremely common technique employed by market research companies, particularly when they are adopting a face-to-face on-street interviewing methodology. It is generally used for large-scale samples of 2000 or more and is a useful alternative to probability samples, such as a random stratified sampling. As with a stratified sample, it is necessary to know certain demographic factors about the sample population (for example, proportions of males/females, age composition, or socioeconomic grouping). This information can be obtained easily through census data. The data are used to calculate quotas for each of the demographic groups that are considered pertinent to the subject of the research being undertaken. Each researcher can then be given a brief that specifies the number of people to interview with these characteristics. Complex quotas can be developed to incorporate all of the critical demographic or other variables.

Application

The main objective in a quota sample is to try to replicate the proportions of particular critical variables in the population as a whole. Imagine, for example, that researchers want to undertake a survey in a town with a population of 64,746 people. They wish to ensure that their sample is representative with respect to three

main variables: gender, age, and housing tenure (owner-occupiers, social renters, and private renters). Using census or similar data, they can determine the numbers of people representing these variables in a particular area (Tables I and II). Researchers would not necessarily be targeting a particular percentage of the population and could start instead with a total sample number (e.g., 500 or 1000). For the sake of simplicity, though, imagine that a 1% sample is the goal. This would mean that, for their quota sample, the entire group of researchers would have to find the numbers of people shown in Tables III and IV. These figures would be divided up among the team undertaking the fieldwork (perhaps based in different parts of the town). Although gender is usually quite apparent and an approximation of age can be made by the researcher, as the fieldwork progressed and the different quotas were met, the researcher would have to establish housing tenure and confirm age fairly early on in the interview with a short filtering question. The following examples of quota sampling have been reported in research literature:

- Research into the perceived efficacy of sales promotions in UK supermarkets. This research used a quota sample that took account of gender and age. The population profile in the United Kingdom was used to ensure that the study's sample would reflect the general population in these demographic variables.
- The way in which students shop for food. This demographic was explored in a questionnaire-based

survey. A quota sample ensured that gender as well as proportional student faculty membership were reflected in the final choice of respondents.

Snowball Sampling

Definition

Just as a snowball gets bigger when rolled in snow, a snowball sample increases in size as a small number of potential respondents suggest the names and/or addresses of other people who fulfill particular criteria. It is a particularly useful technique when looking for respondents with unusual interests/faiths/medical conditions and so on. The researcher begins by contacting two or three people who are thought to fulfill the criteria being sought and asking them if they know of other people with the same interest/condition, etc. If each of three people supplies the names of another three, and those contacts subsequently supply names of potential respondents, a healthy number of participants soon results.

Application

There are countless situations in which a snowball sample can be considered an appropriate strategy, particularly where a criterion for research may be very widely dispersed and difficult to track down using conventional

Table I Quota Sample of Housing Tenure Data for Males^a

Age (years)	Owner-occupier	Social renter	Private renter
18–25	2149	788	645
26–35	2338	857	701
36–45	4573	1677	1372
46–55	2869	1254	659
56–65	2845	1435	2241
Over 65	1865	1697	1611

^a Number of people in the sample who represented a particular variable.

Table II Quota Sample of Housing Tenure Data for Females^a

Age (years)	Owner-occupier	Social renter	Private renter
18–25	2053	920	566
26–35	2247	1007	620
36–45	4217	1890	1163
46–55	2859	1282	789
56–65	4104	1673	1299
Over 65	3759	1884	838

^a Number of people in the sample who represented a particular variable.

Table III Number of Respondents Required for a 1% Sample of Males^a

Age (years)	Owner-occupier	Social renter	Private renter
18–25	21	8	6
26–35	23	9	7
36–45	46	17	14
46–55	29	13	7
56–65	28	14	22
Over 65	19	17	16

^a Relative to quota sample data in Table I.

Table IV Number of Respondents Required for a 1% Sample of Females^a

Age (years)	Owner-occupier	Social renter	Private renter
18–25	21	9	6
26–35	22	10	6
36–45	42	19	12
46–55	29	13	8
56–65	41	17	13
Over 65	38	19	8

^a Relative to quota sample data in Table II.

approaches. The following examples are again taken from the literature:

- An exploration of the ethical precepts held by a sample of Chinese professionals. This study used a snowball sample by asking participants in a management development program to complete a questionnaire and to persuade their peers to do the same.
- A study of factors influencing substance use in 16- to 22-year olds. This study used snowballing techniques to include students and even a drug seller as their contact points.
- Two studies of professional women with children (one focusing on lone mothers). This research drew on snowball techniques to acquire sufficient numbers of respondents.
- A cross-cultural study of consumer decision making. This research used a snowball sample because of the difficulty in contacting Indian-Tamil wives located in India. Initial contacts were asked to provide referrals of female married friends and relatives who would be willing to participate.

Self-Selection

Definition

A self-selected sample is simply one in which the respondents put themselves forward for participation in a survey or similar form of research. The possibility of bias in the sample is extremely high, because those most likely to put themselves forward are those who have a particular interest in the subject. Whereas this interest can be a necessary criterion for some research, there may be instances when only those respondents who have extremely positive or extremely negative experiences pertaining to the study subject volunteer for the study, and the “average” viewpoint may thus not emerge.

Application

Self-selection can be implemented in a number of ways. When research is in the form of a survey, questionnaires can simply be left in a variety of appropriate locations (e.g., medical practice waiting rooms and public libraries). This relies to a high extent on altruism, although incentives such as a prize drawing can play an important part in increasing the size of a self-selected sample. Another form of self-selected sampling involves publicizing through posters or flyers. Details of projects can be given with a request for volunteers to contact the researcher by telephone, post, or email. Finally, self-selection can be incorporated into Internet-based surveys. Emails can be sent to appropriate distribution lists or newsgroups, although care has to be taken to avoid doing this in an inappropriate manner

(“spamming”). Similarly, Web pages can be used, provided that they are publicized sufficiently to encourage respondents to participate. The following examples of self-selection sampling have been reported in research literature:

- Research into international mobility among business and education professionals. Self-selection sampling was accomplished by the use of institution-wide emails to all academic staff in a sample of higher educational institutions in four different countries.
- Major Internet surveys. These surveys have adopted self-selection as a sampling strategy, the most notable being that done by the Georgia Institute of Technology’s Graphics, Visualization, and Usability (GVU), in which Internet usage is monitored on a regular basis.

Conclusions

Although researchers may feel constrained when the lack of an available sampling frame rules out the possibility of a probability sample, there are still a number of options available in the range of non-probability samples. Although non-probability samples do not carry the same weight as probability samples, in statistical terms, they do still provide the opportunity to draw from a representative selection of the population. A true random sample with an extremely low response rate may have no greater chance of being representative than, for example, a carefully constructed quota sample. Not all research requires high degrees of accuracy, and for exploratory research, in particular, a non-probability sample may be a perfectly appropriate strategy.

Non-Response Bias

Nathan Berg

University of Texas, Dallas, Richardson, Texas, USA

Glossary

bias The expected difference between an estimated characteristic of a population and that population's true characteristic.

item non-response A non-response to a particular survey item accompanied by at least one valid measurement for the same respondent, for example, leaving just one item on a questionnaire blank or responding to some questions by saying, "I don't know," but providing a valid response to other questions.

non-response A survey response that falls outside the range of responses that survey designers consider to be valid.

unit One observation or a single vector of measurements, usually corresponding to a particular individual at a given point in time; many units make up a sample.

unit non-response Refusal or failure to provide any valid responses by someone who survey designers intended to include in the survey.

Non-response bias refers to the mistake researchers expect to make in estimating a population characteristic based on a sample of survey data in which, due to non-response, certain types of survey respondents are under-represented.

Motivation for Analyzing Non-Response Bias

To illustrate and underscore the importance of analyzing non-response bias, consider the following scenario. A researcher working for a marketing firm wishes to estimate the average age of New Yorkers who own telephones. In order to do this, the researcher attempts to conduct a phone survey of 1000 individuals drawn from

the population of phone-owning New Yorkers by dialing randomly chosen residential phone numbers. However, after 1000 attempts, the researcher is in possession of only 746 valid responses because 254 individuals never answered the phone and therefore could not be reached. At this point, the researcher averages the ages of the 746 respondents with valid responses and considers whether this average is likely to be too high or too low. Does one expect the 254 non-responders to be roughly the same age as respondents who answered their phones?

After thinking it over, the researcher concludes that the average age of the 746 responders is a biased estimate because the surveys were conducted during business hours when workers (as compared to older retirees) were less likely to be at home. If working age respondents are underrepresented, then the average among the 746 valid age responses is biased upward. In this case, the difference between the biased average and the true but unobserved average age among all telephone owners is precisely non-response bias.

Social scientists often attempt to make inferences about a population by drawing a random sample and studying relationships among the measurements contained in the sample. When individuals from a special subset of the population are systematically omitted from a particular sample, however, the sample cannot be said to be random in the sense that every member of the population is equally likely to be included in the sample. It is important to acknowledge that any patterns uncovered in analyzing a nonrandom sample do not provide valid grounds for generalizing about a population in the same way that patterns present in a random sample do. The mismatch between the average characteristics of respondents in a nonrandom sample and the average characteristics of the population can lead to serious problems in understanding the causes of social phenomena and may lead to misdirected policy action. Therefore,

considerable attention has been given to the problem of non-response bias, both at the stages of data collection and data analysis.

Classifying Types of Error and Bias

Sampling Error

Anytime we generalize about a population based on a sample, as opposed to conducting a complete census of the population, there is an unavoidable possibility of mistaken inference. As such, sampling error arises even under the best of circumstances simply because, due to chance, averages of variables in a random sample are not identical to the corresponding averages in the population. Fortunately, sampling error typically disappears as the sample size increases. More important, sampling error does not lead to bias, because population characteristics can be estimated in such a way that the probability-weighted average of possible overestimates and underestimates is precisely zero.

Nonrepresentative Samples

It is important to distinguish from sampling error an entire family of nonsampling errors that arise when a sample is selected from a population in such a way that some members of the population are less likely to be included than others. In such cases, the sample is said to be nonrandom, or nonrepresentative, with respect to the population we intend to study. In contrast to sampling error, a nonrepresentative sample generally leads to biased estimation.

A number of factors may cause a sample to be nonrepresentative. One possibility is that, because of a flawed survey design, the survey simply fails to reach certain segments of the population. In the previous example, a daytime phone survey tended to underrepresent people who work, just as a survey of rural-area dwellers, or of car owners, would underrepresent users of public transportation.

Systematic mistakes by surveyors in coding survey responses can also lead to non-representative samples. The key issue is whether such mistakes are correlated with the characteristics of the individual being surveyed. For instance, a surveyor who, in the course of interviewing survey respondents, sometimes gets carried away discussing sports and forgets to record the respondent's last few responses will end up with a sample in which sports fans are underrepresented among the complete survey responses.

Perhaps the most common reason for nonrepresentative samples, however, is the behavior of survey respondents themselves. Oftentimes, the very fact of

being a non-responder correlates with other characteristics of interest. When it does, non-response inevitably leads to nonrandom sampling and creates the potential for biased estimation of the characteristics under study. Researchers working with survey data must always consider the possibility that certain types of individuals are more likely to refuse to respond. This problem is acute when one of the key variables of interest determines, in part, who is more likely to select themselves out of a sample by not answering a survey question.

It is often suspected, for example, that individuals with high incomes are less likely to voluntarily disclose their income, biasing survey-based estimates of income downward. Similarly, those engaged in illicit drug activity, fearing the consequences of divulging potentially incriminating information, are probably less likely to participate in a survey about drug use, leading, again, to the potential for systematic underestimation. A slightly more subtle example is the case of estimating the percentage of a population that supports one of two political candidates. Apathetic voters are often thought to be the least likely to cooperate with political pollsters, even though many of them will in fact vote. Basing election forecasts on a sample of only those who agree to answer the poll can be misleading because the opinions of apathetic voters are underrepresented in pollsters' samples.

Dealing with Nonrepresentativeness before or after Data are Collected: Sample Design and Data Analysis Stages

To deal with nonrepresentative samples, it is helpful to distinguish two broad stages in a social science research project: data collection and data analysis. Some researchers conduct surveys themselves and therefore have direct control over the details of data collection. Others work with data sets originally collected by someone else, in which case the researcher exerts no direct control over the data collection stage.

For those who have a say about how the data are to be collected, it is crucial to try to foresee potential flaws in order to reduce the likelihood of bias. A vast literature exists on the topic of survey design, covering everything from the wording of survey questions to the issue of how many times those who do not answer the phone on a phone survey ought to be called back. Sometimes surveys can be designed in such a way as to provide a means of estimating the non-response bias associated with a particular data collection technique, for example, by comparing the results of face-to-face and phone interviews.

Many researchers in the social sciences, rather than collecting new data themselves, study data that have been collected by others, such as the U.S. Census, the Current Population Survey, and the General Social Survey. As a

secondary data analyst, the researcher must decide what to do about survey respondents who failed to answer particular questions, referred to as the missing data problem. An additional issue is what to do about the target respondents who did not participate in the survey at all.

Similarity among Biases with Different Labels

One finds many different labels for biases that are, in fact, instances of one common problem—trying to learn about a population based on a nonrepresentative sample. It is helpful to see the underlying similarity among biases that arise from nonrepresentative samples because a successful approach to dealing with bias in one context often can be applied to new settings. In particular, survey data with missing responses can frequently be analyzed using techniques from the statistical and econometric literature under the heading measurement error. Terms such as “noncompletion bias” or “volunteer bias,” referring to the nonrepresentative sample problem that arises when only special kinds of respondents actually complete a survey questionnaire or to situations in which the subpopulation of volunteers is substantively different from the rest of the population, should be viewed as essentially the same problem.

The connection between non-response bias and selection bias warrants special mention. Non-response is special kind of the selection problem of the type analyzed in the work of James Heckman. Thus, selection bias, when referring to the mechanism by which some survey respondents choose not to answer survey questions (thereby selecting themselves out of the sample), overlaps with what is defined here as non-response bias. Heckman interprets the selection problem more generally as a kind of econometric misspecification. As illustration, it is useful to consider a regression model used frequently by labor economists in which the expected wage depends on demographic variables as well as other factors thought to influence workplace productivity. If no account is taken of the mechanism by which only special kinds of individuals choose to become workers and therefore wind up being included in the sample (implying that regressors are correlated with the error term in the regression model), then the econometric model is, in Heckman's words, “misspecified,” leading to misspecification bias.

Misreporting versus Non-Response

When those collecting data ask respondents to report on their own behavior in connection with activities such as cheating, personal finance, sex, or alcohol and drug use, some respondents, instead of refusing to answer, will misreport their behavior. When interpreted at face

value, a sample in which certain kinds of individuals tend to misreport will not accurately represent the population under study. As with nonrepresentative samples caused by non-response, misreporting usually leads to bias, which can be referred to as misclassification bias, misreporting bias, contaminated data bias, or simply response bias. The task of the researcher is to consider how such misreporting will influence estimates of key population characteristics.

Analysis of Survey Data with Missing Responses

Item versus Unit Non-Response

An important distinction to make regarding non-response is item versus unit non-response, a distinction that turns on whether there is at least one survey item for which a valid response was obtained or whether the entire unit is missing. When entire units are missing from a sample, no test or correction for bias is available without obtaining additional data about the targeted respondents who did not respond to the initial survey. In contrast, samples with item non-response may allow for unbiased estimation because partially completed responses from item non-responders may be used to control for differences across responders and item non-responders. This section discusses techniques for computing unbiased estimates using samples which feature item non-responses.

Little and Rubin's Missing Data Framework

Roderick Little and Donald Rubin, individually and in joint work, have written a number of frequently cited articles on the subject of analyzing data with missing values. Their approach is quite general and applies directly to most situations that applied researchers working with survey data are likely to face.

Imputation

One approach to dealing with missing survey responses is to somehow fill in the missing values, imputing good guesses in place of missing survey entries. Some researchers, for instance, may replace missing measurements with the average value across the complete cases. A more sophisticated approach involves replacing missing values with estimates based on prediction equations that are fitted with the complete cases and subsequently used to predict missing values using the partial responses of item non-responders. After imputing values to fill in the missing data, data analysis proceeds using traditional estimation techniques.

A serious drawback to this technique is that the precision of the estimates computed using the data set with

imputed values will be overstated for two reasons. First, imputed values generally are computed by averaging over other observations and, therefore, will be more tightly clustered about the mean than a fresh collection of bona fide observations would be. And second, the use of traditional statistical techniques after imputing values for missing entries in the data matrix will be based on an overstated sample size because a sample of N observations, some of which have been imputed, will contain fewer than N independent pieces of information. This means that standard errors will be too small and that the nominal size of significance tests will be inflated.

Weighting

Another approach to working with incomplete data involves discarding partial observations and assigning a weight to each complete observation so that the weighted sample better represents the average characteristics of the population. For instance, with a sample of 68 men and 32 women in which women appear to be underrepresented, one might consider placing additional weight on female units in the sample, perhaps based on the gender ratio from the U.S. Census, in order to reduce bias. In principle, weighting should correct for bias that arises from estimation based on nonrepresentative samples. A severe complication, however, is knowing how to compute standard errors that accurately account for the imprecision in the weights themselves. Doing so is notoriously difficult. Therefore, many authors, including Little and Rubin, recommend against weighting techniques. Those authors point out that the most common approach to non-response is simply to discard incomplete responses, effectively giving each of the complete sample units the same weight. Except for the unusually lucky case in which the complete-only subsample is a truly random sample of the population, this technique, although simple to use and widely practiced, leads to biased estimates.

The Maximum-Likelihood Approach

The maximum-likelihood approach is, far and away, the preferred approach to correcting for non-response bias, and it is the one advocated by Little and Rubin. The maximum-likelihood approach begins by writing down a probability distribution that defines the likelihood of the observed sample as a function of population and distribution parameters θ . If x_1 and x_2 represent responses to two different survey questions by a single individual, the likelihood associated with a complete response may be expressed as $f(x_1, x_2; \theta)$, where f is the joint probability density function of x_1 and x_2 . For individuals who only report x_1 , the likelihood associated with x_1 is $\int_{-\infty}^{\infty} f(x_1, x_2; \theta) dx_2$, which can, under the assumption of joint normality, be simplified to a more convenient form. In this way, a likelihood function is specified that includes terms corresponding to each observation,

whether completely or only partially observed. The likelihood objective is then maximized with respect to θ , which produces estimates of the desired characteristics, enjoying all the well-known properties of maximum-likelihood estimation.

Most important among those properties, maximum-likelihood estimates converge to the true value of θ under the assumption that the probability distribution is correctly specified. Maximum-likelihood estimates are also asymptotically normal and asymptotically efficient, meaning that, for large samples, the maximum-likelihood estimate of θ is approximately normal and is the best use of the information contained in the sample. In addition to these advantages, the maximum-likelihood approach makes it possible to estimate fairly elaborate multi-equation models in which the probability that an individual fails to respond depends on other observable variables. Within such a framework, it is often possible to construct a quantitative test of the missing-at-random hypothesis, implemented as a straightforward test of an appropriate parameter restriction. The main drawback to maximum-likelihood estimation is that strong assumptions are required about the distribution of the process generating the survey responses. Still, the advantages are usually thought to outweigh the drawbacks, making it the approach of choice for many quantitative researchers.

Missing-at-Random, Missing-Completely-at-Random, Mixture Modeling, and Multiple Imputation

A frequently mentioned distinction in the missing-data literature involves the two terms, missing-at-random and missing-completely-at-random. If the probability of non-response for a variable Y is the same for every unit of observation in the population, then Y is said to be missing-completely-at-random. If, on the other hand, the probability of non-response systematically relates to other variables in the model, but not to the value of Y itself, then Y is said to be missing-at-random. Defining the random variable $R = 0$ if Y is missing, and $R = 1$ otherwise, another important distinction can be expressed as follows. Selection models require the user to observe the conditional distribution $Y | R = 1$ and model the conditional probability $R = 1 | Y = y$, whereas mixture models require observing $Y | R = 1$ and modeling $Y | R = 0$.

Other Perspectives on Correcting for Non-Response Bias

Lawrence Marsh and his co-authors have proposed a number of non-response models and developed associated maximum-likelihood estimators that appear to work well in practice. Marsh's work, in addition to providing straightforward maximum-likelihood estimators

of non-response bias, compares the performance of maximum-likelihood-based corrections for non-response bias against those associated with alternative techniques of estimation, such as maximum entropy, finding consistent support for the maximum-likelihood approach. These results rest on the existence of auxiliary relations that determine the missing response mechanism. In the absence of auxiliary relations, Lien and Rearden's 1988 article shows that, when the missing observation is the dependent variable in a limited dependent-variable model, nothing is gained by applying maximum-likelihood-based corrections. Thus, special caution is warranted when estimating a model in which the dependent variable is frequently missing.

Measuring Non-Response Bias

Validation

Validation is a general approach to testing for non-response bias that almost always involves comparing two different samples drawn from the same population. The technique of validation permits us to measure non-response bias, to test the hypothesis of no bias, and to identify which variables, if any, are correlated with non-response. This approach is only feasible, however, if we are lucky enough to have two samples drawn from the same population.

Given a pair of samples, it is usually clear, either from the number of missing entries or from descriptive notes attached to the data, which data set has a lower non-response rate. The general philosophy of validation assumes that the sample with the lower non-response rate is, for all practical purposes, the "reliable" one. Accepting this view, significant departures among the observations in the "unreliable" sample relative to the average characteristics in the "reliable" sample can then be attributed to non-response bias, providing a qualitative measure (too high vs. too low) along with a quantitative measure of the severity of the problem.

For instance, it is well accepted that face-to-face interviews typically draw a higher response rate than phone surveys do. Now suppose we draw two samples of measurements on ethnicity, one face-to-face and the other by phone, and discover that the fraction of Asian Americans in the phone data is one-half that of the face-to-face interview data. Taking the estimated racial composition of those who respond to the face-to-face interview as the reliable benchmark, we might plausibly infer that Asian Americans are twice as likely to non-respond in a phone survey compared to other types of Americans. The qualitative finding that phone survey data may underrepresent Asian Americans is valuable in qualifying further estimates of characteristics on which Asian Americans are known to be different from other Americans. Beyond this, the magnitude of the

difference, in this case a factor of one-half, can be used to place additional weight on the phone responses of Asian Americans in order to correct for the fact that they tend to be underrepresented in phone surveys.

Sex researchers, who must routinely deal with survey data suffering from very high non-response rates, have applied validation to gain a feel for the ways in which the respondents in their data are different from the U.S. population at large. A straightforward approach is to compare, say, the age distribution among sex survey respondents with the age distribution of the population of Americans as measured by the U.S. Census. Sex survey respondents, in fact, appear to be younger than average Americans are.

Validation is virtually the only way to learn about the characteristics of unit non-responders because, by definition, there is no information on unit non-responders in the rounds of data collection in which non-response occurs. One 1999 study by Heather Turner used validation techniques to uncover some surprising distinctions that need be made among those who are typically categorized together as non-responders. She identified two types of non-responders, differentiating those who refused to participate twice from those who could not be contacted after 17 attempts. Using data from other sources and from follow-up interviews, she discovered that those non-responders who directly refused to participate in the survey tended to be older, attended church more often, and were more skeptical about the confidentiality of interviews.

In an important finding, rich with policy implications, she produced evidence suggesting that, in contrast to the low-risk lifestyles of those who directly refuse to participate, the difficult-to-reach non-responders tended to have significantly more sexual partners and higher frequencies of risk factors for AIDS. This demonstrates how difficult it can be to generalize about non-responders and make reliable guesses as to whether non-response bias skews estimates up or down.

Measuring non-response bias in telephone surveys is a frequent concern for polling organizations and those conducting market research by telephone. A fundamental issue confronting anyone attempting to learn about the entire population of Americans based on a phone survey is the fact that not all American households have telephones. Previous attempts to measure the characteristics of nontelephone households indicate considerable differences with respect to phone-owning households across a number of important characteristics such as the propensity to have health insurance.

In a novel approach to measuring non-response bias published in 1995, Scott Keeter sought to estimate telephone noncoverage bias by conducting a series of phone surveys on the same randomly drawn sample of phone numbers at several points in time. Among those reached at any given time were, of course, some

households who had only recently gained access to a telephone. And among those reached in earlier rounds of phone surveying were some households whose number later became disconnected. Labeling those who gained or lost telephone service at least once as “transient” and comparing the number of transients in his sample with government and industry estimates of how many American households are nontelephone households, Keeter determined that transients make up roughly one-half of all nontelephone households. Moreover, the demographic characteristics of nontelephone households recorded in other surveys appeared to match those of the transient group in Keeter’s study, bolstering confidence in the ability of existing non-response-corrected phone survey methodologies to produce meaningful insights into the characteristics of American households in general.

Another area of policy research in which non-response bias can play an especially important role is that of valuing natural resources. Developers and government officials often attempt to study the benefits and costs of a proposed building project and must, at some point, put a dollar value on natural resources, including wetlands, endangered animals, and undeveloped green space. Similarly, officials at the Environmental Protection Agency and environmental economists confront the challenge of assessing the value of parks, wildlife, and air quality. Such endeavors must deal with the question of how to reliably elicit valuations that somehow reflect the aggregate preferences of residents. The basic idea is to use samples of citizens to estimate the worth of natural resources in the eyes of an average citizen.

It is fairly obvious that the problem of nonrepresentativeness will have a direct effect on such valuations. Suspecting that those who agree to participate in environmental surveys have higher than average subjective assessments of the value of natural resources, researchers in this area worry that non-response bias may lead to overstated valuations. In a 1993 article, John Whitehead and his colleagues employed a combination mail and phone survey design in an attempt to produce a bias-corrected valuation of a wetlands preservation project. Using the validation principle, these authors attempted to measure differences between non-responders and responders, both in terms of average demographic characteristics and in terms of willingness to pay for environmental amenities. Validation did, in fact, uncover a disparity between those who initially refused to participate and those who participated without hesitation. Although a non-responder with identical observable characteristics was found to be no less willing to pay than a similar responder, the group of eager respondents included more highly educated individuals and more males. After adjusting for non-response bias, the estimated aggregate willingness to pay fell by 33%.

In addition to its application in studying unit non-response, the logic of validation can also be applied to

learn about item non-responders. Emil Kupek’s 1998 article used a large national sex survey in Britain to study the covariates of item non-response. Kupek partitioned his sample into subsamples based on how reluctant individuals were in answering specific questions about their sexual behavior. Specifying the dependent variable to be a measure of each individual’s reluctance to respond, Kupek estimated a model relating other demographic variables to the probability of item non-response. Non-responders in Kupek’s sample turned out to be less educated and to include relatively more nonwhites. Perhaps surprisingly, factors such as gender, declared religious affiliation, age, and marital status seemed to have little effect on the probability of non-response. As in this study, simply establishing which variables correlate with non-response can amount to a key step in thinking through the broader consequences of non-response and, in particular, whether our nonrandom sample will actually lead to bias in estimating the population characteristics of interest.

Designing Surveys So That Non-Response Bias Can Be Estimated

An extensive body of research exists analyzing survey methods, seeking to refine their capacity to overcome potential sources of bias. The results, so far, however, are not reassuring. Survey responses are, without question, very sensitive to the way in which they are elicited. This phenomenon underlies disparaging remarks we frequently hear directed at survey findings in general, such as: “By changing the wording, anything can be shown with surveys.” Although this statement is undoubtedly an exaggeration, the sensitivity of survey results to the fine detail of survey design has been demonstrated in numerous academic studies.

Hurd *et al.*’s 1998 study uses experimental evidence to analyze survey non-response and presents a thorough discussion of survey-response sensitivity in the context of estimating aspects of consumption and savings behavior. The order of survey questions, the gender of the surveyor, rewordings such as “10% survived” instead of “90% died,” and a number of other seemingly innocuous differences in the implementation of surveys can sharply affect the average response. Compared to mail surveys, face-to-face interviews are known to produce higher reported rates of activities with a high degree of social approval such as volunteering, going to church, and engaging in safe rather than unprotected sex. Non-response rates can also vary dramatically depending on whether data are collected using phone, mail, or face-to-face interviews.

Complicating the picture is that these sensitivities to survey design are not always uniform across all segments of the population. For instance, it has been demonstrated that response rates for whites in face-to-face versus mail

surveys are about the same, yet they differ significantly for African American respondents. Such findings underscore the delicate nature of survey design while raising important issues of interpretation that demand consideration even at subsequent stages of data analysis.

Randomized Response

The method of randomized response explicitly aims at reducing non-response and misreporting on survey items that concern sensitive topics. The idea behind randomized response is to introduce random questions or random coding procedures into the construction of response data so that it is impossible for the surveyor to infer the respondent's original response by looking at the data recorded for that individual. A survey question on illegal drug use might employ the following survey design. With probability $1 - q$, respondent i is asked, "Have you ever taken an illegal drug," from which the response datum, $y_i = 1$, is recorded if the answer is "Yes," and $y_i = 0$ otherwise. But with probability q , the response datum is coded $y_i = 1$ no matter i 's answer (or without ever asking i the sensitive question). The advantage of the randomized design is its capacity to convince respondents that it is safe to truthfully disclose private information. If $y_i = 1$, it may be that i answered "Yes," or it may be that i happened to fall in the $(q \times 100)\%$ of the sample for whom y_i is automatically coded 1.

From randomized response data, an unbiased estimator of the true frequency of drug use is easy to compute, assuming that randomization induces perfect compliance (i.e., full response and no misreporting). Denote the true rate of drug use as λ . Because (equation (1)),

$$E y_i = (1 - q)\lambda + q, \quad (1)$$

the estimator

$$\hat{\lambda} = \frac{\frac{1}{N} \sum_i y_i - q}{1 - q} \quad (2)$$

is unbiased. The price to be paid for introducing randomization, however, is a reduction in the precision of estimation, as can be seen by examining the variance formula for $\hat{\lambda}$.

Multivariate versions of randomization are also possible. Fox and Tracy's 1986 monograph, *Randomized Response: A Method for Sensitive Surveys*, provides further details. The goal of randomization, in all its forms, is to reduce respondents' skepticism about the confidentiality of their responses. Whether randomization accomplishes its goal is open to debate, however, because it is not clear whether respondents understand randomization sufficiently well or trust the survey designers to follow through with an honest implementation.

A Budget Constraint Means a Trade-off between Sampling Error and Bias Reduction

Different survey designs have different price tags and, although more data are always desirable, it is not always obvious how to efficiently allocate spending on data collection given a fixed project budget. In designing surveys with the intention of reducing non-response bias in mind, there is often a nontrivial trade-off to consider when selecting a mix of survey techniques. For a given sum of money, an inexpensive mail survey will probably draw a sample with a higher number of units, thereby reducing sampling error. However, a smaller sample collected using face-to-face interviews will probably enjoy the advantage of a lower unit non-response rate. Thus, we are faced with trading off greater precision (increasing the sample size) against a greater chance that non-response bias will contaminate estimation. In this situation, a sound approach generally involves selecting a mix of sampling techniques that will lead to fairly precise estimates while providing reasonably good controls for non-response bias.

Parsing the Meaning of the "Don't Know" Response

A problem faced by most applied researchers working with survey data is interpreting the meaning of the response "Don't know" to a survey question. Those involved at the survey design stage often contemplate whether one should prompt those who respond "Don't know" to relent and provide a valid answer. Interestingly, there is debate about whether such prompting is a good idea or not. Insofar as prompting induces random guessing, it is not helpful. But when additional prompting succeeds at extracting additional information rather than noise, our estimation should, in principle, improve.

For example, public opinion researchers have demonstrated that opinions about political candidates elicited from respondents who say they know nothing about those candidates are, in fact, meaningful indicators of future voting behavior rather than random noise. But in other settings, the evidence points in the opposite direction. As a general rule, the responses of reluctant responders that we collect by means of a special technique of elicitation should be interpreted cautiously, with full acknowledgement that they probably contain more noise than the responses of other respondents.

In some contexts, it may be useful to try identifying multiple subgroups among item non-responders. The issue at stake is the extent to which we can generalize about non-responders. Qualitative information about non-response bias is particularly helpful in instances in which it can be presumed that non-response bias mitigates against finding a significant difference, referring here to an estimated characteristic such as average

income across two groups. In such a case, without doing anything special to correct for bias, discovering a significant difference is especially persuasive, in spite of and, in part, because of the bias. But in other settings, rather than helping to converge to a simple conclusion, gathering additional information about non-responders may complicate the analysis, raising additional questions and revealing the folly of generalizing about non-responders as if they were a homogeneous subset of the population. Oftentimes, they are not.

Panel Data and Attrition

A panel data set contains multiple observations on a fixed group of individuals from whom measurements are collected at several points in time. That is, a random list of individuals is initially chosen, and then those same individuals are surveyed multiple times over the course of months or years. Rather than the snapshot view offered by a cross section in which each observation corresponds to a unique individual, a panel contains a time series for a collection of individuals, which allows researchers to study population characteristics through time.

A frequent problem with panel data is attrition, meaning that some respondents surveyed in the initial period later drop out. Respondents who drop out can be thought of as those who begin as fully cooperative responders but later become non-responders either by choice or circumstance. In this context, non-response bias is sometimes referred to as attrition bias.

Survey panel respondents may be classified as either full-time (those who remain in the sample at all point in time), monotonic attritors, or nonmonotonic attritors. "Nonmonotonic" refers to a respondent who becomes a non-responder at some point in time and then rejoins the survey. When all three types are present in a panel, a three-category logit or probit analysis can demonstrate relationships between the probability of attrition and variables that do not change with time. Simpler still, researchers sometimes run a sequence of regressions and examine the effect on regression coefficients of including or excluding attritors. By creating dummies for full-time, monotonic attritors, and nonmonotonic attritors and interacting those dummies with the regressors of interest, standard *t* tests on interaction terms can produce evidence that attrition is causing bias. As an example, Burkam and Lee's 1998 article applied these techniques to a panel of U.S. high school students, discovering that gender significantly affects the probability of attrition and also that attrition bias leads to an overstatement of black-white disparity on academic achievement tests.

In another useful example of how to deal with attrition, Fitzgerald *et al.*'s 1998 article estimated a structural model of attrition and studied the severity of attrition

bias as it related to a number of standard demographic variables using the Michigan Panel Study on Income Dynamics (PSID). An annual survey panel used frequently by labor economists, the PSID loses roughly 12% of the participants each year. More than 20 years after its inception, fewer than 50% of the original participants remain. Although the observed characteristics of attritors are noticeably different from full-time respondents, coefficient estimates in a variety of models using the PSID, according to Fitzgerald *et al.*, appear to change little when attempts are made to correct for attrition bias. This is good news for researchers attempting to generalize about labor markets in the United States based on the PSID.

Summary

If non-responders are different from responders in ways critical to the main research questions under investigation, the possibility of non-response bias needs to be taken seriously. Whether designing a survey or analyzing previously collected data that have already been collected, a number of useful techniques may be applied to test for and possibly correct for non-response bias. In the data analysis stage, it is usually best, when feasible, to specify a separate equation for the non-response process and estimate all the parameters simultaneously by maximum likelihood. In particular applications, it can be useful to exploit other authors' approaches to dealing with the problem of a nonrepresentative sample, even when the problem is not explicitly referred to as non-response bias. Rather than attempting to solve the problems created by non-response, it is often acceptable simply to be sensitive to the potential problems and state the likely effect of non-response on reported estimates. Careful attention to the problem of non-response is a critical step in conducting high-quality research using survey data.

Nonparametric Item Response Theory Models

Klaas Sijtsma

Tilburg University, Tilburg, The Netherlands

Glossary

invariant item ordering An ordering of items that is the same for each value of the latent trait scale.

monotone homogeneity model A benchmark model within nonparametric item response theory that assumes that all items in a test measure the same latent trait, that the relationship between the item score and the latent trait is monotone, and that the test procedure is free of influences on test performance other than the latent trait.

nonparametric item response theory (NIRT) A version of item response theory that assumes that the relationship between the item score and the latent trait is limited only by order restrictions but is otherwise free.

parametric item response theory (PIRT) A version of item response theory that assumes that the relationship between the item score and the latent trait is defined by a parametric function, such as the logistic or the normal ogive.

stochastic person ordering An ordering of individuals by means of a simple sum score that reflects in a probabilistic way the person ordering on the latent trait scale.

Nonparametric item response theory is a family of item response models for ordinal person and item measurement. The distinctive feature that makes an item response model nonparametric is that in a test either each item response function or the set of all item response functions is restricted by some monotonicity condition, without specifying a parametric family of monotone functions such as the logistic. Instead, item response functions are estimated from the test data and the hypothesized monotonicity condition is evaluated. Several models have been proposed and several methods and software packages are available to evaluate the fit of a model to the data. Nonparametric models are primarily data-oriented in that they study features of the data necessary to obtain ordinal scales for people and sometimes, items as well.

Ordinal scales are useful in applications such as selecting the best applicants for a job or identifying the worst-performing students for remedial teaching.

Measurement Using Nonparametric Item Response Theory Models

Tests consist of well-chosen collections of items—exercises, tasks, questions, and statements—that are used to measure different aspects of a hypothetical construct, for example, arithmetic ability, spatial orientation, knowledge of national history, and introversion. A hypothetical construct is a theoretical structure that explains the relationships among a particular set of behaviors. Nonparametric item response theory (NIRT) models are statistical methods that are used to analyze the item response data collected in a sample of individuals to find out whether the items can be considered to be indicators of the same hypothetical construct. If the answer is affirmative, NIRT models provide an ordinal scale for the theoretical construct of interest. This scale is called the latent trait scale. A rank ordering of individuals allows for statements such as “For this expensive follow-up course, we will admit only the 10 students having the highest arithmetic scores” and “For this job, we will hire the candidate with the highest scale score on general knowledge.”

In addition to a person scale, a successful NIRT analysis also provides information on the quality of the individual items and the whole test as a measurement instrument for a particular theoretical construct. Information on individual items may reveal two things: (1) Whether the item sharply distinguishes people with relatively low latent trait values from others with relatively high latent trait values, and (2) whether the item

measures the same latent trait as the other items in the test. These issues relate to the well-known issues of reliability and validity, respectively. In the phase of test construction, an item that does not distinguish people well or clearly measures a latent trait other than the other items may be removed from the test and replaced by a better one, in order to improve the overall measurement quality of the test.

Assumptions of Nonparametric Item Response Theory Models

Common Assumptions

Methodologically, the latent trait represents an operationalization of the hypothetical construct by means of the collection of items in the test. Semantically, the term latent trait is used to summarize the psychological influences that drive the responses of individuals to each of the items in a test. NIRT assumes that during testing a person's latent trait value is not affected by practice effects, such as those due to learning and development, or flaws in item construction that produce structural dependencies between items. Also, items are related to the latent trait in a way that is specified by the particular NIRT model. This is the common context of most NIRT models. Some models alternatively assume a more complex underlying latent trait structure or formalize practice or training effects during testing that affect test performance. Although potentially interesting and important, these models are not the core of NIRT.

Let X_j be the random variable for the score on item j , and let this score be $x_j = 0, 1, \dots, m$. The assumption of unidimensionality (UD) means that the relationships between J items in the test can be explained by one common latent trait, that is denoted θ . The assumption of local independence (LI) means that given the latent trait value the probability of a score x_j on item j , $P(X_j = x_j | \theta)$, is independent of the scores on the other $J-1$ items in the test. That is, given θ for a vector of J item score random variables, \mathbf{X} , and its realization, \mathbf{x} , we have:

$$P(\mathbf{X} = \mathbf{x} | \theta) = \prod_{j=1}^J P(X_j = x_j | \theta). \quad (1)$$

An implication of LI is that for any pair of items, say j and k , their conditional covariance equals 0; that is, $\text{Cov}(X_j, X_k | \theta) = 0$.

The third assumption defines the relationship between the item score, X_j , and the latent trait, θ , known as the response function; this is the conditional probability, $P(X_j = x_j | \theta)$. NIRT models typically specify order restrictions on this relationship but no other restrictions. For simplicity, we assume that items are scored dichotomously, with $X_j = 0, 1$. These scores may, for example, indicate that the answer was incorrect (score 0) or correct (score 1). Later on, we return to the general case of $m + 1$ ordered item scores. The probability $P_j(\theta) = P(X_j = 1 | \theta)$ is known as the item response function (IRF). A simple assumption that specifies an order relation on the IRF assumes that it is a monotone nondecreasing function. That is, for item j and two fixed arbitrary values of θ , denoted θ_a and θ_b :

$$P_j(\theta_a) \leq P_j(\theta_b) \quad \text{whenever } \theta_a < \theta_b, \text{ and for all } j. \quad (2)$$

This is the monotonicity (M) assumption. Examples of IRFs that satisfy the assumption M are given in Fig. 1A. The assumptions of UD, LI, and M together define the NIRT model, known as the monotone homogeneity model and introduced in 1971 by Mokken. This model can be seen as a benchmark within NIRT.

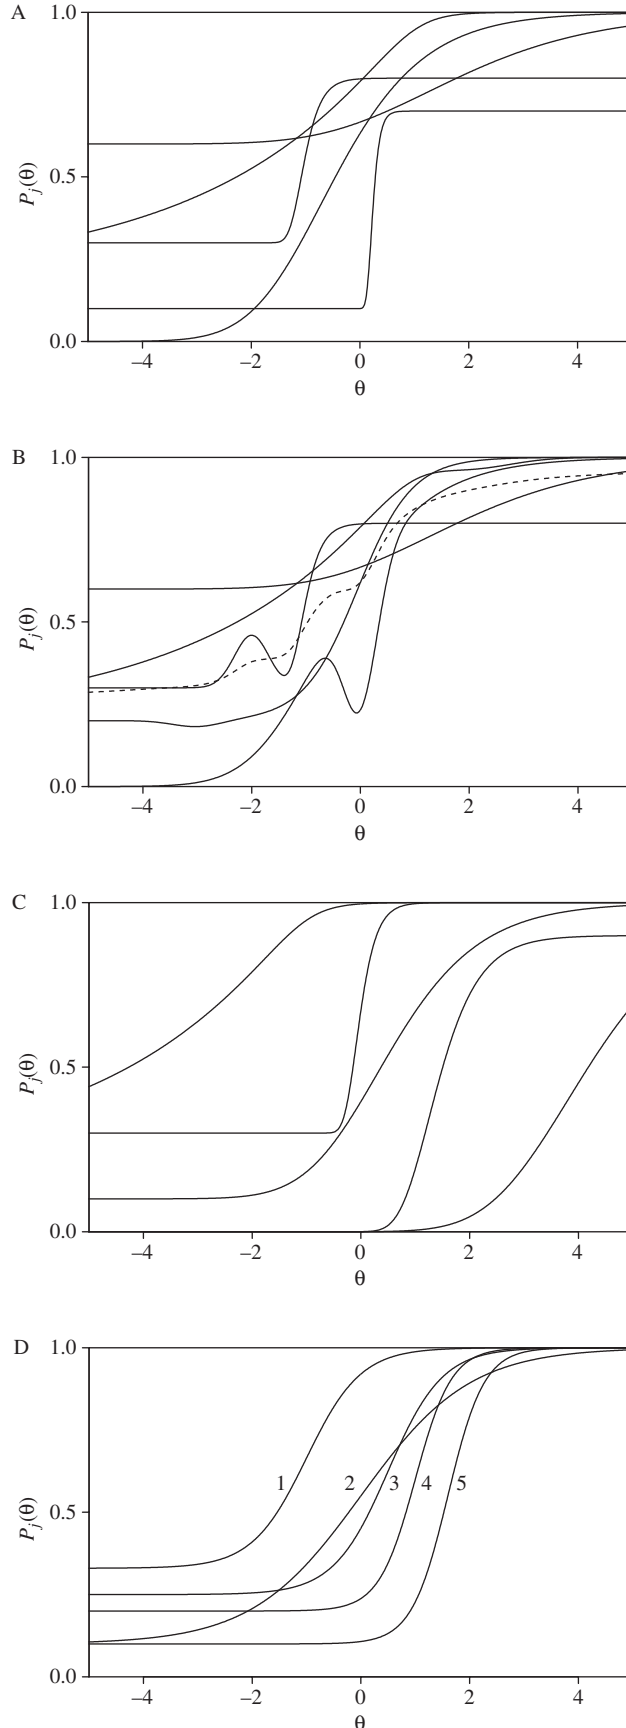

Typical of NIRT is the research into relaxations of the assumptions of UD, LI, and, M that seek to restrict the data as little as possible while maintaining important measurement properties such as the ordinal scale for individuals. For example, in 1990 Stout introduced the relaxation of strict unidimensionality to essential unidimensionality, which assumes one dominant latent trait and several nuisance traits whose influence on all statistical properties of the test vanishes for large J (in fact, $J \rightarrow \infty$). Another relaxation is that of LI to essential independence, which allows some conditional interitem covariances to be positive or negative while in the long run ($J \rightarrow \infty$) the mean across all absolute item pair covariances equals 0. A third example is weak monotonicity, which says that the mean of J IRFs is an increasing function in θ . This mean represents the average response to the test and is known as the test response function. Weak monotonicity does not restrict the individual IRFs as long as their mean is increasing; this means that assumption M is dropped at the individual item level. See Fig. 1B for an example of weak monotonicity. Junker showed in 1993 that none of the three assumptions, UD, LI, and M, can be dropped entirely and still leave enough structure in the data for ordering individuals consistently on a dominant latent trait.

Additional Assumptions

Whereas this and other work are aimed at ordinal person measurement under weak (or the weakest possible) assumptions, models that have more restrictions have been defined for studying item properties. For example, it may be assumed that the J IRFs do not intersect; that is, if for some θ_0 we know for items j and k that $P_j(\theta_0) < P_k(\theta_0)$, then

$$P_j(\theta) \leq P_k(\theta) \quad \text{for all } \theta \quad \text{and} \quad \text{all } j, k; j \neq k. \quad (3)$$

This is the assumption of invariant item ordering (IIO), which says that the J items have the same ordering by

response probability for all θ s, with the possible exception of some θ s for which ties may exist; see Fig. 1C for examples of nonintersecting IRFs that also satisfy assumption M. An interesting NIRT model that is defined by UD, LI, M, and IIO is the double monotonicity model, which was introduced by Mokken in 1971.

Models that have even more restrictions have been proposed by Sijtsma and Hemker in 1998 for items that have polytomous scoring ($m \geq 2$), and that imply that for J items an ordering,

$$E(X_1 | \theta) \leq E(X_2 | \theta) \leq \dots \leq E(X_J | \theta) \quad \text{for all } \theta \quad (4)$$

exists after the appropriate renumbering of the items. For polytomous items, this ordering of expected conditional item scores defines the concept IIO. Because for dichotomous items $E(X_j | \theta) = P_j(\theta)$, the item ordering for polytomous items captures IIO for dichotomous items as a special case.

Finally, local homogeneity is an example of an assumption that is needed when it is assumed that an NIRT model holds in each subgroup from the population of interest. Ellis and Van den Wollenberg showed in 1993 that it is necessary to distinguish between latent trait values θ and individuals when it is assumed that the response probability $P_j(\theta)$ is a within-person expectation of a propensity distribution of the item score for that person. Then different individuals with the same θ value must have the same $P_j(\theta)$ and no other person differences can influence this probability. This is important, for example, in differential item functioning research.

Parametric Item Response Theory Models

Parametric item response theory (PIRT) models are different from NIRT models in that they assume a specific parametric IRF, such as a normal ogive or a logistic function. An example is the three-parameter logistic model, defined as:

$$P_j(\theta) = \gamma_j + (1 - \gamma_j) \frac{\exp[\alpha_j(\theta - \delta_j)]}{1 + \exp[\alpha_j(\theta - \delta_j)]}. \quad (5)$$

Figure 1 (A) Five IRFs satisfying assumption M. (B) Two IRFs (solid curves) that satisfy assumption M, three IRFs that are not monotone increasing, and the test response function that is monotone increasing (dashed curve). (C) Five nonintersecting IRFs that satisfy assumption M. (D) Five IRFs under the three-parameter logistic model (parameter values: $\gamma_1 = 0.33$, $\gamma_2 = 0.10$, $\gamma_3 = 0.25$, $\gamma_4 = 0.20$, $\gamma_5 = 0.10$; $\delta_1 = -0.10$, $\delta_2 = 0.00$, $\delta_3 = 0.50$, $\delta_4 = 1.00$, $\delta_5 = 1.60$; $\alpha_1 = 2.00$, $\alpha_2 = 1.00$, $\alpha_3 = 2.00$, $\alpha_4 = 3.00$, $\alpha_5 = 3.00$).

Here, γ_j is the lower asymptote for $\theta \rightarrow -\infty$, α_j is a slope parameter, and δ_j is a location parameter; see Fig. 1D for examples of three-parameter logistic IRFs. For a data matrix produced by N individuals who responded to J items, the likelihood may be solved for each of these item parameters and the latent trait parameter. The resulting estimates give information on the probability (γ_j) that someone with a low scale value correctly solves item j (or gives an affirmative response); the item's location on the scale (δ_j) sometimes called its difficulty; the item's potential to distinguish between people with low and high scale values (α_j , called the discrimination power) to the left and the right of location δ_j ; and the individuals' scale values (θ). Because NIRT models impose order restrictions on the IRFs but do not impose a logistic or another parametric restriction, they do not have likelihood functions from which these parameters can be solved. Nevertheless, they also provide information on the latent trait and the item parameters; however, they use other statistics and parameters, to be discussed shortly.

Measurement Properties of Nonparametric Item Response Theory Models

Person Measurement

The monotone homogeneity model is a measurement model for individuals. It implies an ordinal person scale in a stochastic ordering sense. Let test performance be summarized in a total score:

$$X_+ = \sum_{j=1}^J X_j \quad (6)$$

and let x_{+a} and x_{+b} be an arbitrarily chosen pair of realizations of X_+ such that $x_{+a} < x_{+b}$. Further, let t be an arbitrary value of θ . Then, the monotone homogeneity model for dichotomous items implies that:

$$P(\theta \geq t | X_+ = x_{+a}) \leq P(\theta \geq t | X_+ = x_{+b}). \quad (7)$$

An implication of this stochastic ordering property is $E(\theta | X_+ = x_{+a}) \leq E(\theta | X_+ = x_{+b})$. Thus, the higher the total score X_+ , the higher the θ value. In an NIRT context, Grayson showed in 1988 that the observable total score X_+ replaces latent trait θ for ordinally measuring individuals.

For polytomous items, Hemker, Sijtsma, Molenaar, and Junker showed in 1997 that the monotone homogeneity model, defined by UD, LI, and a monotonicity assumption on response function $P(X_j \geq x_j | \theta)$ for $x_j = 1, \dots, m$ (for $x_j = 0$, this probability trivially equals 1) does not imply the stochastic ordering property. Van der Ark showed in 2002 that for most realistic tests

and distributions of θ an ordering of individuals on X_+ reflects an ordering on θ , but sometimes with reversals for adjacent X_+ values. Reversals of scores this close are unimportant for the practical use of tests because they represent only small differences with respect to the latent trait. For the polytomous NIRT model based on UD, LI, and M, and for NIRT approaches to polytomous items (and dichotomous items as a special case) based on weaker assumptions, X_+ is a consistent estimator of θ . This means that for infinitely many polytomous items the ordering of individuals using X_+ gives the exact ordering on θ , and Junker showed in 1991 that this result is true for several versions of polytomous NIRT models.

Item Measurement

The double monotonicity model is a measurement model for both individuals and items. Because it is a special case of the monotone homogeneity model, it has the same stochastic ordering and consistency properties for person measurement as that model. In addition, it implies an IIO, discussed, for example, by Sijtsma and Molenaar in 2002; see Eq. (4). An IIO implies that for expected item scores in the whole group:

$$E(X_1) \leq E(X_2) \leq \dots \leq E(X_J). \quad (8)$$

These expectations can be estimated from sample data using the mean item score:

$$\bar{X}_j = J^{-1} \sum_{i=1}^N X_{ij}, \quad j = 1, \dots, J. \quad (9)$$

If the double monotonicity model fits the data, these sample means are then used to estimate the ordering of the expected conditional item scores, $E(X_j | \theta)$, $j = 1, \dots, J$.

The IIO property can be used in several kinds of test applications in which it is important that individuals or subgroups have the same item ordering. For example, person-fit analysis and differential item functioning analysis of real data are better understood if an IIO can be hypothesized for the population, and results that deviate at the level of individuals or subgroups can be interpreted relative to this ordering. Also, in other research an IIO can be the null hypothesis when it is assumed that, for example, the items reflect ascending developmental stages and the equality of this ordering can be tested between age groups. Intelligence tests such as the Wechsler Intelligence Scale for Children use starting and stopping rules that assume an IIO—children of a particular age group start at an item that is easy for them (assuming that the previous items are of trivial difficulty), then are administered items in ascending difficulty ordering, and stop when they fail on several consecutive items (assuming that they would fail also on the next items that are even more difficult).

Fitting Nonparametric Item Response Theory Models to Test Data

If the monotone homogeneity model or a more relaxed version of it fits the test data, an ordinal person scale based on X_+ ordering is implied. If the double monotonicity model fits, not only is an ordinal person scale implied but also an IIO. The question is how to investigate the fit of these models to the test data. NIRT implies two properties of observable variables that are the basis of a variety of methods for investigating model-data fit.

Conditional Association

The first property, introduced by Holland and Rosenbaum in 1986, is conditional association. In principle, if a subgroup of individuals is selected from the population of interest on the basis of their performance on a subset of the items from the test, then within this subgroup the covariance between two sum scores based on another item subset must be nonnegative. The item scores may be dichotomous, polytomous, or continuous. A simple example to start with is that all individuals are selected, thus ignoring a subgroup structure altogether. Then all covariances between two items j and k must be non-negative [$\text{Cov}(X_j, X_k) \geq 0$] and negative covariances give evidence of model-data misfit.

A procedure for selecting one or more unidimensional item subsets from a larger item pool uses item scalability coefficients, denoted H_j , based on this nonnegative covariance property. The outcome of this procedure (implemented in the computer program MSP5 introduced in 2000 by Molenaar and Sijtsma) is one or more subsets of items that each measure another latent trait with items that have discrimination power with a lower bound defined by the researcher. Discrimination power is expressed for items by the scalability coefficients H_j and for the total test by the scalability coefficient H .

A more complex example is the following. $J-2$ items, not including items j and k , are used to define a sum score $R_{(-j,-k)} = \sum_{h \neq j,k} X_h$. Then within subgroups of individuals based on values r of $R_{(-j,-k)}$, conditional association means that $\text{Cov}(X_j, X_k | R_{(-j,-k)} = r) \geq 0$, for all values r . This is the basis of other procedures (implemented in the computer programs DETECT and HCA/CCPROX, and discussed by Stout *et al.* in 1996) that try to find a subset structure for the whole test that approximates local independence as good as possible. The optimal solution best represents the latent trait structure of the test data.

Manifest Monotonicity

The second property, introduced in 1993 by Junker, is manifest monotonicity. This property can be used to

Figure 2 (A) Discrete estimate of an IRF that violates assumption M. (B) Two discrete estimates of IRFs that are intersecting.

investigate whether an IRF, $P_j(\theta)$, is monotone nondecreasing, as assumption M requires. To estimate the IRF for item j , first a sum score on $J-1$ items excluding item j , $R_{(-j)} = \sum_{k \neq j} X_k$, is used as an estimate of θ and then the conditional probability $P[X_j = 1 | R_{(-j)} = r]$ is calculated for all values r of $R_{(-j)}$. Given the monotone homogeneity model, the conditional probability $P[X_j = 1 | R_{(-j)}]$ must be nondecreasing in $R_{(-j)}$; this is manifest monotonicity. For real test data, manifest monotonicity is investigated for each item in the test, and violations are tested for significance; see Fig. 2A for an example of a discrete estimate of the IRF that violates assumption M. The program MSP5 can be used for estimating such discrete response functions and testing violations of monotonicity for significance. The program TestGraf98 made available by Ramsay in 2000, estimates continuous response functions using kernel smoothing and provides many graphics. The theory underlying this program was discussed by Ramsay in 1991.

Manifest monotonicity is also basic to the investigation whether the IRFs of different items are nonintersecting, as the assumption of IIO requires. To investigate IIO for the items j and k , the sign of the difference of the conditional probabilities $P[X_j = 1 | R_{(-j,-k)}]$ and

$P[X_k = 1 | R_{(-j, -k)}]$ can be determined for each value r of the sum score $R_{(-j, -k)}$ and compared with the sign of the difference of the sample item means (\bar{X}_j and \bar{X}_k) for the whole group. Opposite signs for some value r of $R_{(-j, -k)}$ indicate intersection of the IRFs and are tested against the null hypothesis that $P[X_j = 1 | R_{(-j, -k)} = r] = P[X_k = 1 | R_{(-j, -k)} = r]$ in the population (which means that these probabilities are the same but that their ordering is not opposite to the overall ordering). See Fig. 2B for an example of two observed IRFs that give evidence of intersecting IRFs in the population. This and other methods for investigating an IIO have been discussed and compared by Sijtsma and Molenaar in 2002. The program MSP5 can be used for investigating IIO.

For evaluating the monotonicity assumption of the response functions of a polytomous item, $P(X_j \geq x_j | \theta)$ for $x_j = 1, \dots, m$, and the nonintersection of the response functions of different polytomous items, $P(X_j \geq x_j | \theta)$ and $P(X_k \geq x_k | \theta)$, several of these methods are also available in MSP5. Theoretical research to further support the underpinnings of these methods is in progress.

Nonparametric Item Response Theory Models for Nonmonotone Response Functions

For some latent traits and particular item types, a monotone nondecreasing response function cannot adequately describe the probability of an affirmative response. For example, as part of a questionnaire that measures the attitude toward the government's crime-fighting policy people may be asked to indicate whether they think that a 6-month prison term is an adequate sentence for burglary. Both opponents and proponents of long prison sentences may have a low probability of giving an affirmative response to this item, but for opposite reasons, and people having a moderate attitude may have higher probabilities. An NIRT model that successfully describes item scores produced this way thus has to assume that the relationship between the item score and the latent trait first increases and then decreases after a certain latent trait value or interval. In an NIRT context, such a response function could look like the irregular (solid) curve in Fig. 3. The NIRT monotonicity assumption now could be something like: First the IRF increases monotonically, then for some value θ_0 it reaches a maximum value $P_j(\theta_0)$ or a θ range in which it has a constant value, and then it decreases monotonically. Such an order restriction may be compared with a smooth parametric response function (dashed curve in Fig. 3) from a hypothetical parametric model, defined as:

$$P(X_j = 1 | \theta) = \frac{\lambda_j \exp[q(\theta - \delta_j)]}{1 + \exp[q(\theta - \delta_j)]} \quad (10)$$

Figure 3 Irregular nonparametric IRF (solid curve) and smooth parametric IRF (dashed curve; $\lambda_j = 1.7$; $\delta_j = 0.0$) for preference data.

with $q = 1$ if $\theta - \delta_j < 0$, and otherwise $q = -1$; and $0 < \lambda_j < 2$. It may be noted that the nonparametric model encompasses the parametric model as a special case.

In 1992, Post studied the theoretical foundation of NIRT models for nonmonotone response functions and also derived methods for investigating model-data fit. Van Schuur proposed in 1984 a scaling procedure for selecting the best fitting items. Due both to their mathematical complexity and to the scarceness of real data that require nonmonotone response functions, NIRT models for nonmonotone response functions have not gained the popularity of the other NIRT models discussed here.

Practical Applications of Nonparametric Item Response Theory Models

NIRT models are particularly useful for the construction of ordinal scales for person and item measurement. They have proven their usefulness in many fields of applied research, such as psychology (nonverbal intelligence, induction reasoning, and tiredness from workload), sociology (attitudes toward abortion and machiavellism), political science (trustworthiness of inhabitants of foreign countries and political efficacy), marketing research (recency, frequency, and monetary value of purchase applied to market segmentation), and health-related quality-of-life research (quality of life for cancer patients and genital sensations and body image after surgery). Each of the scales for these properties allows the ordering of individuals and groups of individuals and, if the double monotonicity model fits, the ordering of items. What are the typical contributions of NIRT to the analysis of test data?

Item Quality

Compare the monotone homogeneity model with the three-parameter logistic model. An item analysis using the monotone homogeneity model investigates the IRFs by means of discrete estimates $P[X_j=1 | R_{(-j)}]$ (in MSP5) or continuous estimates (in TestGraf98), and these estimates provide information on how IRFs may deviate from assumption M. For example, estimated curves may show zero or negative discrimination for parts of the distribution of θ (Fig. 2A) or even suggest that the IRF is bell-shaped (Fig. 3). When the item discriminates weakly for the lower and the middle part of the θ distribution and also has a low $P_j(\theta)$ for those θ s, this may suggest that the item would be more appropriate in a test for a higher θ group. Bell-shaped IRFs suggest a nonmonotone NIRT model. An analysis using the three-parameter logistic model fits the S-shaped curve (Fig. 1D) to such items, which has the effect of driving the slope parameter α_j to 0 instead of giving diagnostic information about the misfit. Thus, instead of stretching a grid over the data that bends only in some directions but fails to detect other deviations, as is typical of a PIRT approach, an NIRT approach is more data-oriented in that it catches most of the peculiarities of the IRFs. When assumption M is satisfied, NIRT models use the item mean $E(X_j)$ and the item scalability coefficient H_j to replace location δ_j and slope α_j from PIRT, respectively. Items with empirical IRFs that do not have the typical logistic S-shape but that satisfy assumption M and have item scalability coefficients H_j that are reasonably high may be included in a test because they contribute to reliable person measurement.

Dimensionality

PIRT models usually fit a unidimensional model to the data, and multidimensional PIRT models may be used when the data are suspected to be driven by multiple latent traits. Fitting models yield useful parameter estimates that can be the basis for building item banks, equating scales, and adaptive testing. Within NIRT, algorithms have been produced that explore the data for the optimal dimensionality structure using assumption LI (e.g., program DETECT) or assumption M (program MSP5). Thus, NIRT explores the data more than PIRT, which is typically more oriented toward fitting an *a priori* chosen model. NIRT also imposes restrictions on the data, but compared to PIRT these restrictions are weaker, which renders NIRT more data-oriented and exploratory than PIRT.

NIRT models may be used because often little is known about the hypothetical construct, and a model that forces little structure onto the data, while maintaining ordinal measurement scales, may be a wise choice to start with. Given its exploratory orientation, NIRT could then

be used as a precursor to PIRT by exploring the dimensionality structure of the data before a more restrictive hypothesis is tested by means of a PIRT model. Also, when starting with a PIRT model, instead, that does not fit the test data, an NIRT model can then be an alternative to fit to the data. The result of a fitting NIRT model is an ordinal scale for individuals (and items). Depending on the purpose of the test, such a scale is useful for selecting the best applicants for a job, the best students for a follow-up course, or the lowest-scoring pupils for remedial teaching or, in scientific research, for establishing relationships of the test score to other variables of interest.

NORC's 1990 Sampling Design

Rachel Harter

National Opinion Research Center (NORC), Chicago, Illinois, USA

Glossary

cluster sampling Method of sampling in which the ultimate sampling units are naturally grouped in some way, and a sample of the groups (clusters) is selected. If the initial groups are geographical areas, then it is an *area probability design*. If the units within the selected groups are subsampled, then it is a *multistage design*, and the hierarchical clustering and sampling can be repeated for multiple levels. Cluster sampling is often used when a complete list or *frame* of the target population is not available, but a list of the primary sampling units is available. Cluster sampling in this context saves costs by minimizing travel among selected housing units. Because units within a cluster tend to be more alike than units in different clusters, a cluster sample typically provides less information than an unclustered sample of the same size.

design effect A measure of precision of a sample relative to a simple random sample of the same size, defined as the ratio of the variance of a statistic under the design to the variance of the same statistic assuming the sample had been selected by simple random sampling. The lower the design effect, the better. Cluster designs generally have design effects larger than 1, while stratified designs can have design effects less than 1.

half-open interval technique Method of giving housing units not in the national sampling frame a chance of selection, also known as a *missed housing unit procedure*. The half-open interval includes one housing unit on the list as the first closed endpoint, and covers the territory up to but not including the next housing unit on the list as the open endpoint. The interval is well defined because the housing units were originally listed in a prescribed order. A housing unit found within the interval (new construction, for example) has a chance of selection when the first endpoint is selected.

housing unit (HU) A house, apartment, mobile home, trailer, single room, or group of rooms intended for separate living quarters, in which the occupants live and eat separately

from others in the building, and having direct access from outside or through a common hall.

Kish table Also called *objective respondent selection table* by Kish, a table of numbers preassigned to the selected housing unit; when combined with a list of eligible persons in the household, the table enables the interviewer to objectively and randomly select one person for interviewing.

national sampling frame Geographically representative sample of geographical areas and the listed housing unit addresses within those geographical areas, used as a sampling frame for national surveys of residential populations. The process of collecting the addresses is called *listing*.

primary sampling unit The units that have an opportunity for selection at the first stage of a multistage design; each selected primary sampling unit is a cluster of subunits (secondary sampling units) for sampling at the second stage. The lowest levels of sampling units are called *ultimate sampling units*.

self-weighting design Design in which each sampling unit has the same chance of selection. For area probability designs of the residential population, often the housing units have an equal chance of selection.

stratification Technique for grouping units into strata according to similarities prior to selection. Stratification differs from cluster designs in that units from every stratum are included in the sample. Selection of units within a stratum is independent of selection of units in other strata. Stratification is usually done to improve the representativeness of the sample.

systematic sampling Probability sampling design in which the units are sorted in an ordered list, a selection interval k is determined to generate the desired sample size, a first unit is selected randomly between 1 and k , and every k th unit thereafter is selected.

Ideally, a sample selected for a survey is drawn from a well-defined list, or frame, of the units being studied. For example, a sample of persons would be selected from

a complete list of all eligible persons, or a sample of households would be selected from a complete list of all households. Unfortunately, for studies of the United States population or U.S. households, such lists are not publicly available. Studies of this sort are often accomplished by first selecting a sample of geographical areas, creating lists of all housing units within the selected geographical areas, and then selecting a sample of the listed households. This is known as an area probability design. At least once per decade, generally shortly after the decennial census, the National Opinion Research Center (NORC) goes through the process of selecting geographical areas and collecting lists of housing units within the areas. The resulting list is known as NORC's National Sampling Frame. Many national surveys obtain their samples from this frame. To illustrate the concepts and an area probability design, this chapter describes NORC's National Sampling Frame based on the 1990 census.

Introduction

Studies of households, particularly national studies, have had no national sampling frame of households from which a sample can be selected. Government records typically are not available to social scientists outside the government agency. Frames of potential telephone numbers are impractical when face-to-face interviewing is desired.

Area probability designs were developed to compensate for the lack of a comprehensive national list of households. In area probability designs, the basis is a frame of geographies. The frame units are based on well-defined geographical entities such as states, counties, or metropolitan statistical areas. Geographical areas are selected in a multistage cluster design. Address lists are collected for the smallest geographical units selected, resulting in a frame of housing units for the selected geographies. Housing units can then be selected from this frame. If only certain types of households or persons are eligible for the interview, persons can be selected when the sample households are screened for eligibility.

Area probability designs are clustered, and clustered designs are less efficient, statistically, than simple random sampling or stratified random sampling. Specifically, homogeneity within clusters cause design effects that are larger than 1. But because national lists of housing units have not been publicly available, and the cost of assembling such a list is prohibitive, area probability designs provide a reasonable compromise between statistical efficiency and practicality.

Collecting addresses for a sample of geographical areas is not inexpensive, however. Over the years, very few organizations have been able to develop and maintain area probability frames of addresses for national U.S. samples. The National Opinion Research Center

(NORC) at the University of Chicago is one organization that has maintained a national area probability frame. After each decennial census, NORC has redefined and reselected the geographical areas and collected addresses for housing units within the selected addresses. (After the 1980 census, NORC cooperated with the University of Michigan's Institute for Statistical Research in the development of a frame.) The national sampling frames were then used for national studies throughout the decade. The best known of NORC's national area probability studies is the General Social Survey, a repeated cross sectional survey that has been fielded every 1–2 years since 1972.

In this article we describe NORC's national area probability frame as designed following the 1990 decennial census. The design was first described by Tourangeau *et al.* in an NORC internal report, and most of the tables in this article are taken from that report. The design included primary sampling units of counties and metropolitan statistical areas, secondary sampling units of blocks or block groups, subdivisions of blocks under certain circumstances, the selection of housing units, and the selection of persons within housing units. Each stage in the multistage design is described in the following sections.

As of this writing, NORC's 2000 national sampling frame is not yet complete, even though 2000 census data have been available for some time. There are two reasons why the 2000 frame has been deferred. First, national sampling frames are best when they are fresh, before new construction and demolitions alter the landscape. Due to the cyclical nature of many of NORC's area probability studies, the demand for a 2000 frame was not pressing until 2004. NORC opted to develop the new frame as late as possible so that the frame would be as fresh as possible. Second, new informational and technological developments provide opportunities for higher quality and greater efficiency in frame construction. These new developments, which are described at the end of this article, may change the way area probability studies are implemented in the future. By postponing the development of a 2000 national sampling frame, NORC has had additional time to test these new developments and incorporate the best and most up-to-date innovations. Nevertheless, the basic design concepts of a national sampling frame remain the same, and the 1990 national sampling frame illustrates these concepts just as well.

The Multistage Area Probability Design

Primary Sampling Units

The first stage units in the multistage design are called Primary Sampling Units (PSUs). For NORC's 1990

national sampling frame, the PSUs were stratified into two types—metropolitan and non-metropolitan. PSUs in both strata are based on counties or county-like units. All 50 states and the District of Columbia are completely covered by 3141 nonoverlapping counties or county-like units, as of 1990. The metropolitan stratum consisted of all Metropolitan Statistical Areas (MSAs) and New England County Metropolitan Areas (NECMAs), as defined by the Office of Management and Budget. An MSA is a city of at least 50,000 persons with the surrounding county or counties, or an urbanized area of at least 50,000 with a total metropolitan population of at least 100,000, where the U.S. Census Bureau determines urbanized areas. Multiple MSAs with integrated economies and societies are combined into a Consolidated Metropolitan Statistical Area (CMSA) if they have a population of one million or more; each component MSA is called a Primary MSA (PMSA). For example, the Chicago CMSA consists of the Chicago PSMA, the Gary PMSA, and the Kenosha PMSA. Where CMSAs exist, the CMSAs rather than the component PMSAs were the primary sampling units. In New England, MSAs are based on townships rather than counties, which means that MSAs sometimes subdivide a county. NECMAs, on the other hand, are based on whole counties. For consistency with the rest of the frame, NORC used NECMAs rather than MSAs as primary sampling units in New England. Altogether, 259 metropolitan PSUs were defined.

The non-metropolitan PSUs covered 2394 counties that were not part of any metropolitan PSU. Non-metropolitan PSUs were primarily defined by individual counties. If a county had fewer than 2000 housing units (HUs), it was combined with an adjacent county to form a PSU. That is, PSUs had a minimum size of 2000 HUs to support the sampling needs of multiple national studies. Where necessary, smaller counties as identified by census STF-1C files were linked to an adjacent county, where an adjacent county was identified sorting on latitudes and longitudes of county centers. The non-metropolitan stratum consisted of 2197 PSUs. Table I summarizes the number of counties and PSUs defined in the metropolitan and non-metropolitan strata.

Table I PSUs by Stratum

<i>Stratum</i>	<i>Number of counties</i>	<i>Number of PSUs</i>
Metropolitan PSUs	737	292
CMSAs	87	8
MSAs/NECMAs	660	284
Non-metropolitan PSUs	2394	2197
Total PSUs	3141	2489

Briefly, a sample of PSUs was selected by systematic sampling. The PSUs were first sorted to achieve implicit stratification. The PSUs were selected systematically with probability proportional to size, where the measure of size was the 1990 census count of the number of housing units in the PSUs. Each of these concepts is explained below.

In systematic selection, the units are sorted in an ordered list. A selection interval is determined to generate the desired sample size. For example, for a frame of size N and a desired sample of size n , the interval is $k = N/n$, which is not necessarily an integer. A first unit is selected randomly between 1 and k , and every k th unit thereafter is selected. (When k is not an integer, select the first unit whose position is greater than or equal to the next multiple of k .) In this example, units are selected with equal probability n/N . Systematic sampling is described more fully in Cochran and other sampling texts.

For NORC's national sampling frame, units were selected with probability proportional to the number of housing units in the PSUs. One way of conceptualizing the method is to imagine that N is the number of housing units in the frame, and each PSU is listed multiple times in the frame for the number of HUs in the PSU. For example, a PSU with 10,000 HUs would have 10,000 chances of being selected. The probability of selection is the PSU size divided by the total frame size.

Some PSUs had size greater than the selection interval k , which means that these PSUs were selected with certainty. These PSUs, selected with probability 1, are sometimes referred to as self-representing PSUs. Certainty units were selected through an iterative process. An initial selection interval was calculated based on the desired sample size and the total frame size. Any PSU larger than the selection interval was selected automatically and removed from the list. The frame size and the number of units to select were decreased by the certainty PSUs, and the selection interval was recalculated. Additional PSUs were selected with certainty based on the new selection interval, so they were removed and a newer selection interval was recalculated as before. The process continued until all remaining PSUs had size smaller than the selection interval. The remainder of the sample was selected systematically with probability proportional to size as described above. After iterations, NORC's 1990 frame had 19 metropolitan PSUs selected with certainty. None of the non-metropolitan PSUs was selected with certainty.

Some samplers are uncomfortable calling certainty units PSUs. Because these units were selected with certainty, they were not "sampled" at all. The certainty units can be thought of as comprising a stratum. What would be called secondary sampling units in other PSUs were technically PSUs within these certainty units. Because of the different ways the nomenclature can be used, comparisons of the number of PSUs across designs can be misleading.

Before systematic selection was carried out for the remainder of the sample, the units were sorted to distribute the sample across the spectrum of the sort variables. In this way, the sampled units broadly represented different classes without explicitly stratifying by these classes. The noncertainty PSUs were sorted primarily by level of urbanization, with the metropolitan units listed first followed by the non-metropolitan units. The metropolitan units were sorted geographically by the nine census divisions. If a PSU crossed division boundaries, it was assigned to the single division that contained the majority of its population. Within division the units were sorted by quartiles of the percent minority population (here defined as African-American and Hispanic population), based on 1990 census data. Finally, the metropolitan units were sorted by per capita income, where the income figures were obtained from a private firm. Non-metropolitan units were sorted geographically by census region (Northeast, Midwest, South, and West), state, minority quartile, and per capita income.

To avoid jumps in the sort order for minority quartile and per capita income, NORC used a "serpentine" procedure where variables were alternatively ascending and descending. For example, within one census division the units were sorted by ascending minority quartile, and in the next division they were sorted by descending minority quartile. This serpentine order helped ensure that the sample was representative across all of the sort variables.

Altogether, 100 PSUs were selected, counting the certainty units as sample PSUs. The PSUs covered 51.4% of all housing units in the U.S. The selected PSUs mirrored the distribution of the population of HUs geographically, as well. [Table II](#) summarizes the sample of PSUs by geography. [Table III](#) compares the distribution of the non-

certainty sample of PSUs to the noncertainty population of HUs. For example, 51 of the 81 noncertainty PSUs in the sample (63%) were metropolitan; similarly, 63% of the HUs in the geography covered by the population of noncertainty PSUs were in metropolitan PSUs. For the sake of illustration, [Fig. 1](#) is a map of a hypothetical sample of PSUs.

Secondary Sampling Units

PSUs were still too large to manually obtain complete address lists, so the PSUs were subdivided into Secondary Sampling Units (SSUs). A sample of SSUs was selected for address collection. SSUs were ordered and selected by systematic sampling with probability proportional to size, in much the same fashion as PSUs were selected. Aspects of SSU selection are discussed in this section.

It has been NORC policy to avoid using the same HU more than once during the 10-year life of the frame. Therefore, each SSU should contain enough HUs to support the needs of various area probability samples over the course of a decade. The number of such studies is not known in advance with certainty, so to some extent the decision is a gamble. If the SSUs are too small, all of the HUs are selected eventually, and the SSU must be replaced. If the SSUs are much larger than necessary, the cost of obtaining address lists is wasteful. The size of the SSUs must be balanced with the number of SSUs selected, as both affect costs and design effects.

For the 1990 frame, NORC defined SSUs to be individual blocks or groups of blocks containing at least 50 HUs. For the 1990 census, the entire U.S. was divided into blocks for the first time. Blocks with fewer than 50 HUs were linked to another block in the same census tract. If all the blocks in a tract contained fewer than 50 HUs combined,

Table II Geographical Summary of the Sample of PSUs

	<i>Northeast</i>	<i>Midwest</i>	<i>South</i>	<i>West</i>	<i>Total</i>
Certainty PSUs	4	4	6	5	19
Noncertainty Metropolitan PSUs	8	13	21	9	51
Noncertainty Non-metropolitan PSUs	4	9	13	4	30
Total	16	26	40	18	100

Table III Comparison of sample PSUs with population HUs

	<i>Metropolitan</i>		<i>Non-Metropolitan</i>	
Noncertainty sample PSUs	63%		37%	
Noncertainty population of HUs	63%		37%	
	<i>Northeast</i>	<i>Midwest</i>	<i>South</i>	<i>West</i>
Noncertainty sample of PSUs	14.8%	27.2%	42.0%	16.0%
Noncertainty population of HUs	14.2%	26.9%	42.9%	16.0%

Figure 1 Map of hypothetical sample of PSUs.

then they were linked to the last segment from the previous tract; such multitract SSUs were rare. To link blocks, the blocks were first sorted by census block number within census tract, linking with adjacent blocks in sort order. Usually the linked blocks were geographically adjacent.

Altogether, NORC selected 3046 SSUs. A subsample of 384 SSUs was selected for address collection. The remaining selected SSUs were held in reserve for custom larger studies or for SSU replacement when all HUs in selected SSUs were used up. For all noncertainty PSUs, NORC selected 24 SSUs and subsampled three for address collection. For the certainty PSUs, NORC selected at least 25 SSUs with at least three for address collection; the number selected was proportional to the PSU size. The largest PSU (New York) had 210 selected SSUs, with 26 subsampled for address collection.

The SSUs were selected by systematic sampling with probability proportional to size, where again the measure of size was the number of HUs. The SSUs were sorted prior to selection, imposing an implicit stratification on the sort variables. The purpose of the implicit stratification was to increase precision to the extent that the sort variables were correlated with the survey variables. Within each PSU, SSUs were sorted by (1) central city vs noncentral city, (2) state, (3) county, (4) census place, (5) quartile of tract's percent minority, and (6) census tract. When subsampling for address collection, the sample SSUs were again selected systematically in the order they were first selected from the PSU. [Figure 2](#) illustrates a hypothetical sample of SSUs within a PSU.

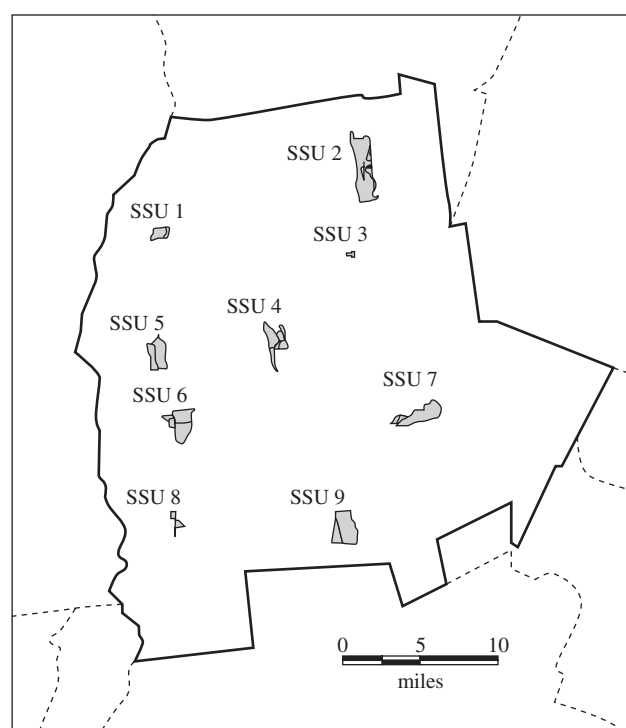

Figure 2 Map of hypothetical sample of SSUs within a PSU.

Housing Units

Before a sample of housing units can be selected from the SSUs, a frame list of HUs in the SSUs is needed. The process of collecting addresses in the SSUs is called

listing. The lister, or field person who collects the addresses, travels to the SSU. Starting at the northwest corner of the lowest numbered block in the SSU, the lister travels around the block in a clockwise direction, writing down the address of every HU in order. When the lister returns to the starting place, she moves to the northwest corner of the next lowest numbered block in the SSU and begins listing that block. The process continues until the entire SSU is listed. Figure 3 shows a single SSU with blocks and HUs.

The process of listing is not as simple as it seems. Block boundaries are not always clear, so custom maps are created of the SSU as a whole and of the individual blocks within it. Special rules govern the procedures for listing cul-de-sacs, alleys, and other configurations. Where addresses are not obvious, the lister must describe the permanent characteristics of the HUs in terms that are clear and unambiguous. Additional rules specify the proper order in which to list individual apartments that have the same street address. Having a prescribed order is important to aid interviewers in locating the selected HUs during a study.

In rare instances, an SSU was too large to be practical and cost-effective for listing. Such SSUs consisted of large, urban high-rises, or a broad geographical area requiring extensive travel time. These SSUs were subdivided into smaller areas called chunks, and a single chunk was selected in place of the entire SSU. Technically, chunking was a third stage of sample selection, but it was applied only rarely. The lister first traveled the entire SSU, keeping a quick count of the number of HUs by block, sub-block, or building without writing down individual addresses. If the quick count of HUs exceeded a certain threshold (both 1000 and 500 have been used as thresholds), the lister divided the SSU into chunks; otherwise, the lister collected addresses for the

entire SSU. Each chunk was required to have the minimum number of HUs to stand in place of the entire SSU. The lister called the supervisor, who entered the chunk sizes into a program that selected one chunk for listing. The program also stored the probability of selection so that sampling weights could be adjusted properly. The lister then proceeded to list just the selected chunk using the usual procedures for listing an entire SSU.

When the paper listings were returned to headquarters, the addresses and descriptions were keyed. The keyed listings were compiled into a large database maintained by the sampling statisticians who selected samples of HUs for area probability studies. A number of quality checks were performed before, after, and throughout the transmission processes.

NORC developed custom software to maintain the database of addresses and select samples as needed. Given a desired sample size, the software allocates sample sizes to SSUs so that, unconditionally, all HUs have an equal probability of selection. From the allocation, the software determines a selection interval and selects a sample of HUs systematically in listed order. Selection is independent from one SSU to the next. The software marks the selected HUs so that they are not available for selection in subsequent sample draws. The sample of HUs is provided to the field force for screening and interviewing.

Persons

Sometimes the unit of analysis for a study is the household, in which case no additional sampling is necessary. Any knowledgeable adult in a selected household can respond to the main questionnaire about the household. Other times the person is the unit of analysis. Most studies do not interview all members of a household because of the high correlations in their responses. More commonly, one person per household is selected. Thus, there is one additional stage of sampling.

Often the selection of persons takes place in the field following a short screener interview of the household. Sometimes the household members are rostered, and a person is selected using an objective respondent selection table, commonly known as a Kish table, or a programmed selection routine in the interviewer's computer. Rostering can be a slow process, reducing screener completion rates. An alternative is to use a simple selection routine such as the nearest birthday method, in which the person selected is the one who most recently had a birthday, or some variation of that rule. The method that is used for selecting persons is specific to the study and is not a characteristic of the national area probability frame.

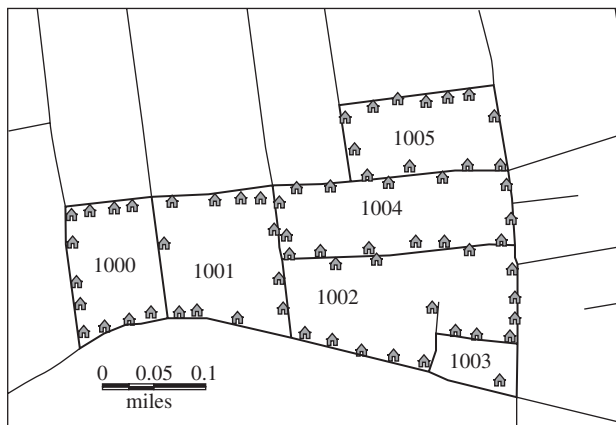

Figure 3 Map of hypothetical SSU (6 blocks) with housing units shown.

NORC's national sampling frame is designed to give every housing unit in the U.S. an equal probability of selection. (Chunking introduces some deviations, but the effect is assumed to be minor.) Thus, every housing unit has approximately the same sampling weight. Assuming similar response patterns throughout, studies of U.S. households selected from the national sampling frame can be analyzed on an unweighted basis. The design is said to be self-weighting. When persons are the unit of analysis, then the probability of selecting persons within households should be taken into account. Depending on the method used, the person weights may vary according to the size and composition of the households.

Frame Maintenance

The population of housing units is in constant flux. New homes are built, and existing homes are demolished or subdivided. Garages and basements are converted to apartments. Buildings constructed as homes are converted to businesses, and vice-versa. By the time a sample of HUs is selected, the frame is already out of date. The older the frame, the greater the number of HUs that are not on the list. In addition, lister errors and the inaccessibility of some HUs lead to imperfections in the frame from the start. If every HU in the country is to have a chance of selection, then some provision must be made for these situations.

One option is to update the frame periodically through listing updates. For example, listers might periodically return to the SSUs to verify or update the lists. While this approach keeps the frame as fresh as possible, it never entirely eliminates the problem of missed HUs because of inevitable time lags, however small. Listing updates are relatively expensive, as well, because they require on-site visits.

NORC more commonly employs at the interviewing stage a procedure for identifying HUs that are not on the list and giving them a chance of being in the sample. The missed housing unit procedure is based on the concept of half-open intervals. A half-open interval is an interval which includes one endpoint and all points up to but not including the next endpoint. In this context, a half-open interval includes an HU on the list and all territory up to but not including the next HU on the list. Recall that the listing procedure originally specified a process for covering all the area within selected SSUs. Therefore, all geographical points within the SSU would have been searched for HUs in a prescribed order. If a new HU is identified during the interviewing phase of a survey, the interviewer can identify where on the list the new HU would have been if it had been found by the lister. Because the new HU is in the preceding HU's half-open interval, it is added to the sample if and only if the

preceding HU on the list is in the sample. In this way, the probability for the new HU is the same as the probability of the HU that precedes it on the list.

If multiple missed HUs are found within the same half-open interval, then all of them have a chance of being included in the sample based on whether or not the preceding listed HU is in the sample. However, if the number of missed HUs in an interval is large, the risk to the interviewing budget and schedule may be unacceptably high. Typically NORC studies restrict the number of missed HUs in a single half-open interval to three; if more than three missed HUs are found in a single selected interval, then three of the missed HUs are selected randomly and weighted accordingly.

New Developments in Area Probability Designs

Design Options

Although NORC's area probability design used HU counts as the primary measure of size, other measures of size are possible. Studies that target minorities might be better served with a design based on the number of minority persons. Studies of youths might be more efficient if the design were based on youth populations. For example, the National Longitudinal Study of Youth 1997 had a custom area probability design that incorporated counts of black and Hispanic youths as a measure of size.

Demographic concepts change over time. The 2000 census was the first to allow persons to classify themselves in multiple race categories. This has implications for the measures of size that can be used, and for the way PSUs and SSUs are sorted for systematic selection.

Geographical area definitions also change over time. Metropolitan areas from the 1980 census were known as Standard Metropolitan Areas. For the 1990 census, the metropolitan areas were redefined and called Metropolitan Statistical Areas. New geographical areas are now defined based on the results of the 2000 census. Not only do geographical areas change in size, which causes different geographies to meet metropolitan criteria, but the criteria themselves may change to define new types of metropolitan areas.

Design changes are not always the result of definitional changes. Sometimes new statistical research and new developments make new ideas practical. One new development is an algorithm for maximizing or minimizing the overlap of new sample units with units selected for another sample from the same frame. The Ernst procedure, for example, can be used to encourage or discourage the selection of the same PSUs and SSUs that were selected last decade. See Further Reading below for more details.

Sometimes design changes are dictated by changes in research interests. The frame may be designed differently depending on whether the analytical needs relate to the residential population, the total population including group quarters and institutions, or specific demographic groups. Alternatively, if customers shift their focus to regional or community studies rather than national studies, the chosen design is likely to be quite different.

Finally, design changes and operational changes, which are related, are sometimes driven by cost concerns. For example, one goal may be to minimize the amount of time between address collection and HU selection; having the interviewers conduct the listing and selection of HUs in the field can reduce or eliminate this time gap.

New Data Sources

The American Community Survey will provide the same information collected in the census long form. The ACS will collect data more often, which may free survey organizations from the once-per-decade frame development cycle. For example, PSUs may be reselected on a rolling basis, spreading the costs over the decade.

Recently, address lists from the U.S. Postal Service have become commercially available through third party vendors. Some survey organizations are researching the use of the address lists in lieu of manually collected addresses. While rural route and post office box addresses will never be an adequate substitute, the use of the USPS list in some geographies is promising.

New Hardware/Software

Traditionally, the listing operation to collect housing unit addresses has been done with pencil and paper. Pencil and paper are inexpensive and highly portable. At some point, however, the listed addresses must be converted into electronic form to consolidate the frame for sample selection. The data entry step, while not difficult, nevertheless adds to the expense, the time, and the chance of errors.

Portable electronic devices are changing rapidly, introducing opportunities for electronic address collection. The variety of devices include laptop computers, tablet computers, palmtop computers, and personal digital assistants. Combined with sophisticated software and easy data transmission, such devices have the potential to allow for electronic updates to maps, built-in edit checks, and rapid assembly of the frame. Barriers to the widespread use of these devices for listing addresses have included high costs, poor battery life, poor visibility of the screen (especially outdoors), poor handwriting recognition capabilities, weight and awkwardness relative to paper, and lack of compatibility with software and systems

in the home office. These obstacles are rapidly being overcome.

Another technological development is the accessibility of the Global Positioning System (GPS) and inexpensive devices that record geographical coordinates. In many areas, the precision of the latitudes and longitudes can distinguish individual housing units. The coordinates enable the housing units to be displayed on maps. Combined with on-line travel directions, the availability of coordinates greatly simplifies the interviewer's job of locating a selected housing unit that may have been listed by somebody else. Like names and addresses, geographical coordinates must be strictly protected to avoid the risk of disclosing the identities of respondents.

Mapping software and databases are far more sophisticated than in the past. Most databases are built on the census Topologically Integrated Geographic Encoding and Referencing (TIGER) system, which dramatically improved mapping capabilities when they became publicly available more than a decade ago. Today, commercial vendors enhance the TIGER data with regular updates and additional data sources, making their mapping systems more current and accurate than ever before. Better maps mean less time locating the geographical areas for listing addresses, and less time locating selected housing units. Zoom capabilities and geographical coordinates of individual housing units enhance the usefulness of the maps. Sophisticated mapping software may even be able to optimize travel routes.

Summary

The 1990 National Sampling Frame for area probability studies, as described in this article, was a multistage cluster design with systematic sampling of geographies and housing units. The sampling stages are summarized in Fig. 4. The geographical sampling units in the first two stages were selected with probability proportional to the number of housing units. Lists of addresses were collected for the smallest geographical sampling units. The address listings comprised the frame for nationally representative samples of housing units requiring face-to-face interviewing. When HUs were selected, the sample was allocated to the geographies such that all HUs had an equal probability of selection. The National Sampling Frame was the basis for a number of high profile studies throughout the past decade.

While the basic principles of area probability designs have changed little over the years, technological advancements are making implementation quicker and cheaper. Organizations such as NORC can take advantage of these developments to reduce costs and to increase the statistical efficiency of the basic designs.

Glossary

generalized estimating equations (GEE) An extension of the generalized linear model developed to deal with clustered and longitudinal data, such as panel models, by first estimating regression parameters then estimating associations among parameters.

latent variable An unmeasured variable that represents an underlying construct (often in the context of structural equation or latent structure modeling).

nonrecursive path model A structural equation model that hypothesizes reciprocal relationships wherein a variable can be both the cause of and an effect of another variable.

principal components Constructions formed from interrelated items that are reduced to a smaller number of well-formed composite measures (components) for further analyses; principal components should not be confused with “factors” that are constructed using a different treatment of the diagonal elements of covariance or correlation matrices.

structural equation modeling (SEM) The development and statistical testing of either an exploratory or explanatory model of hypothesized relationships among variables using simultaneous equations to estimate parameters.

Nursing research involves a systematic search for and validation of knowledge about issues of importance to the nursing profession. Nurses are the largest group of professionals engaged in the provision of health care services in the United States. Like other professionals, nurses are expected to document their “social relevance,” including their role in the delivery of services to clients. Nursing research helps to define the unique roles of nurses and

their expanding body of professional knowledge. Additionally, nursing research, whether evaluative or basic, contributes to the accountability of the profession for services provided to clients and payers.

Introduction

What Is (and Why) Nursing Research?

Historically, entry into nursing practice has been through a number of paths including diploma programs in hospitals, associates programs at community and technical colleges, and university-based Bachelors of Science in Nursing (BSN) degrees. Increasingly, the emphasis of nursing education has shifted toward the BSN and graduate degrees for advanced practice. Advanced practice programs often require masters theses or research projects, directed by doctorally prepared faculty. This educational upgrading of curricula in nursing is consistent with a currently expanded view of nursing practice. Good nursing practice now is viewed as based on “evidence,” continuous measurement, evaluation and review, and practice improvement based on patient outcomes after interventions.

The Context: Outcomes Research and Evidence-Based Nursing Practice

Doctoral programs offering degrees in nursing developed only about three decades ago. As a result, most nurses who obtained research-oriented degrees matriculated in education, the social sciences (particularly psychology and sociology), and a number of other disciplines. Within

recent years, research training has expanded in doctoral programs in nursing. Nurses also continue to obtain research degrees in the areas previously mentioned and in physiology, informatics, statistics, and epidemiology. Various academic disciplines emphasize different research methods and strategies; as a consequence, heterogeneity in the advanced education of nurses promotes diversity in methods and research strategies among nurses that may surprise outside observers.

Despite diverse research foci, studies are being done and emphasis given to what is sometimes loosely called “outcomes research”—this concept shall be used as an organizing and limiting construct for this article. Outcomes research emphasizes the use of advanced statistical methods and research designs to determine how interventions used by nurses or other clinicians affect the health trajectories of patients. An outcomes approach to research is now seen by many as useful for building the knowledge base of nursing, providing accountability to clients and society more generally, and, most importantly, promoting improved care. Due to space limitations, research methods now being used by nurses in biomedical bench research, qualitative research, and statistics and epidemiology will not be discussed in this article, although these are important areas of research in nursing.

As health care organizations and governments attempt to promote efficiency, improve effectiveness, and reduce levels of health care expenditures, outcomes research and evidence-based nursing practice have gained attention and support. Outcomes research assesses changes in individuals’ (or communities’) health status as a result of interventions provided in health care settings. The idea of measuring outcomes or documenting evidence of the value of services is not new in nursing. Barnes (1969), in *Nursing Clinics of North America*, for example, shows that interventions by a pediatric clinical nurse specialist (CNS, a masters prepared nurse) produced valuable patient outcomes. The outcomes identified included the following: An increase in successful oral dilatation without anesthesia. Cost of dilatation decreased. Mastery of the child’s care by mother improved. The total hours of CNS care decreased over time. Weight and verbalizations by the child improved. These outcomes are reflected at multiple levels: patient, family, provider, and organizational.

Social science methods were applied in the Barnes study, and they have been applied in the great majority of research done by nurses. Current methods of choice are largely multivariate and correlational, with attempts made to statistically control for covariates that might produce confounding among intervention associated variables.

Although few patient outcomes have been identified that are affected solely by nursing interventions, there are a number of measures of outcomes that are considered “nursing sensitive.” Marek gives specific examples with

children suffering from sickle cell disease. In the sense noted by Barnes and other nurse researchers, Marek views these nursing outcomes as multilevel. That is, the outcomes of nursing interventions can range from the physiologic (e.g., lower patient complication rate), to family outcomes (e.g., lower parental stress), to “systems” issues (e.g., fewer emergency room visits).

Nursing quality indicators have been developed for acute care settings, and these indicators often capture multilevel outcomes. These quality indicators are often classified into measures of outcome, process, and structure. Patient outcomes and process indicators have included patient injury rate, nosocomial infection rate, maintenance of skin integrity, and patient satisfaction (e.g., with pain management, with educational information, with care). At the nurse provider level, outcomes have included staff satisfaction and intent to stay on the job. Structural or organizational indicators of quality have included the total nursing care hours provided per patient and the “skill mix” of registered nurses (RNs), licensed practical nurses (LPNs), and unlicensed staff caring for patients, and other indicators reflecting the structure of the institutions in which nurses work.

Social Science Measurement Concepts in Nursing Research

Nursing research uses social science measurement methods, concepts, and definitions similar to those in the disciplines of psychology and sociology. Thus, scientific research is defined as the systematic, controlled, empirical, and critical investigation of hypothesized relationships among phenomena. Measurement is defined as the assignment of numbers to objects or events according to rules. Measurement may be nominal, ordinal, interval, or ratio; these measurements determine the type of data analyses (nonparametric, parametric) used. To measure variables in a study, researchers are advised to select instruments or tools that are reliable and valid, also referred to as the tools’ psychometric properties. Nurses educated in research-oriented doctoral programs in nursing and other disciplines are thoroughly familiar with such works as those of Kerlinger and others that emphasize assessments of validity and reliability. Research design and statistics is introduced at the undergraduate level in most quality BSN programs and an increasing number of texts present research methods and measurement specifically for nurses (e.g., Polit and Hungler). In general, nursing research has given considerable attention to content validity, criterion-related validity (concurrent, predictive), and construct validity.

Data collection tools used in nursing research include self-report scales, tests that measure various attributes,

questionnaires, interview schedules, and observation checklists. Strategies to avoid measurement errors are emphasized. In selecting measurement tools for a study, nurses use various compendia in the social sciences (psychology, sociology) that describe data collection instruments and their psychometric properties. Some nurses are authors of these texts (Waltz *et al.*; Ward and Lindeman). A few of the constructs used in nursing research are outlined below.

Patient/Client

Clinical status as an outcome of care received by individual patients or clients is measured physiologically and behaviorally. Behavioral indicators include measures of *psychosocial status* (such as mood, anxiety, depression, stress, coping, self-esteem), *functional status* (such as activities of daily living); *cognitive status* (such as knowledge of the disease); *attitude* (such as satisfaction with nursing care or care overall or with educational information); and *other aspects* (such as self-care methods for symptom management, quality of life, child development).

Family Members (and the Family System)

Individual family members' behaviors may be studied also using many indicators that measure *psychosocial*, *functional*, and *cognitive* status, and *attitudes*. In addition, the *role of family members as informal caregivers at home* has been studied in nursing research with concepts such as *motivation to help*, *preparedness to help*, and *mutuality*, as well as *role strain*, *burden*, and *related concepts*. Consistent with systems theory, these variables are recognized as interrelated within the *family system*. For example, our path analysis results in a study of children on apnea monitors and their caregivers (mothers) show that *family cohesion*, *caregiver self-esteem*, and *social support* are related to positive *family coping strategies*, positive *caregiver-child interactions*, and higher *expressive language development* in the children.

Nurse Providers

Commitment, *satisfaction*, *intent to stay on the job*, *burn-out*, and *job stress* are some of the individual professional provider variables measured in nursing research. These variables often are correlated with the characteristics of the nurse as well as those of the workplace. For example, Taunton *et al.*, using structural equation modeling based on Leavitt's theory of behavior within an organization, reported that manager leadership characteristics influenced nurse retention through work characteristics, *job stress*, *job satisfaction*, *commitment*, and *nurses' intent*

to stay on the job. These findings are consistent with those of many other researchers, including Aiken *et al.*'s cross-cultural study in five countries (United States, Canada, England, Scotland, Germany). These authors report that nurses' negative perceptions of staffing adequacy and workforce management policies are key variables that significantly explained *nurses' job dissatisfaction* and *burn-out*.

Attempts are now being made by a number of nurses to study how provider characteristics and institutional setting directly and indirectly affect patient outcomes. This is a laudable attempt to bring together research at the client and institutional levels to assess how patient care can be immediately improved. Nurses historically and today practice in institutional settings in which they are greatly impacted by organizational structures and processes. These structure and processes are likely to be strongly associated with patient outcomes.

Social Science Research Design Methods and Analyses

Nurse researchers have long been advised that studies need to be planned with careful attention to logical consistency, theory, design, and analysis. Sociological models such as Gibbs' have been cited and discussed in the nursing literature. Using a modified version of the Gibbs substruction model, Dulock and Holzemer describe how a study's conceptual or theoretical model or system are linked with the "operational system" and the empirical indicators that measure the variables studied.

Within nursing research, selection of data analysis technique has been dependent on the study design: descriptive, predictive, experimental, or quasi-experimental. Social science methods of sampling (probability, nonprobability) and sample size determination (power analysis) usually are carefully assessed. Because of its distinct relationship with medical research, nursing research may emphasize power analysis more than some social science disciplines. The use of epidemiologic methods also is growing in nursing. Nurse researchers conduct studies using both experimental and nonexperimental designs, guided by the social science and nursing literature.

Consistent with the outcomes research framework of this article, selected examples of "true experiments" are identified. These are considered to be the strongest designs in that measurement of cause-effect relationships between treatments or interventions and the outcome variables often is less ambiguous than in observational studies. Experimental designs satisfy three criteria: namely, manipulation of the independent

variable, presence of a control group, and random assignment of study subjects to the experimental and control groups. The last criterion is not satisfied in “quasi-experiments;” “pre-experiments” meet only the first criterion. Pre-experiments usually are done in nursing as pilot or preliminary studies prior to the implementation of a true experiment. Pre-experimental designs may be combined with nonexperimental approaches including content analysis and other qualitative methods.

Nurses have done nonexperimental and observational research that test patterned or structural relationships among variables (such as structural equation modeling). Outside the discipline of education, nurses were among the earlier adopters of LISREL and structural equation models. Yet, the use of multilevel modeling has grown somewhat slower in nursing than in some other social science disciplines. Due to the inherent multilevel nature of many nursing outcome studies, however, one can anticipate that such modeling is likely to be used increasingly, applying LISREL, HLM, Mplus, or other software.

Due to the fact that many nurse researchers obtained their earlier experiences in educational psychology and that measurement is heavily emphasized in outcomes research, it is not surprising that much attention has been and continues to be given to instrument development and assessment. Current research attention is turning toward how measurement instruments might be more easily adapted to clinical practice settings. Unfortunately, studies of predictive validity in nursing have been few.

New funding sources have enhanced the ability of nurses to engage in outcomes research with strong designs. In 1986, a National Center of Nursing Research was established at the National Institutes of Health; in 1993, the Center became the National Institute of Nursing Research, NINR. Funding through the Institute enables nurse researchers to collaborate with other disciplines, including medicine and the social sciences. Additionally, a number of foundations, particularly those interested in health care, are aggressively supporting well-designed nursing research.

True Experimental Designs in Nursing Intervention and Outcomes Research

Nursing intervention and outcomes research using true experimental designs are mentioned briefly below. In these examples, the measurement of outcomes includes behavioral indicators (in italics) as well as physiologic and organizational ones. Outcomes research done abroad also is mentioned. Outside of clinical settings, true experimental designs have been used to test nursing interventions that have direct implications for clinical practice. As in most clinical disciplines,

increasing attention is now being given to the “translation” (or application) of research findings into clinical practice. This “translational research” is a growth area in nursing and medicine.

Brooten *et al.* completed a well-known “true experiment” to test a model of early hospital discharge and transitional care (as compared to a routine care control group) for very low birth weight infants (<1500 Gm). A perinatal clinical nurse specialist or CNS provided instruction, counseling, home visits and daily on-call (telephone) availability for the experimental, E group. Compared to the routine care control group, the E group: (a) was discharged 11 days earlier and 2 weeks younger; (b) was equally as “safe” (that is, there was no difference in *infant growth and development outcomes*, acute care visits, or rehospitalizations; and *maternal health and psychosocial measures*); and (c) had lower cost (hospital charges were 27% less and MD charges were 22% less; hospital cost saving was \$18,000 per infant). Brooten *et al.* further tested the “model of transitional care” as provided by a CNS similar to the above in randomized clinical trials on three high risk, high volume, high cost groups of patients, namely those with unplanned Caesarean section births, pregnant women with diabetes, and post-hysterectomy women. They found that compared to the routine care control groups, the E groups showed: higher patient satisfaction, higher infant immunizations, lower rehospitalizations, and health care cost reductions up to 38%. Several of the unique contributions of these studies were their publication in both medical and nursing journals, their strong research design, and the attention paid to the relationship between outcomes and costs.

Naylor *et al.* also tested the “transitional care model” as provided by a CNS to another population: elderly patients with congestive heart failure and their family caregivers, the E group. The CNS care included a comprehensive discharge plan provided while the patient was in the hospital and during the first two weeks after discharge. Findings showed that compared to the routine care group, the E group had fewer total days in hospital, fewer readmissions, lower re-admission charges, and lower total charges for healthcare services.

Of interest is the review by Brooten and Naylor of nursing studies that used experimental designs. They identified four key questions in nursing research relative to changing patient outcomes. What outcomes should be measured? What “nurse dose” (i.e., what nurse intervention in what amount) is needed to show an effect? What nurse dose is needed in a given health care environment to show a treatment effect? What nurse dose works for which patient group? After a decade, these remain fundamental questions in nursing research. With the varying paths of entry into nursing practice ranging from associate degree, to bachelors degree, to masters or doctorate,

the difference in settings in which nurses practice and the varying needs of patients, the measurement of “nursing dose,” for example, has been elusive. What combinations of education, credentialing, and setting constitute valid and reliable measures of “dose?”

High quality nursing research has been done outside the United States. These studies are important not only due to their immediate impact on nursing research in the United States, but their distinct differences in organizational and institutional setting provide possible opportunities for assessment of institutional and cross-cultural effects on outcomes. These can impact practice in the United States. Unfortunately, the use of experimental designs in such studies has been limited.

Campbell *et al.* report the results of a randomized trial of nurse-led primary care (the experimental group) in Scotland on the secondary prevention of coronary heart disease, CHD, and a usual care control group. A random sample of 19 general practices in the northeast was used; 1173 participants were under 80 years old, diagnosed with CHD, but not house bound nor with terminal illness or dementia. Eligible patients were stratified by age, gender, and general practice, and randomized (by individual) using a table of random numbers. The components of secondary prevention measured at baseline and one year later included lifestyle measures such as *engagement in physical activity*, *intake of dietary fat*, and *smoking* as well as other clinical measures such as aspirin use, blood pressure management, and lipid management. One year from baseline, as compared to the control group, significant positive outcomes of the nurse-led primary care were found on all outcome measures, except smoking cessation. Most patients gained at least one effective component of secondary prevention; future cardiovascular events and mortality were reduced by up to one-third.

Research using nonexperimental designs, physiologic, and organizational indicators has demonstrated the value of nursing care, thus increasing the generalizability or external validity of outcomes research findings. For example, conclusions from research on organizational indicators of quality (e.g., total hours of nursing care provided and the RN “skill mix”) and patient outcomes have demonstrated that patients have fewer urinary tract infections, falls, pneumonias, and bedsores under a number of conditions. These desired outcomes are more likely to occur when staffing is higher, higher educated nurses are employed, and nurses can devote more time to patients. Aiken *et al.* have shown additionally that mortality rates for such patients can be substantially reduced.

In home health settings, studies have shown immediate and long-term effects on low-income families home visited by nurses that produced *improved pregnancy outcomes* and *lessened child abuse and neglect*. Similar research is being conducted of training families to cope with chronic care at home.

Emerging Nonexperimental Design Approaches

Nonexperimental design approaches to test structural equation relationships among study variables, such as structural equation modeling, also are used in nursing research. An early description of what was then labeled “causal inference” by Blalock has had some impact in nursing. Nursing studies have used path analytic and other modeling approaches. A structural equation modeling example is given below. As noted above, the delivery of nursing care would appear to fit well with techniques now developed for multilevel modeling research. A significant barrier to application is likely to be sample size requirements.

Two areas of immediate need in health services research and policy are studies of costs or expenditure relative to treatment effects and outcomes over time (longitudinal studies). Much work in these areas is likely to remain non-experimental; however, recent efforts are being made to incorporate cost-effectiveness research into experimental designs including randomized clinical trials (RCT).

Instrument Development Research

To measure constructs and processes of interest to nursing, methods used in education and social sciences have been followed to design instruments with good psychometric properties. Most doctoral programs in nursing contain courses in instrument development, test construction, and item analysis. Nurses have been active in developing instruments and scales to measure patient and provider attitudes, quality of life, patient satisfaction, and other constructs. Work has been directed toward practice settings such as in hospitals in which patients have specific illness conditions such as cancer. Instruments also have been developed for assessment of health promotion services in community settings. Example 3 under the Examples section below includes a brief description of the developmental of a clinical instrument using principal components.

Other Nursing Research

The brief description below is based on two comprehensive summaries of two decades of research reviews (1983–2003) published in the *Annual Review of Nursing Research (ARNR)*. Both summaries use similar categories of content foci or themes; thus, facilitating comparisons of content themes in nursing research over two decades. The content categories used are: life span development, clinical or nursing practice research, research on nursing care delivery, research on professional issues, educational research in nursing, and international nursing research. Life span development has subcategories such as

maternal-child health, infants, and young children; school-age children and adolescents; adulthood; older adult issues and problems; and family research. During these two decades, research in life span development was common, with a total of 25 reviews for the first decade and 49 reviews for the second decade.

Nursing Practice Research also has subcategories such as nursing diagnoses and interventions; symptoms and problems; risk behaviors and forms of abuse; physiologic mechanisms and biologic rhythms; care problems of specific diseases; research in nursing specialty areas; crises, grief, loss, and bereavement; and research on special populations such as rural health; health among minorities, migrants, the homeless. The largest number of review chapters published in *ARNR* is in the Nursing Practice Research category, with a total of 42 reviews for the first decade and 61 for the second decade.

Commonly studied were combinations of a nursing practice research problem within a specific age cohort or subcategory of the lifespan. Examples of reviews reflecting these combined categories include: Fatigue During the Childbearing Period; Prenatal and Parenting Programs for Adolescent Mothers; Child Sexual Abuse: Initial Effects; Motivation for Physical Activity Among Children and Adolescents; Children with Epilepsy: Quality of Life and Psychosocial Needs; Family Interventions to Prevent Substance Abuse: Children and Adolescents; Women as Mothers and Grandmothers; Health Promotion for Family Caregivers of Chronically Ill Elders; End-of-Life Care for Older Adults in ICUs; Interventions for Children with Diabetes and their Families; Quality of Life and Caregiving in Technological Home Care; and Sleep Promotion in Adults (*ARNR*, 1994–2002). Also, nursing research in other countries (Scotland, Canada, Philippines, Korea, Israel, Brazil, Taiwan, Italy) has been reviewed (*ARNR*, 1984, 1986, 1988, 1994, 1996, 1997, 1999). Social science methods mentioned above were used in many of the studies reviewed.

Nurse researchers have used several publication guides (e.g., the American Psychological Association). Nursing, medical, social science, and other journals (see Further Reading) are used for research dissemination, as is the *Cumulative Index to Nursing and Allied Health Literature (CINAHL)* (www.cinahl.com). Another key bibliographic resource for nursing research is *MEDLINE*, at the U.S. National Library of Medicine (www.nlm.gov).

Examples

Experimental Design: The ISEE Study

(Adapted from Williams *et al.* (2003) with permission of Mosby, Inc.) The Intervention for Siblings: Experience

Enhancement (ISEE) was provided to siblings in families of children with a chronic illness or disability. The objective of the study was to determine whether the intervention (designed by nurses and physicians) improved the measured outcomes of *sibling behavior problems, sibling knowledge about the illness of the brother or sister, sibling attitude toward the illness, sibling mood, sibling self-esteem, and sibling feelings of social support*. The six outcomes were identified in a literature review as important to the current and later development of the sibling. Instruments with published psychometric properties were used to measure outcomes.

The ISEE study was designed as a randomized trial. After IRB approval and permissions and assents were obtained, siblings were blocked by age (7–10 versus 11–15 years) and gender. A sibling (closest in age to the ill child) and the mother were then randomized into two experimental and one control group. These groups were as follows: a full experimental group who received the intervention at a five-day residential summer camp; a partial treatment group who did not receive the full intervention but who were provided the usual summer residential experience at one of the regularly scheduled camp sessions; and a waiting list control group who received a residential camp experience after completion of the ISEE study at the same accredited camp.

The siblings in the ISEE study had a brother or sister less than 18 years of age who had cystic fibrosis, spina bifida, cancer (more than 18 months survival anticipated by the attending physicians), Type I diabetes, or developmental disabilities such as cerebral palsy, autism, etc. Similar but differentiated intervention materials and educational experiences were designed for siblings in each of these illness or disability groups. Parents in all groups discussed and learned about sibling and family issues as well as general approaches to child behavior management. Appropriately trained advance practice nurses provided the interventions.

Data were collected at baseline, at 5 days, and 4, 9, and 12 months after the delivery of intervention. Two hundred fifty-two parent–child dyads completed the study (13.9% attrition), and were used in data analyses. Technical information concerning randomization, the allocation of subjects, intervention materials, and measurement instruments can be found in Williams *et al.*

Generalized estimating equations (GEE) were used to analyze study outcomes. GEE is sensitive to clustering, repeated measures, conveniently handles covariates, and can lead to improved statistical power. Although these estimating equations have favorable features compared to others commonly used in social and behavioral research such as ANOVA, their use in nursing and health services research is relatively recent.

The results of the above NIH-sponsored study were very favorable to the intervention. The intervention had

statistically significant effects on all outcomes over most time periods. The profile of the six outcomes is shown in Table I. These outcomes can be easily displayed graphically to show changes within the three study groups over time, but cannot be done in this chapter due to space constraints. An example of a GEE (sibling knowledge score on independent variables) is shown in Table II. The equation bears some similarity to a multiple regression equation.

The estimates of parameters FULLVIS2 through CONTVIS5 are the ones of central interest, since these exhibit effects from baseline of the knowledge scores in each group over the observation periods, controlling for covariates at baseline. *These covariates are knowledge scores of the siblings in the three study groups at baseline, diagnosis of the ill child, education of the mother, age of the sibling, cohesion within the family, and maternal mood.* Maternal education served as a proxy for socioeconomic status, SES, while cohesion within the family and maternal mood at the beginning of the study (baseline) could otherwise attenuate treatment effects. The other covariates were used to “standardize” the knowledge instruments for sibling age and the differences of items on the instrument related to the specific illness or disability familiar to the sibling.

In terms of nursing and child development research some of the covariates are of interest, but these cannot be further commented upon here. The standard errors in parentheses are semi-robust to account for clustering effects and, as usual for GEE, the Wald chi-square is

used in a manner similar to the coefficient of determination in many generalized linear model regressions.

Structural Equation Model: Analysis of ISEE Baseline Measures

(Adapted from Williams *et al.* (2002) with permission of Kluwer Academic/Plenum Publishers.) Alert readers of the above section probably wonder whether some of the outcome variables analyzed as independent in the GEE are in fact interrelated. This, indeed, is the case. These relationships can be assessed using simultaneous equation models. Results reported below examined relationships at baseline. More complex models can be developed to assess changes over time. The model reported below is a nonrecursive path analysis; the only latent variable constructed is SES. AMOS version 4.0 was used to estimate parameters.

Figure 1 shows estimated relationships among the study variables. The numbers on the arrows are path coefficients (beta weights) indicating the effects of each variable on the others. Coefficients of determination are inside the boxes with the abbreviations of the study variables. Covariates related to the “standardization” of the knowledge scores are shown. Additionally, sibling age is used as a covariate with sibling knowledge scores (as mentioned previously), sibling attitude, sibling self-esteem, and sibling behavior scores. These four outcomes were found to be sensitive to age of the sibling in the ISEE

Note: The data in columns 2 and 3 are from Williams *et al.* By permission of Mosby, Inc.

study. All relationships shown in the model are statistically significant at $p < 0.05$ or lower.

Additional material can be reported using tables of total, direct, and indirect effects of each of the variables on the other. For example, the combined effects of the variables account for 45% of the variance in *behavior problems* among study siblings. This is a *combination of direct effects such as sibling knowledge on sibling behavior problems and indirect effects of family cohesion*, which has a direct effect of (-0.23) and *several indirect effects, including such complex ones as family cohesion affecting sibling attitude, sibling mood, sibling perceptions of social support, then sibling social support affecting sibling behavior problems*. All such effects can be quantitated, but the use of such complex models depends upon the accumulation of research results that indicate that the model may be reasonable. In this particular instance, components of the model had been tested over almost twenty years by the researchers before the path diagram describing variable interactions was constructed. Additionally, the

hypothesized relationships among variables were consistent with our literature review.

The estimation of such a model depends upon having validated and reliable instruments to measure the constructs used in the model. Detailed descriptions of the instruments used in this study appear in the literature by Williams *et al.* (2002). The instruments used in the path analysis and the ISEE study had been developed, tested, and reported in peer-reviewed publications of psychologists, nurses, and others.

A tendency exists to use complex structural equation models with latent variables to incorporate constructs that do not have well known and previously reported measurement properties. Indeed, these models and related computer software were often developed to assist researchers in exploratory studies for model development. Nevertheless, too often these models are used to refit parameters many times until a "good fit" is obtained. Such an approach to data analysis raises a number of troubling issues in both design and measurement and should only

be used at the earliest phases of a research program—and even then with great caution.

Instrument Development: The Therapy-Related Symptom Checklist, TRSC

(Adapted from Williams *et al.* (2000, 2001) with permission of the authors and Elsevier Science.) The ISEE study above used a number of valid and reliable instruments to measure treatment outcomes. Such a complex research study could not have been undertaken without measures that had been previously constructed and validated by other researchers. Unfortunately, while the number of measurement instruments available for research is relatively large, the number of instruments available for use by nurses and others in clinic settings is small.

The average clinical consult in the United States is estimated to range between 12 and 15 minutes. Few social measurement instruments, including those designed by providers allegedly for clinic use, can be completed within such a time frame. Perhaps fewer than 36% of instruments designated as “clinical” can be self-administered to patients.

Nurses and others have developed “clinical checklists” that allow patients to subjectively identify their negative

or positive responses to items on a list of symptoms, conditions, or signs common to the illness being treated. Usually, these checklists have Likert type scales. The development and use of instruments sensitive to patient subjective concerns is consistent with the recognition that these patient responses can provide essential information to improve treatment regimens. The checklist approach also is consistent with several studies that have shown that unless a systematic listing is used during the clinical consult many treatment symptoms fail to be recorded in the medical record. For example, one study found that medical records contained on average only 1.5 patient symptoms, while patients identified an average of 11 symptoms of concern to them on symptom checklists.

Distinct differences in approach exist between clinical checklist development and commonly used outcome measurement procedures. The development of most instruments designed for outcome measurements tend to be more research than clinical oriented. Following the educational, behavioral, and social sciences, a common approach to instrument development in nursing has been the application of data reduction techniques such as factor analysis to produce instruments with the greatest parsimony. The small number of items remaining on such instruments, often as few as 12, is purported to measure a single patient outcome, such as quality of life (QOL). After data reduction

and validation, the instrument is frequently assumed to be clinically applicable and interpretable.

Over the past 10 years, a group of nurse researchers have worked to develop an instrument that enables oncology patients to self-report treatment symptoms using a checklist. This instrument also provides researchers with valid and reliable aggregate measures of five therapy-related constructs: fatigue, eating difficulties, oropharynx disturbance, pain, and patient concern with overall treatment symptoms (labeled “symptom concern”). This checklist has been placed in medical records, and is

used by clinicians to follow patient symptoms over time. This instrument is shown in Fig. 2. In order to construct an instrument with an optimal number of symptoms (items) for use by clinicians, principal component analysis was used but in a manner different from common factor analysis. These procedures are fully described and justified by Williams *et al.* (2000, 2001).

Initially, 37 symptoms were identified from the literature and clinical experience of the researchers as common to oncology patients undergoing chemotherapy, radiation, or combination therapy. The preliminary

Figure 2 Therapy-related symptoms checklist (TRSC). From Williams *et al.* (2001). *Int. J. Nursing Stud.* 38, 359–367, by permission of Elsevier Science.

research checklist developed by these researchers allowed patients to rate the severity of the symptom on a 5-point scale from NONE to VERY SEVERE. The checklist was self-administered to 360 patients who were provided spaces to list other symptoms of concern to them. No additional symptoms were listed.

The data obtained were analyzed using principal component analysis. Measures of sampling adequacy were obtained with items having an adequacy of less than 0.70 excluded from further analysis. This procedure raised the Kaiser–Meyer–Olkin value above 0.80. Unlike most factor analytic approaches, the Jolliffe criterion rather than the Kaiser criterion was used to extract principal components. The former criterion retains components with eigenvalues as small as 0.70 in contrast to the more familiar Kaiser criterion, which retains eigenvalues of only 1.0 or more. Several good statistical reasons exist for choosing the Jolliffe criterion. A most important reason is that a larger amount of variance among patients on symptoms is accounted for in the analysis.

The instrument constructed referred to as the Therapy Related Symptom Checklist (TRSC) retained 25 items with loadings at or exceeding 0.50 on 14 components after varimax rotation. As previously noted, the TRSC has been found to be easily completed, can be retained in medical records (paper or electronic), appears to measure five constructs useful to clinicians and researchers, and has been assessed for discriminant validity, construct validity, and internal consistency.

While the differences between this and factor analytic approaches may appear small, about 20% more variance (79% versus about 59%) was accounted for using this approach, and six additional symptoms or items were retained on the TRSC. Few patients have used the open spaces on the instrument to list additional symptoms. Furthermore, all the items retained on components with eigenvalues between 0.70 and 1.0 correlated significantly with clinician-rated Karnofsky scores of patients. Additionally, these items were statistically significant when a linear discriminant analysis was done to predict the classification of patients into radiation therapy and chemotherapy groups.

Conclusions

Nursing has become a field of professional and advanced (graduate degree) study in the United States that is rapidly developing a distinct body of knowledge through scientific research. The outcomes approach to research is now seen by many as useful for building the knowledge base of nursing, providing accountability to clients and society more generally, and, most importantly, promoting improved care. As in most clinical disciplines, increased

attention is now being given to the “translation” (or application) of research findings into clinical practice.

Much nursing research is applied and patient or practice focused. Conspicuously limited in the nursing literature is basic research in areas of methodology. More often, such research is likely to appear in the future as nurses are enrolling in doctoral programs in statistics, epidemiology, psychometrics, and areas specifically emphasizing methods and study design.

Social science research design, sampling, and analytic methods are selectively mentioned in this article. Examples are provided of nursing studies using (a) experimental research design; (b) structural equation modeling; and (c) instrument development. Literature reviews in nursing, a few of which are cited in this article, provide more detailed descriptions of research methods as well as substantive findings.

Objectivity, Quest for

Majid Yar

Lancaster University, Lancaster, United Kingdom

Glossary

deduction The process of logically deriving a conclusion that necessarily follows from a given set of premises; the conclusion must be true if the premises are true.

empiricism The view that all knowledge is based on or derived from sensory experience.

epistemological anarchism The position, associated with Paul Feyerabend, that refuses to acknowledge both the existence of a universal scientific method and the legitimacy of distinguishing between science and nonscientific world-views on the basis of the former's supposed epistemological superiority.

epistemology A branch of philosophy dealing with the nature of knowledge, what and how it is possible to know.

hypothesis Any proposition that is advanced for testing or appraisal as a generalization about a phenomenon.

incommensurability The radical incompatibility that exists between different paradigms. Different paradigms will have divergent views of fundamental features of reality. Hence, Kuhn claims that adherents of different paradigms are, in some sense, living in different worlds.

induction The method by which a general statement, suggesting a regular association between two or more variables, is derived from a series of empirical observations.

interpretation (*Verstehen*) A perspective or method that emphasizes the understanding of intentional human conduct.

ontology A branch of philosophy dealing with the nature of existence or reality.

paradigm According to Kuhn, a framework "made up of the general theoretical assumptions and laws and the techniques for their application that members of a particular scientific community adopt" that "sets the standards for legitimate work within the science it governs. It co-ordinates and directs the puzzle-solving activity of the scientists that work within it."

positivism The doctrine formulated by Comte that asserts that true knowledge about society is scientific knowledge—it is

knowledge that describes and explains the coexistence and succession of observable social phenomena.

realism The ontological assertion that the objects in the world have an existence independent of our conception of them.

This article reviews the attempts to establish social science as an objective form of inquiry and the various challenges with which such objectivism has been met. It begins by outlining the ways in which the natural sciences were established as supposedly objective forms of inquiry, and how 19th century positivist social thinkers borrowed these epistemological and methodological prescriptions so as to place social inquiry on an equally objective footing. It then reviews a number of challenges to this quest for objectivity, including critiques of objectivism emanating from within the philosophy of science and criticisms of social scientific positivism associated variously with interpretive social science, feminism, and postmodernism. The article concludes by outlining the counterresponse to such critiques and the attempts to reassert the possibility of objectivity in some degree, especially in realist contributions to the philosophy of social science.

Introduction

Objectivity is the quality of any account that represents the external world as it is, independent of our subjective conceptions of it. The foundations of social inquiry are bound up with the search for such objective knowledge of the social world. This search is apparent in the philosophical and methodological programs of the social scientific pioneers of the 19th century. By treating the social world as analogous to the natural world and by following (or adapting) the methodology of natural scientific

inquiry, these pioneers hoped to place social scientific knowledge on a par with that of other established sciences such as physics and biology. These methodological foundations (usually identified with positivism) continue to exert influence across the social sciences. However, the quest for objectivity has been challenged on a number of fronts from the late 19th century to the 21st. Interpretive social scientists, philosophers and sociologists of natural and social science, feminists, and postmodernists have all assaulted conventional accounts of scientific certitude and its applicability to the social world. More recently, against the supposed relativizing implications of this assault, those favoring a realist philosophy and methodology of social science have sought to reclaim in some form the possibility of objective social scientific knowledge. The dispute between objectivists and anti-objectivists remains unresolved and continues to manifest itself in the wide variety of research paradigms favored by practitioners across the disciplines.

Science and Objectivity

The quest for objectivity in the social sciences is based on the philosophical and methodological warrants given for scientific knowledge as a whole. The groundwork supporting the objectivity of science was developed by natural philosophers such as Francis Bacon. Rejecting rationalist deduction and metaphysical speculation, the modern philosophers of science favored the painstaking collection of empirical data, via observational and experimental methods, and the inductive generalization from these observations and experiments so as to arrive at generally applicable lawlike statements that covered all instances of a similar kind. The possibility of generating objective knowledge in this way was predicated on three basic assumptions:

1. That the universe is ordered and regular, such that the properties of bodies and substances, and the relations of cause and effect that pertain between them, are constant and not subject to random or arbitrary variation.
2. That it is possible neutrally to observe and record the bare facts of experience, such that all normal observers (those in possession of typical human sensory abilities and cognitive faculties) would agree on the phenomenon that has been observed.
3. That by observing the regularities and patterns presented across such observational instances it is possible to generalize to other like instances, including future occurrences. This permits us to formulate general lawlike statements of the kind, "If an acid is added to an alkaline, salt is produced" or "A moving body will continue in a straight line in uniform motion unless it is acted upon by some other force."

In short, objectivity is assured by (1) the regular and ordered character of the natural world, (2) the availability of that world for unbiased and communally available observation, and (3) the reliability of inductive inferences that extrapolate from a finite set of observational instances to anticipate further instances of a like kind.

Social Science and Objectivity: The Positivist Orthodoxy

The pioneering social scientists of the 19th century, such as Comte and Durkheim, drew on the empiricist accounts of science developed by the likes of Bacon, Locke, Hume, and the Enlightenment *philosophes* such as Diderot. August Comte (1798–1857) coined the terms positivist philosophy and social physics (as well as sociology) to postulate a science of society that would be methodologically grounded in the accumulation of empirical evidence alone. Hence, the viability of studying the social world in the manner of the natural scientists was predicated not only on the supposed objectivity of scientific method, but also on the claim that the social world was in principle of the same kind (or logical type) as the natural world. Just as the natural world was seen as regular, ordered, and governed by lawful causal relations and interconnections, so was the social. Human behavior was scientifically explicable by reference to mechanisms of cause and effect of which behavior was the outcome. Detailed observation of the occurrence of social phenomena would permit the formulation of explanatory accounts that identified their causes. Social phenomena were in principle observationally available in the same way as their natural counterparts. Thus Emile Durkheim (1858–1917) claimed that social science ought to concern itself solely with the scientific study of social facts. For Durkheim, society comprised things that existed outside of, and independently from, individuals and their beliefs about the world and thus could be studied objectively by the social scientific observer. Hence, for example, social phenomena such as crime and suicide could be identified and classified by externally manifest signs that distinguished them from other social phenomena. The appearance of these phenomena was explicable by reference to other social facts or phenomena that could be established as their causes.

The extrapolation from the natural to the social world was further supported by analogies drawn from biology and the life sciences. Just as living organisms were seen as coherent systems comprising functionally interdependent elements that acted on one another in a regular way, so the social world was conceived as a unified system in which different functions were assigned to its elements. The influence of evolutionary thinking was also notable,

with thinkers from Saint-Simon, Condorcet, and Comte to Spencer and Durkheim arguing that objective evolutionary processes were responsible for social change.

The 19th century positivists' search for objectivity in social inquiry was reiterated and refined in the early 20th century by the philosophers of the Vienna Circle (such as Carnap, Neurath, and Hempel). Their doctrines are generally identified under the label logical positivism. The objectivity of scientific knowledge (natural or social) was to be assured by the application of what they called the verification principle. Only statements that could be verified by sense experience could be considered true. Any statements not of this kind were deemed to be literally meaningless. In this view, social science comprises a set of logically interrelated propositions, each of which is grounded in basic facts derived from sense data alone. The view of the logical positivists (along with revisions such as Popper's falsificationism) contributed to the consolidation of the standard view of social scientific methodology, a view dominant in the middle decades of the 20th century (especially in Anglo-American contexts). The methodological prescription of achieving objective social knowledge was grounded in a logical empiricism that took physics as its ideal model and aspired to reproduce its rigor and reliability.

The positivists' affinity with the natural sciences is evinced in their methods of inquiry. As with the natural sciences, the collection of discrete observational data is emphasized so as to permit generalizations and to establish correlations and causal connections (although the tendency is to eschew the natural scientists' use of experiments, given the near impossibility of artificially recreating social life in a laboratory setting; instead observation and comparison are favored). Equally, a premium is placed on assigning numerical values to social phenomena, permitting quantitative analysis via the use of statistical methods. The apparent association between variables, numerically rendered, thus enables causal hypotheses to be formulated and tested. The use of random sampling permits researchers to make inferential generalizations from that sample to a larger population. In this way, covering laws can be discovered, laws that could account for the appearance of particular social phenomena by relating them to their causal antecedents. In its most systematic application, such an approach yields a mathematical social science, drawing on approaches such as game theory and probabilistic modeling.

The Challenge from Interpretive Social Science

The interpretive challenge to objectivism in social science dates from the 19th century. It emerged primarily in

Germany, drawing on the traditions of hermeneutics (the theory and method of textual interpretation, originally concerned with Biblical exegesis) and the *Geisteswissenschaften* ("sciences of spirit"; as opposed to "sciences of nature," *Naturwissenschaften*). The interpretive tradition contests the supposed homology between the natural and social worlds. It claims that the social is distinctive because human action (unlike the behavior of objects in the natural world) issues from motivations, these motivations themselves being constituted in accordance with the meanings or interpretations that conscious human subjects give to the world and their own experiences. Consequently, human conduct cannot be subjected to any explanatory model that sees it as the mechanical effect of causal forces that act on individuals or groups. Nor can humans be treated in behavioral terms like nonhuman animals, attributing human conduct to a stimulus-response mechanism. Humans are instead viewed as agents who attach meanings to the world they encounter and who consequently choose to act in ways that are consonant with those meanings.

The translation of this viewpoint into social scientific methodology is associated primarily with the economic historian and sociologist Max Weber (1864–1920). Weber argued for the methodological centrality of *Verstehen* ("understanding" or "interpretation") in social science. Any valid account of social phenomena (i.e., Why it is that individuals or groups act or behave as they do) has to take into account the meaningful and motivated character of those actions. It is not enough to observe patterns in outward behavior and to link these to other factors, events, or conditions so as to derive a cause-effect type hypothesis. Rather, investigation must give centrality to understanding the meanings that actors themselves attach to their experiences, circumstances and activities. Thus, in his most celebrated study, *The Protestant Ethic and the Spirit of Capitalism*, Weber opposed those accounts that sought to explain the emergence of modern capitalism by sole reference to objective factors, such as the organization of productive forces, the development of new techniques and technologies, demographic changes, the relations of supply and demand, and so on. Instead, he sought to uncover the interpretive frameworks or structures of meaning that disposed certain sociocultural groups to radically reform their economic behavior, thereby setting in motion the process of extensive capital accumulation.

However, beyond a general recognition of the meaningful character of human action, interpretive social scientists have been divided about the extent to which this commitment can be reconciled with the striving for objectivity. Some, following Weber's cue, insist that it is possible for the social scientist to render an objective account of actors' subjective meanings; a systematic method of interpretive inquiry makes this goal achievable, at

least in principle. Moreover, actors' motives or reasons can be treated as the causes of their actions, thus permitting the investigator to identify the causal antecedents of particular forms of action. Finally, the supposedly ordered character of human behavior permits the social scientist to make lawlike generalizations (or statements of tendency) from interpretively apprehended data.

However, other interpretive positions have cast greater doubt on the possibility of achieving objective social scientific knowledge. The sociology developed by the symbolic interactionists in the early decades of the 20th century, for example, stressed the symbolically constructed character of actors' worlds, including objects, other people, and individuals' own self-awareness. As such, reality is always and inevitably a variable construct, and this construct is not a fixed formation but continually in the process of production and transformation through interaction and communication with others. Meanings, motivations and actions are thus (1) inextricably intertwined, (2) continually in the process of production, and (3) specific to particular people in particular social-interactional contexts. This carries a number of significant implications. First, social phenomena cannot be conceived as social facts existing independently of subjective conceptions of them; rather, what comes to count as part of a particular class of phenomena (say, crime or deviance) is the contingent outcome of actors' definitions. Second, given the context-specificity of understanding and actions, it is deemed problematic to generalize interpretive accounts across different contexts and interactional engagements. Hence, deriving covering laws (of the kind "When confronted with situation X, individuals will tend to act in manner Y") is likely to lead to inappropriate and distorting explanations. Third, given that symbolic mediation is deemed a universal and fundamental feature of social life, the social scientist him- or herself cannot be exempted from its implications. In other words, the investigator cannot offer a *stricto sensu* objective account of others' subjective understandings, but only a (socially and contextually embedded) interpretation of others' interpretations. Hence, there is no Archimedean point of epistemic neutrality, independent of subjective conceptions, from which the scientist can view the social world. The last point has been captured by Anthony Giddens in terms of the double hermeneutic of social science—just as lay actors produce their world and act on it through their interpretations, so social scientists themselves re-interpret this already interpretively generated domain.

At the most extreme end in the interpretive continuum, the linguistically, culturally, and symbolically constructed character of the social world has been claimed to necessitate a relativist conception of social science. Thus, for example, in 1958 Peter Winch, drawing on Wittgenstein's notion of language games as forms of life, argues that the

"truths" pertaining to social phenomena are relative or specific to the order of social practices within which they are embedded. Hence, the aspiration to generalize across local contexts is based on a fundamental misapprehension about the contextual relativity of any given phenomena. Moreover, there is no way of epistemically privileging any one account of reality over any other, including that of the social scientist. The kinds of criteria habitually mobilized by scientists to warrant their claims (evidence, proof, rationality, logical inference, and so on) have no special status, being specific to the practices of inquiry (or form of life) in which they feature.

The Challenge from Philosophy of Science

The possibility of objectivity in the social sciences has also come under challenge as a result of developments in the philosophy of science. The philosophy of science in the 20th century was marked by an increasing skepticism about the picture of epistemically neutral inquiry propounded by objectivist accounts. A number of claims were raised, each of which impacted on the equation of science with objectively valid and universal knowledge. Their effect on the philosophy and methodology of social science has been particularly marked.

First, there was a renewed interest in the skeptical aspects of Humean epistemology, especially in relation to causation. Conventional accounts of scientific method invoked the objective status of relations of cause and effect—these were presented as ontologically prior to and independent of human perceptions. In *An Inquiry Concerning Human Understanding*, Hume claimed that causal relations between events are subjective attributions made by observers. Instead of being real relations between things in the world, causal connections are impositions made by humans in order to organize their sense experiences in a coherent way. Causation, in short, is a way of organizing essentially unconnected sensations, something we learn to do from custom and habit. This being the case, it follows that the relations of different phenomena in causal chains (on which scientific explanation depends) are a contingent outcome of subjective cognitive activities—there is no essential or objective relation between things in the world that necessitates such a connection.

A second philosophical objection posed against objectivism is what is commonly referred to as the problem of induction. Unlike logico-deductive inferences (wherein a conclusion *necessarily* follows from given premises), inductive inferences are logically unwarranted because the validity of the conclusions can only ever be probabilistic in character. That is to say, inductive

inference is based on a generalization from a finite set of past observations, extending the observed pattern or relation to other future instances or instances occurring elsewhere. However, there is no *logical* reason why the same pattern or relation should hold in the future or in other places—it can only be a judgment of likelihood based on the fact that this pattern or relation was evident in the instances of a phenomenon already observed. This implies that the transition from a finite set of observations to lawlike generalizations (from “some to all” in Hume’s words) cannot be warranted. Thus Karl Popper, for example, claimed that no observationally based generalization about the world can ever be verified as true.

A third, and even more troubling, objection to objectivism concerns the possibility of empirical observations that are free from any prior conceptions about the world on the part of the observer. The objection lodged by philosophers of science often passes under the label the theory-dependence of observation. It is pointed out that even apparently simple and uncontentious observational statements in fact depend on preexisting presuppositions about the world and mobilize already existing cognitive schema that are historically or culturally contingent. Put most simply, what we observe is crucially dependent on the assumptions and knowledge we already have about the world. Moreover, the activity of observation in scientific inquiry necessarily entails a process of selection—only certain phenomena are selected as noteworthy and relevant for the development of an explanatory hypothesis. The criteria for selection can only be derived from presuppositions on the part of the observer vis-à-vis what is likely to be relevant for formulating an explanation, and this notion of relevance is dependent on existing ideas about how the world works.

This point in particular led to the revision of the objectivist account of science. In the work of Thomas Kuhn (1922–1996), scientific practices and criteria of validity are depicted as relative to socially and historically specific paradigms or frameworks of theoretical assumptions. What counts as a legitimate scientific claim will always be determined on the basis of the shared presuppositions that have dominance in a scientific research community in a particular time and place. Because each of these paradigms or frameworks comprises self-contained and interdependent assumptions of a fundamental kind, they are in principle incommensurable with one another. That is to say, they are mutually exclusive standpoints on the world, and there is no standpoint external to such a paradigm from which their competing claims could be assessed or arbitrated.

The work of Paul Feyerabend (1924–1994) presents the most strenuous development of the relativistic implications in Kuhn’s work (which Kuhn himself resisted). Feyerabend called his own position one of epistemological anarchism. He claimed that there is no method on

the basis of which one paradigmatic structure can be privileged over another. Nor, Feyerabend argued, is it even possible to distinguish some privileged form of knowledge called science from other, supposedly lesser, forms of knowledge; that is, the very privileging of scientific paradigms over other nonscientific worldviews (such as common sense, ideology, magic, and superstition) cannot be sustained. What we call science is, for Feyerabend, just another way of knowing the world, and it has no intrinsic superiority to any other. This being the case, the quest for an objective social science that has a privileged view point on the social world would have to be abandoned.

The Challenges from Feminism and Postmodernism

Quite apart from the impact of philosophy of science, aspirations for social scientific objectivity have also come under pressure from anti-objectivist positions developed within the social sciences themselves. We have already noted the critique developed within the interpretive tradition. More recently, strenuous lines of objection have emerged from feminist and postmodernist perspectives. Each has mobilized both epistemological and normative critiques of objectivist science.

Advocates of feminist epistemology have claimed that objectivist science is profoundly engendered with a masculinist or androcentric bias; dominant masculine experiences, perceptions, ideologies, and values are said to significantly structure the epistemological presuppositions and methodological procedures of mainstream science. Thus, for example, it is claimed that this view of science privileges cognition, rationality, and disinterestedness at the expense of the aesthetic, affective, and somatic dimensions of our experiences. Hence, objectivism mobilizes a distorted and incomplete conception of the knowing subject. Normatively, this view point has been criticized for its imbrication with patterns of male domination in society—the equation of rationality and emotional neutrality with masculinity (and irrationality and emotionality with femininity) amounts to an ideological maneuver that privileges male accounts of the world. This has led some feminist scholars (for example, Evelyn Fox Keller) to advocate the development of a feminist science, one that embodies the neglected epistemological virtues of empathy, holism, and intuitive understanding. In the social sciences, this had led feminists to call for a rejection of objectivist aspirations, disinterested observation, and quantification. Instead, there has emerged an advocacy of qualitative research predicated on interpretation, emotional engagement, and social participation on the part of the researcher. In its most radical form, this appeal to feminist epistemology has led to the eschewal

of formal description and analysis, supplanting it with literary, poetic, and artistic experiments in narrating subjective social experience.

Postmodern thinkers have mobilized epistemological, sociological, and normative critiques to similarly repudiate objectivity, claiming it to be neither possible nor desirable. The philosophies of Kuhn, Winch, and Wittgenstein (among others) have been mobilized so as to press their supposedly relativist implications. Jean-Francois Lyotard viewed the equation of epistemological legitimacy with objectivity as the way in which modern science rhetorically legitimates its authority. By claiming that its criterion of epistemological legitimacy is universally valid, science has set itself up as the sole arbiter of what is to count as knowledge. Yet, Lyotard claimed, the appeal to totalizing, transcendent, and timeless conceptions of legitimacy is now received with incredulity. The loss of faith in such universal criteria exposes the underlying plurality and relativity of language games, each of which has its own internal standards of validity. Behind the rhetoric of objective science, lies the reality of multiple view points that are radically incompatible and cannot be subordinated to some context-independent criteria of legitimacy. The quest for objectivity has also been challenged on political and normative grounds. It is claimed that the search to establish generalizations and laws leads to the violation or suppression of differences and divergences that characterize social life. Zygmunt Bauman identified the objectivist standpoint with the aspiration for legislative prediction and control of society, and as such it stands against human freedom and the cultivation of distinctiveness. In place of the objectivity of science, social inquiry ought to orient itself to interpretive explanation of the very plurality of standpoints and experiences that the social world comprises and should eschew the temptation to see its own interpretations as epistemologically superior.

Resistance to the Anti-Objectivist Critique

Despite the many different cases made against the quest for objectivity, much of mainstream social science continues to operate (implicitly or explicitly) under the objectivist influence of the positivist legacy. A number of reasons can be identified for this:

1. The penetration of anti-objectivist critiques has been very uneven, varying in extent across disciplines and sub-disciplines and across national and regional research traditions. Thus, for example, although Anglophone sociology has incorporated these positions to a considerable extent, the research paradigms in, say, mainstream

economics and psychology retain a strong objectivist orientation.

2. Although the anti-objectivist arguments might be accepted in principle, it has been argued that the practical demands of social inquiry necessitate the retention of some methodological criteria by which to discriminate between more and less sound, partial, or distorted accounts.

3. It has been argued that anti-objectivist accounts of the relativizing kind are logically self-defeating and hence epistemologically vacuous. That is to say, any claim of the kind "all knowledge is relative" inevitably encompasses itself within that claim; hence, the relativist claim can offer no epistemological warrant for its own validity because by logical implication it is itself nonobjective.

4. There have been serious and ongoing philosophical attempts to refute the relativist critique of science. For example, W. V. Quine's (1908–2001) defense of observational language, in a manner conducive to empiricist accounts of science, has been very influential. Others, such as Hilary Putnam (1926–) and Richard Rorty (1931–) have sought to validate a general scientific method on pragmatic grounds (drawing on the philosophical position developed a century or so earlier by C. S. Peirce, William James, and others). For pragmatists, the truth of a belief is distinguished by its leading to a successful action, by the demonstration of its practical efficacy. From this viewpoint, the conventional procedures of scientific inquiry are validated not by some transcendental epistemological warrant but by the fact that they generate robust knowledge that works, that is, that furnishes consistent explanations and predictions about the behavior of the phenomena in question. Hence, for Rorty, it is "better for us to believe" the truths generated by tried-and-tested scientific methods precisely because such truths "are successful in helping us do what we want to do."

Reclaiming Objectivity: The Realist Response

The most significant recent intervention in the debate about objectivity in the social sciences has been that adapted from scientific realism, often passing under the label critical realism. Realists reject the presuppositions of both empiricism (on which the positivist orthodoxy draws) and the relativizing consequences of radical anti-objectivism. Empiricists who follow Hume maintain that any objective characteristics possessed by the external world remain in principle unknowable from the standpoint of a knower, who is limited to his or her subjective sense perceptions of it. Nevertheless, they argue that knowledge generated from the careful attendance to observationally acquired sense data can be judged robust if

it is consistent with what we observe of the world and hence enables us to understand it. Antipositivists go much further and insist that not only are the objective properties attributed to things in the world a matter of cognitive construction, but that such constructions are contextually (socially, historically, and politically) specific, and in principle no epistemological discrimination can be made between different constructions of reality.

In contrast, realists such as Roy Bhaskar start from the claim that the external world is characterized by ontological structures, properties, and mechanisms that are objective in character—they are not produced by our subjective conceptions of them. Hence, relations of cause and effect, for example, are mind-independent features of the real world. Things that exist in the world have their own natures and causal powers. To this proposition is added the further claim that in perception we mentally apprehend qualities and objects that are part of that objectively existing world. Hence, the objects of our sense-making activity are not sense perceptions, sense data or phenomena, but real and independently existing features of things themselves. The ontology of the social world is no different from that of the natural world in this respect—real effects occur as the result of real causes. Thus, for example, our reasons for acting can be treated as the causes of our behavior, the latter being an effect of the former. Similarly, social structures are real features of the social world that will have effects quite independently of whether we recognize them or not.

However, critical realists, as the name implies, are not naïve in the sense that our knowledge claims are held to *necessarily* uncover the real structure of social reality. It is quite possible for our particular descriptions of the social world to misapprehend its real features or to be incomplete by having failed to identify all the relevant mechanisms and causes that produce a particular effect or behavior. Nevertheless, because real social structures, objects, and processes are deemed to exist in and of themselves, the production of an adequate account of them becomes possible through scientific investigation that is (1) methodologically refined and (2) open-ended, so as to leave space for the continual correction, revision, and elaboration of our explanatory hypotheses. As Bhaskar put it in 1978, “Things exist and act independently of our descriptions, but we can only know them under particular descriptions. . . . Science . . . is the systematic attempt to express in thought the structures and ways of

acting of things that exist and act independently of thought.”

This position thus attempts to incorporate (1) the view that social reality is an independent order with objective properties and causes and (2) an acknowledgement of the epistemological caution and revisability that scientific attempts to uncover that reality ought to adopt. In such a formulation, the quest for objectivity in social science is reaffirmed, albeit with a modesty that takes cognizance of the objections that have been lodged against a crudely objectivist conception of social inquiry. Nevertheless, practitioners remain profoundly divided over what an objective social scientific view point might entail, whether or not such a stance is in principle possible, and whether or not it is in fact desirable to aspire to such a goal.

Glossary

continuous recording The observer records the sequence of behaviors using predetermined protocols.

duration recording The observer records the time that elapses between the initiation and conclusion of the targeted behavior.

event sampling The observer samples and records the occurrence of a particular form of behavior.

frequency recording The observer tallies the number of times the targeted behaviors occur.

interval recording The observer defines the types of behavior that occur in an interval of specified duration.

lags The observer records the number of events or time units between sequential events.

nonsequential observation The observer records a behavior as a discrete interval or event.

sequential observation The observer records the continuing stem of a behavior.

time sampling The observer samples a particular time period and records the focal behaviors that occur during that time period.

Observational studies are an essential methodological approach for the study of human behavior among many disciplines: sociology, anthropology, education, management, nursing, and psychology. The aim of this entry is to provide the reader with an overview of the scientific methods of using fundamental observational techniques

to conduct research. Emphasis is placed on the design, measurement, and data analysis of observational methods. Challenges and practical and ethical issues are also discussed.

Introduction

Observation is an important vehicle of data collection and is used widely in many fields including psychology, sociology, education, anthropology, nursing, and management. It offers the advantage of gathering data of overt behavior directly and systematically. Observation was the most important research tool used by early intellectual forerunners such as Darwin and Freud aiming to study different populations and behaviors in laboratory, clinical, and naturalistic settings. Today, it remains the preferred method for investigating nonverbal behaviors as well as very complex social interactions.

Defining Observational Studies

The meaning of observational studies has two origins: in the context of experimental design it refers to, according to McKinlay, studies “concerned with investigating relationships among characteristics of human populations, after the manner of an experiment, but comparing groups among which the ‘treatments’ are not randomly assigned.” In this context, the observer does not have any control on the subject’s exposure status. These

characteristics underline the main differences between observational and experimental studies. In the framework of social measurement, observational studies are those in which a researcher seeks to quantify interactive behavior, either human or animal, by systematically assigning codes to behavioral events as they unfold over time. This quantification may occur in either a naturalistic or an experimental setting. Such studies are particularly useful when the interest is in processes (as opposed to outcomes), or in characterization of the stream of behavior through objective quantification by one or more observers. These characterizations are an alternative to those employing tools of survey research that can be biased by the respondents (e.g., self-reporting techniques, interviews). The execution of systematic observational studies requires attention (a) to specifics in design; (b) to the details of measurement procedures and their quality; and (c) to the analysis applied to the data. These topics and some of the challenges associated with implementing observational studies are addressed below.

Design

The design of an observational study is optimally affected by research questions and the related hypotheses. That is, what does the researcher wish to prompt or support? Additionally, the research questions and hypotheses have major implications for what is to be observed and under what conditions; for defining behaviors; for methods of collecting and recording data; and for data analysis. Therefore, theory and prior research determine what behaviors and or interactions are the focus of the observation. For example, is the researcher interested in teacher initiatives or pupil initiatives? In a nursing situation, is the focus the nurses' behavior or the patients' behavior or the interaction between the two? The behaviors or interactions of interest affect (a) the type of setting for the observation; (b) the sampling and recording or coding procedures for the observation; and (c) whether the observation is intrusive or unobtrusive.

Type of Setting and Researcher Control

Data collection associated with observational studies may be gathered either in a naturalistic setting, as with field studies, or in a more controlled, laboratory setting. The investigator may simply observe the stream of interaction without any manipulation of the context or introduce an intervention in which some aspect of the setting is manipulated. In the naturalistic setting, the researcher describes what occurs, including natural changes in the environment of the interaction. In the laboratory or experimental context, the researcher manipulates some aspect of the environment. Thus, a naturalistic context can

become an experimental or laboratory setting if the researcher introduces an intervention.

What Is to Be Observed, Sampled, and Recorded

Typically, some form of behavior or interaction is the observational object. It might be the behavior of an individual being considered for social support services, an aspect of teacher–pupil interaction in a classroom, or the interaction of child, mother, and grandmother in a home setting. The form of the observed behavior might be sequential or nonsequential. In the sequential case, the continuing stream of behavior is observed and recorded. In this context, the interest is in the dependencies among successive behaviors. In the non-sequential instance, discrete intervals or events are recorded. This distinction between sequential and non-sequential observation affects both the form of sampling and the methods of recording employed in the observation period.

The more common methods of sampling in observational studies are event sampling and time sampling. In event sampling, the observer looks for the occurrence of a particular form of behavior. For example, in the classroom setting, it might be an open-ended question asked by a teacher. In the child–mother–grandmother context, it might be the mother's or grandmother's support of a child's attention. In these two examples, both behaviors—the questioning and the support—are discrete events. In time sampling, the observer samples a particular time period and records the focal behaviors that occur during that time period. Time sampling involves observation of behaviors in intermittent points in time for periods of predetermined duration.

Once sampling procedures have been identified, defining the behaviors to be observed or developing behavior codes is a critical task in observational studies. Coding of observational data consists of recording events as they occur in time. A behavior code is a written description of the events to be observed and recorded. In addition, a behavior code outlines certain rules regarding how the observation and recording are to be evaluated. The use of existing and appropriate coding systems of known measurement characteristics is recommended over case-specific procedures when possible. However, researchers do develop their own schemes reflecting the variables under study. Overall, attributes of the coding must include a scheme for the coding; specification of coding entries; and extended definitions. Generally, four major recording procedures are reported in the literature: duration recording, frequency recording, interval recording, and continuous recording. In duration recording, the observer records the time that elapses between the initiation and conclusion of the targeted behavior. In frequency

recording, the observer tallies the number of times the targeted behaviors occur. In interval recording, the observer specifies the types of behavior that occur in an interval of specified duration. In continuous recording, the observer records the sequence of behaviors using predetermined protocols. Recording methods should facilitate converting observed behavior into quantitative data.

Intrusive vs. Unobtrusive Observation

The settings in which behaviors are recorded differ in terms of whether the observer is actually present during the occurrence of the interaction, in which case the observer intrudes on the setting, or the observer does the recording from a taping—audio or video—of the interaction. In this latter case, the recording may be intrusive but the observer is not the source of the intrusion. Although potentially intrusive, recordings do offer the advantage associated with observer convenience and the use of multiple observers to code the same setting. The latter is useful in training observers and establishing observer agreement or reliability. In addition, some forms of technology used in coding observations are facilitated by the availability of recordings of the observational setting.

Measurement

Measurement is the means by which replication and comparison become possible in observational studies. Measurement here is complex. The complexities relate to obtaining reliable, accurate, and valid observation. Such observation requires care in developing detailed observation manuals, and in selecting, training, and monitoring observers.

The Observation Process: Training and Monitoring Observers

Observing is a human process. The information about behavior that is essential in the social sciences depends heavily on the observing person. Observational studies require the careful selection of observers and their careful training in using observational forms and in recording and evaluating behavior to acceptable levels of agreement and accuracy. Thus, coding schemes must be clearly defined and articulated. Some researchers call for developing an observational manual (see Hartman) that provides explicit definitions and examples assisting the observers in making accurate evaluations and preventing them from drawing unnecessary inferences. Training observers with observations of videotapes accompanied by use of the observational forms and coding schemes is a means of achieving desired levels of rater agreement or reliability. A level of

interrater reliability of at least 0.70 has been recommended. Accuracy and reliability are enhanced through monitoring observers during actual data collection.

Agreement, Reliability, and Validity

The criteria for accurate, reliable, and valid observation are of critical importance. Generally, these relate to minimizing error in recording behavior. Traditionally, reliability has been defined as the degree to which data are consistent. However, reliability in observational research is greatly influenced by the continuous interaction between the observer and the recording system. This influence leads to obtaining between and within-observer consistency. In between-observer consistency (or interobserver agreement or interobserver reliability), two or more observers observe the same event. In within-observer consistency (or intraobserver agreement or intraobserver reliability), the same observer observes the behavior of the same subjects under the same conditions. However, there is not universal agreement on the conceptual definitions of these terms.

Methods of computing interobserver agreement include percentages, occurrence agreement (nonoccurrence), and the statistic Kappa. Overall, these indices describe the degree of agreement between observers. A researcher who obtains a high agreement index may conclude that the observers are interchangeable, and that data from any of the observers are free from measurement error. In regard to intraobserver reliability, problems arise from the fact that identical behaviors and conditions cannot be replicated to estimate the consistency of an observer. Pearson's r could be used to compute interobserver reliability, if the classical parallel test assumptions are met between two or more observers. Those assumptions require that two observers produce the same means and standard deviations. Suen argues that this could be possible if the observers are matched (e.g., gender, education, and training). Finally, the intraclass correlation, which does not require the classical parallel assumptions, can be used as an alternative to the intraobserver reliability index and interobserver agreement indices. The approach estimates through analysis of variance the error from different sources.

Validity in observational studies requires that the observation procedure measure the behavior it purports to measure. An important aspect of validity is the accuracy with which the observational protocols measure the behavior of interest. Accuracy refers to the extent to which there is correspondence between an observer's scores and the criterion (e.g., scores from an expert observer). Other kinds of validity in addition to accuracy are required in observational research. Generally, validity in research centers on content, criterion, and construct validity. Content validity refers to behaviors that are to be

observed based on the theory that represents a construct. Criterion validity can be established by determining what behaviors relate to the concept under study. The source of those behaviors is the relevant theory of interest to the researcher. Finally, when a set of behaviors are produced deductively from the theory, and postulated to measure a construct, then validation of the construct is necessary.

Improvement in the reliability and validity of an observational study can be accomplished with the aid of technologies. Technologies such as audio recorders, video recorders and computer programs may result in higher reliability and validity by allowing the observer to review (play back) the event many times. This also allows the observer to record several different behaviors that occur closely together and the opportunity of having more than one observer, thereby increasing interobserver reliability.

Data Analysis

Some commonly used descriptive measures and inferential statistics for nonsequential and sequential observations are presented below; aspects of drawing causal inferences in observational studies are discussed.

Descriptive Statistics for Observational Data

In observational studies, the branch of descriptive statistics is composed of a variety of tools whose selection for data representation depends mainly on the manner in which a data set has been recorded. Some simple summary statistics include frequencies and rates. A frequency of an event represents a count, which indicates the number of times that particular event has occurred. Simple event sequences can be represented as frequencies. Frequencies, however, should be converted to rates, which are more informative and appropriate for comparisons across different cases since they take into consideration the element of time in observing a particular behavior.

Probabilities and percentages are also important descriptive statistical tools. Specifically, if a procedure is described as event-based, a percentage or a probability denotes the proportion of events that were coded in a particular way relative to the total number of events coded. Additionally, when onset and offset times are recorded (i.e., the time that elapses between the initiation and conclusion of an activity or behavior) for a behavior, proportions of total time that correspond to different activities can be recorded along with the activity. The selection of a percentage or a probability as means of describing a data set can be justified by the research

question posed. Mean event durations can be reported whenever time information is recorded. These measurements are obtained by dividing the amount of time coded for a particular event by the number of times that event was coded. Finally, transitional probabilities constitute a key descriptive measure for sequential observational data. Transitional probabilities are conditional probabilities that indicate the probability of events that occurred at different times. They can be summarized graphically in state transition diagrams, which provide a powerful visual tool for events that are sequenced in time.

Overall, mean durations, percentages, and probabilities provide redundant information. Consequently, researchers choose those that are most informative, given the behavior under investigation. Additional considerations are taken into account when using these summary statistics since the usual parametric assumptions must be satisfied (e.g., a normal distribution of scores).

Nonsequential and Sequential Analyses

In observational studies, statistical analysis and inference are contingent upon numerous elements including the research question, study design, and data coding. Specifically, in a sequential data set where dependencies among behaviors are of interest, the researcher may utilize tools of data analysis that differ from those used in a nonsequential setting. In a nonsequential setting where time is not considered important, the choice of data analytic procedures depends mainly on the research question under investigation. Some commonly utilized data analysis techniques are principal components analysis, orthogonal factor analysis, and discriminant procedures. In principal components analysis, the focus is on transforming the observations into uncorrelated components, while in factor analysis the purpose may be either to produce a set of uncorrelated or correlated factors. In both techniques, the common goal is data reduction. On the other hand, the discriminant function finds the linear combination that best discriminates between two events or behaviors. This procedure is designed for cases where it is difficult to provide an independent check on classifying events.

A traditional approach of sequential data analysis involves tools such as a *t*-test, ANOVA, or multiple regression methodologies. For instance, these techniques could be used in a two-group design where a researcher may be interested in determining whether a sequential pattern is more characteristic of one group than the other. In other cases, where the purpose is to define a particular sequence by reporting the frequency and probability of its occurrence, a *z*-score can be utilized to determine the extent to which an observed frequency exceeds its expected value. In general, *z*-score computations must be based on sufficient data in order to justify significance of

Table I An Example of a 2×2 Table with Specified Cell Frequencies

	E	\bar{E}
A	a	b
\bar{A}	c	d

results. The z -score, however, does not provide information on the magnitude of an effect. If individual or group differences or effects of research factors are of interest, then statistics such as the odds ratio, log odds ratio, Yule's Q and ϕ are utilized. Odds ratio is one of the most common statistics for 2×2 tables. The odds ratio varies from 0 to infinity and equals 1 when the odds are the same for two groups. The natural logarithm (\ln) of the odds ratio, which is called log odds ratio, is relatively easy to compute and interpret. Yule's Q is a transformation of the odds ratio. It ranges from -1 to $+1$ with zero indicating no effect. For instance, let us consider a 2×2 table (Table I) that consists of events A and E and their complements \bar{A} and \bar{E} (where rows represent lag 0 and columns lag 1) with individual cells, which are labeled a , b , c , and d , representing cell frequencies. The odds ratio can be estimated as: odds ratio = ad/bc . The log odds ratio is expressed as $\ln(ad/bc)$, while Yule's Q becomes

$$ab - bc/ad + bc.$$

Another common index for 2×2 tables is the ϕ coefficient or the Pearson product-moment correlation coefficient. This statistic also varies from -1 to 1 with zero indicating no association. Although, there are some computational differences between Yule's Q and the ϕ coefficient, Bakeman, McArthur, and Quera concluded that in testing for group differences, the choice of one method versus the other has no impact on inference.

A second approach to sequence detection includes the lag-sequential method. Lags are defined as the number of events or time units between sequential events. Its purpose is to detect commonly occurring sequences by examining codes pairwise.

Observational data summarized in multiway contingency tables can also be analyzed using log-linear techniques. Log-linear analyses offer an advantageous alternative to lag-sequential analysis. Regardless of overlapping sampling or repetition of consecutive codes, log-linear analysis provides an integrated method for determining whether there are effects at various lags.

Drawing Causal Inferences

In observational studies, statistical associations do not always imply causality. Associations can be classified as spurious, indirect and causal. Spurious associations are

the result of selection bias, information bias, and chance. In contrast, indirect associations, which stem from confounding, are real but not causal. Confounding can be controlled by restriction, matching or stratification, while bias can be examined through a variety of techniques. In general, causal inferences in observational studies require a coherent unbiased association between an exposure and outcome. According to Rosenbaum, a coherent association is one that is consistent with the hypothesis under consideration. Criteria for judgment of causal associations include temporal sequence (did exposure precede outcome?), strength and consistency of association, specificity (does exposure lead only to outcome?), coherence with existing knowledge, and analogy (is the association similar to others?). These guidelines for judgment of associations in observational studies can be an asset not only to the researcher but also to the reader in deciding whether a casual link exists.

Challenges

Problems and Ethical Considerations in Observational Studies

Observation of human behavior on interaction is rarely a neutral occasion. How the observer and the observed react to each other and how these reactions affect the contents of the observational record can be problematic. Issues of this kind, as applied to the observers, are generally subsumed under the label of bias and can arise from the gender, race, or cultural perspective of the observer. Additionally, bias can also arise from what the observer views as the intended purpose of the observation. Fatigue, intention, or boredom of the observer may also affect the accuracy, reliability, and validity of the observations. From the perspective of the person being observed, the presence of the observer or the act of being observed has a potential to affect the behavior of the observed. In order to eliminate these problems, observers should record events as unobtrusively as possible.

Other challenges in observational studies are related to recording and coding procedures and enhancing the accuracy, reliability, and validity of those procedures. Laying the groundwork by establishing a training instruction booklet with explicit instructions of what is to be observed and how it is to be recorded and evaluated may positively affect validity and reliability of the study. Reducing the error variance between and within-observers has the potential for increasing the accuracy and reliability of the observations. Additionally, refinement of the observational procedures through the use of generalizability theory can offer promise for addressing these issues. Finally, given that in observational studies replication of a setting is virtually impossible, it is difficult to establish validity using traditional psychometric procedures

wherein an instrument is correlated through its use in multiple contexts.

As with any type of research there are ethical considerations that must be taken into account. Research involving observation requires that confidentiality of the participants is protected and that there is no exposure to any physical or psychological harm. Researchers should consider having each coder sign a written statement emphasizing the importance of data confidentiality. Ethical considerations should be outlined clearly in observation manuals.

Omitted Variable Bias

Paul A. Jargowsky

University of Texas, Dallas, Richardson, Texas, USA

Glossary

bias The difference between the expected value of an estimator and the parameter being estimated.

coefficient In regression, the estimated effect of an independent variable on the dependent variable, controlling for the other independent variables in the model.

correlation A measure of the linear association between two quantitative variables.

estimator A statistic based on a sample for the purpose of providing information about a population parameter.

expected value The mean of the probability distribution of a random variable.

partial correlation A measure of the linear association between two quantitative variables after controlling for the effect of one or more additional variables.

unbiased The property of an estimator having an expected value equal to the parameter being estimated.

Omitted variable bias, also known as left-out variable bias, is the difference between the expected value of an estimator and the true value of the underlying parameter due to failure to control for a relevant explanatory variable or variables. This entry develops the concept in the context of regression analysis.

The Danger of Omitted Variable Bias

The usual goal of a quantitative social science study is to estimate the direction, magnitude, and statistical significance of the effect of an independent variable on a dependent variable. When one or more variables that ought to be included in a model has been left out, our estimate of the effect of the variables we do include in the model is likely to be in error. Even increasing the sample size or repeating the study multiple times will not help to solve the problem.

Social science phenomena are, by their very nature, multivariate. Yet human reasoning tends to operate in a bivariate manner. When we see two variables correlated in time or space, we tend to leap to the conclusion that one variable must be causing the other. Moreover, data tables and graphics are printed on a two-dimensional page and are most effective at showing bivariate relationships. Unfortunately, except under very favorable circumstances, conclusions based on bivariate reasoning are likely to be incorrect to one degree or another because of omitted variable bias. In fact, even analyses that take dozens of variables into account will still be biased if even one important explanatory variable is overlooked. In all likelihood, omitted variable bias is the most serious and pervasive threat to the validity of social science research.

This entry describes why left-out variable bias occurs, why researchers need to be concerned about it, and how to deal with it. We work here within a linear regression framework, but the concerns are generalizable to many different types of analysis, both more and less sophisticated than linear regression. The entry first describes how an omitted variable biases the coefficient in a bivariate regression, setting forth guidelines for determining the direction of the bias. The analysis is then extended to multiple regression, describing a more refined rule for predicting the direction of the bias, which is less well known than the procedure for the bivariate case. Last, strategies are identified for coping with omitted variable bias.

Omitted Variable Bias in the Bivariate Case

This section addresses omitted variable bias in the context of a bivariate regression.

The Algebra of the Bias

For the purpose of understanding how the influence of an omitted variable can be picked up by other variables in an analysis, we begin with a simple case in which a dependent variable Y is determined by two variables X_2 and X_3 , plus a stochastic disturbance term. Thus, the true model is:

$$Y_i = \beta_1 + \beta_2 X_{2i} + \beta_3 X_{3i} + u_i \quad (1)$$

where the β s are the parameters to be estimated, and the disturbance term, u_i , is assumed to be uncorrelated with the X variables.

Let us assume, however, that the researcher lacks data on the variable X_3 and proposes to regress Y on X_2 alone. To clear X_3 from the equation, and thus recast the true model solely as a function of X_2 , we first need to express X_3 as a function of X_2 :

$$X_{3i} = \gamma_1 + \gamma_2 X_{2i} + \varepsilon_i. \quad (2)$$

We need not concern ourselves with whether Eq. (2) expresses a causal relationship or merely a spurious correlation; the γ s are simply the parameters of the ideal line that captures the linear correlation between the two X variables. The ε term is the difference between the actual value of X_3 and the conditional mean of X_3 given X_2 . In other words, it is the part of X_3 that is uncorrelated with X_2 .

To clear X_3 from the model, we simply substitute Eq. (2) into Eq. (1):

$$\begin{aligned} Y_i &= \beta_1 + \beta_2 X_{2i} + \beta_3 (\gamma_1 + \gamma_2 X_{2i} + \varepsilon_i) + u_i \\ &= \beta_1 + \beta_2 X_{2i} + \beta_3 \gamma_1 + \beta_3 \gamma_2 X_{2i} + \beta_3 \varepsilon_i + u_i \\ &= \underbrace{(\beta_1 + \beta_3 \gamma_1)}_{\alpha_1} + \underbrace{(\beta_2 + \beta_3 \gamma_2)}_{\alpha_2} X_{2i} + \underbrace{(\beta_3 \varepsilon_i + u_i)}_{\tilde{u}_i}. \end{aligned} \quad (3)$$

After regrouping, the terms in the first parenthesis are all constants, so for convenience we can label the sum of these constants α_1 . The terms in the second parenthesis are slopes—that is, changes in Y associated with changes in X_2 . We label the sum of these slopes α_2 . The terms in the final parenthesis are a weighted combination of stochastic (random error) terms that are uncorrelated with X_2 .

The point is that when we mistakenly estimate the bivariate regression of Y on X_2 , omitting X_3 and assuming that the disturbance term is uncorrelated with X_2 , we actually obtain an unbiased estimate of α_2 rather than an unbiased estimate of the true causal effect, γ_2 . Specifically,

$$E[\hat{\alpha}_2] = \alpha_2 = \beta_2 + \beta_3 \gamma_2. \quad (4)$$

The first term (β_2) is the true causal effect, the quantity we wish to estimate. The second term is the omitted variable bias. (The formal derivation of omitted variable bias involves substituting the true model for Y_i into the formula for the ordinary least squares, OLS, slope coefficient and then taking the expectation. See the Appendix at the end

of the entry.) Note that the bias has two components. The first (β_3) is the true effect of the omitted variable. The second (γ_2) is the parameter on X_2 in Eq. (2). Because Eq. (2) is in the form of a bivariate regression, we can express this parameter as follows:

$$\gamma_2 = \rho_{23} \left(\frac{\sigma_3}{\sigma_2} \right) \quad (5)$$

in which ρ_{23} is the correlation between X_2 and X_3 , and the σ s are the standard deviations of the corresponding X variables.

The Direction of the Bias

The two components of the bias make it possible to estimate the direction of the bias. Because standard deviations are always positive, the sign of the bias will be determined by the product of the signs of β_3 , the true effect of the omitted variable, and the correlation between the included and the excluded variables. If both are positive, or both are negative, then the bias is positive, meaning that the coefficient estimate in the bivariate estimation is likely to be high. If one is positive and the other negative, then the bias term is negative, and the coefficient estimate in the bivariate case is likely to be too low. If either of these two terms is zero, then we need not worry about an omitted variable bias.

We do not know these signs for certain; after all, the variable has been omitted from our analysis. But often it is possible to get a good idea about the probable signs of these quantities based on theoretical considerations, prior empirical research, or common sense.

Examples

Suppose we regress wages in dollars on years of education, but omit a variable for experience. We might obtain a result like the following bivariate regression:

$$\text{Wage} = 1.00 + 0.75 * \text{Educ.}$$

If our model has been correctly specified, we are justified in inferring that an additional year of education leads to an increase of 75 cents in the wage rate. However, we have omitted experience, which is not directly available in most cross-sectional data sets, such as the Current Population Survey.

Even without a variable for experience, we can make an educated guess about the direction of the bias. Based on human capital considerations, we expect the sign of experience to be positive. The correlation between education and experience is likely to be negative, both because people stay out of the labor market to pursue education and because older cohorts of workers generally have obtained less education but have accumulated much work

experience. A positive times a negative is negative, so the bias is negative. The bivariate estimate of the effect of education on wage is, therefore, likely to be too low relative to the unbiased estimate that controls for experience.

Although a biased estimate is a bad thing, at least in this case we can say that our estimate of the effect of education on wage is conservative; if we had been able to include experience, the coefficient would probably be even higher. That is, the effect of education on wage is probably greater than 75 cents per year of education.

On the other hand, we have also omitted ability. Ability is likely to have a positive effect on wages and a positive correlation with education. Therefore the bias is positive as well. In this case, the bias is more troubling. Depending on the size of the bias, the true effect of education could be zero or even negative.

As the two examples show, an educated guess about the direction of the bias can be very helpful, particularly if the bias has the opposite sign of the coefficient. A positive coefficient with a negative bias is likely to be an even larger positive number; similarly, a negative coefficient with a positive bias is likely to indicate a larger—that is, more negative—coefficient.

It is worth noting at this point that bias is a property of the expected value of the coefficient, not any specific estimate. In any given sample, the value of a coefficient can be quite different than its expectation, so there is no guarantee that a negatively biased coefficient will be smaller than the true parameter value or vice versa.

Omitted Variable Bias in Multivariate Analyses

The analysis of omitted variable bias in the bivariate case is useful in developing an understanding about the mechanics of the bias. Most of the time, however, we are concerned about the effect of an omitted variable in a multiple regression analysis.

The Algebra of the Bias

Anticipating the direction of the bias is somewhat more complex when we move beyond bivariate regression models. For example, suppose the true causal model is:

$$Y_i = \beta_1 + \beta_2 X_{2i} + \beta_3 X_{3i} + \beta_4 X_{4i} + u_i. \quad (6)$$

Further, suppose that X_4 is related to X_2 and X_3 as follows:

$$X_{4i} = \gamma_1 + \gamma_2 X_{2i} + \gamma_3 X_{3i} + \varepsilon_i. \quad (7)$$

Substituting and rearranging terms:

$$\begin{aligned} Y_i &= \beta_1 + \beta_2 X_{2i} + \beta_3 X_{3i} + \beta_4 (\gamma_1 + \gamma_2 X_{2i} + \gamma_3 X_{3i} + \varepsilon_i) + u_i \\ &= \underbrace{(\beta_1 + \beta_4 \gamma_1)}_{\alpha_1} + \underbrace{(\beta_2 + \beta_4 \gamma_2)}_{\alpha_2} X_{2i} + \underbrace{(\beta_3 + \beta_4 \gamma_3)}_{\alpha_3} X_{3i} \\ &\quad + \underbrace{(u_i + \beta_4 \varepsilon_i)}_{\tilde{u}_i}. \end{aligned} \quad (8)$$

Thus, when estimating the regression of Y on X_2 and X_3 , omitting X_4 , the slope parameters for both of the included independent variables are potentially biased. The expected values for the slope parameters are:

$$\begin{aligned} E[\hat{\alpha}_2] &= \beta_2 + \beta_4 \gamma_2 \\ E[\hat{\alpha}_3] &= \beta_3 + \beta_4 \gamma_3. \end{aligned} \quad (9)$$

As in the bivariate case, there is no bias if β_4 the true effect of the omitted variable, is zero. Unlike the bivariate case, the γ s are now multiple regression coefficients. Thus, they cannot be expressed as a function of the simple bivariate correlation coefficients between the omitted variable and the included variables. Instead, γ_2 is the slope coefficient for X_2 that we obtain from a regression of X_4 (the missing variable) on X_2 and X_3 . If that coefficient is zero, there is no bias. The sign of that coefficient is the sign of the *partial* correlation between X_2 and X_4 , controlling for X_3 . As in the bivariate case, the direction of the bias is determined by the product of the signs of the two terms in the bias equation.

The extension to situations involving more variables is straightforward; Greene (2000) provided a formal derivation of the bias in the multivariate case. If there are two excluded variables, X_4 and X_5 , the expected value of the coefficient on X_2 is:

$$E[\hat{\alpha}_2] = \beta_2 + \beta_4 \gamma_{42} + \beta_5 \gamma_{52} \quad (10)$$

where γ_{42} is the coefficient expressing the partial effect of X_2 on X_4 and γ_{52} is the coefficient expressing the partial effect of X_2 on X_5 , with X_3 controlled in both cases.

In general, if X_j are the J variables included in the regression, and Z_k are the K variables omitted from the regression, the expected value of the coefficient any one of the included variables is:

$$E[\hat{\alpha}_j] = \beta_j + \sum_k \beta_k \gamma_{kj}. \quad (11)$$

Thus, each left-out variable potentially contributes to the bias. For a given left-out variable k , there is no bias if the omitted variable has no effect on the dependent variable after controlling for the included variables, that is, $\beta_k = 0$ for that variable. There is also no bias for a given included variable j if the partial correlation

Table I Existence and Direction of Omitted Variable Bias^a

Partial correlation between omitted variable and the included variable of interest ^b	Marginal effect of the omitted variable on the dependent variable ^c		
	Negative	Zero	Positive
Negative	Positive bias	None	Negative bias
Zero	None	None	None
Positive	Negative bias	None	Positive bias

^a If more than one variable is omitted, each can cause a bias. If the biases are in opposite directions, it is difficult if not impossible to tell the net expected direction of the bias.

^b Net of the other included variables.

^c Controlling for all other variables.

between the omitted and the included variables is zero after controlling for the other included variables, that is, $\gamma_{kj} = 0$.

Although it is clearly more difficult in the multivariate case, we can still anticipate the direction of omitted variable bias by making educated guesses about the sign of the effect of the excluded variable and the *partial* correlation of the included variables in questions and the excluded variable. Most of the time, but certainly not always, the sign of the partial correlation and the simple bivariate correlation are the same. Nevertheless, we must guard against uncritically applying the bivariate analysis in the multivariate case, and the distinction is not as well appreciated as it ought to be. Table I summarizes the issues involved in evaluating the existence and direction of the bias. However, if there are several omitted variables and some of the expected biases are positive and some are negative, it may be difficult (if not impossible) to anticipate direction of the net expected bias.

Broader Implications

An often neglected point is that omitting relevant variables affects the standard errors of the included variables as well. There are several potentially offsetting effects, so that the standard errors may be larger or smaller relative to the correctly specified model. However, in view of the bias in the coefficients when relevant variables are left out, the effects on the standard errors seem like a second-order concern because the wrong quantity is being estimated. There is no bias if the omitted variable is not correlated with the included variable, but the standard errors of the coefficients on the included variables will still be affected. On the one hand, including an omitted variable uses up one degree of freedom, potentially increasing the standard error. On the other hand, including an omitted variable reduces the residual variance, which will tend to reduce the standard errors of the coefficients of the included variables. In practice, the latter effect will usually predominate,

especially in larger data sets in which degrees of freedom are plentiful.

The foregoing discussion has been framed in the context of OLS regression, but the ideas developed are applicable to a broad array of models that include a linear function of several variables as part of their specification. Omitted variable bias has roughly the same properties in all models in which the dependent variable is modeled as some function of a linear combination of dependent variables and parameters.

For example, a logit model is specified as follows:

$$P_i = \frac{1}{1 + e^{-(\beta_1 + \beta_2 X_{2i} + \dots + \beta_k X_{ki})}}. \quad (12)$$

Solving for the linear function of the independent variables, the model can be written as:

$$\ln\left(\frac{P_i}{1 - P_i}\right) = \beta_1 + \beta_2 X_{2i} + \dots + \beta_k X_{ki}. \quad (13)$$

Although the relationship between the X s and P_i is clearly nonlinear, the relationship is monotonic; therefore, a positive β implies that the probability increases as X increases, a negative coefficient implies that the probability decreases as X increases, and a larger coefficient implies a larger effect, other things equal. Omitted variable bias is a function of the relationship between the X variables, not the functional form of the relationship with the dependent variable. In other words, we can still make the same generalizations about the *direction* of the bias as previously described when considering logit, probit, tobit, Poisson, and many other models.

On a conceptual level, we can also extend these ideas to tables, graphs, and maps. For example, given the rise of Geographic Information Systems (GIS), it is common for researchers to show maps and note that two variables, say percentage of blacks and the high school dropout rate, are geographically concentrated in the same neighborhoods. This is nothing more than a visual bivariate correlation, without even the benefit of a test of significance. Any conclusion we would wish to draw from such maps is

tainted by the omission of other variables, such as the poverty rate, which may well partly or fully determine the outcome variable.

As discussed by Alwyn and Hauser in 1975, omitted variable bias is very closely related to path analysis. In fact, the mathematics of the two are identical; they differ only in the assumptions about the relations among the variables. What has been described as a bias in this entry is called an indirect effect in path analysis. In order for the indirect effect interpretation to be valid, the researcher must be able to correctly specify the causal ordering of the variables in the model.

Coping with Omitted Variable Bias

The definitive solution to omitted variable bias is to conduct a classic experiment, in which individuals are randomly assigned to treatment and control groups. Because both groups are random draws from the same population, they have the same expected value for any variable other than the treatment. Because no other variable, measured or unmeasured, known or unknown, is likely to be correlated with the treatment, there is little reason to be concerned with omitted variable bias in the analysis of experimental data. In many issues studied by social scientists, however, it is not possible to conduct experiments or, in cases in which it might be possible, it is often not ethical. We cannot randomly assign workers to a gender, and we would not randomly assign children to abusive parents. And even when experiments are possible and ethical, they are expensive and difficult to conduct. Thus, nonexperimental research is an unavoidable necessity, despite the possibility and probability of omitted variable bias.

The second best way to correct omitted variable bias is to collect new data that include the variables omitted in previous analyses. We should then include the formerly omitted variables and perform the relevant t or F tests; and, depending on the results of these tests, we should either include or exclude the variable from the final model. However, this is not always practical or possible. For example, some variables are intrinsically hard to measure, such as a person's level of motivation. And in some cases, a researcher may not even be aware of the variable that is being omitted because of a lack of understanding of the phenomenon under study.

For all of these reasons, researchers often have no choice but to conduct analyses on data that may be missing important explanatory variables. This section addresses strategies and techniques for recognizing and addressing omitted variable bias when conducting an experiment or collecting new data is not possible.

Testing for Omitted Variable Bias

Any time the R^2 from a regression is less than 1, some aspect of the process that generates the dependent variable is unknown. Thus, the first diagnostic for omitted variables is a low R^2 statistic. However, R^2 less than 1 is a necessary but not a sufficient condition for omitted variable bias. The unexplained variation could be random noise, or it could be the systematic impact of omitted variables which, taken together, are uncorrelated with any of the included variables.

A number of tests have been developed that can aid the researcher in diagnosing the likelihood of left-out variable bias. The most commonly used is the regression specification error test (RESET) proposed by Ramsey in 1969. The intuition behind the test is that the residuals from a regression with a left-out variable will include a systematic component, reflecting the net influence of the omitted variables. However, by construction, the residuals are orthogonal to both the predicted values and all the included independent variables. Thus, the residuals from the suspect regression are themselves regressed against squares and higher powers of either the predicted values or the independent variables. Under the null hypothesis of no specification error, the sum of the squared residuals from the auxiliary will have an F distribution. Unfortunately, the test is a general misspecification test and cannot distinguish between omitted variables and incorrect functional form.

Correcting Omitted Variable Bias

When the data do not contain one or more variables of interest, there are a number of ways to control for them implicitly. In panel data, fixed effects models may be estimated. The fixed effect model implicitly controls for all variables that are unchanging over the period in question. For example, fixed effects at the individual level can be used to control for innate ability in a wage regression; fixed effects for multiple-sibling families can be used to control for unmeasured characteristics of the parents. Similarly, paired difference tests and difference-in-difference estimators allow individual observations to serve as their own control.

An instrumental variable (IV) approach may be attempted if variables can be found that are related to the included variables but not to the omitted variables. By purging the included variable of its correlation with the omitted variable, consistent estimates of the included variable's influence may be obtained. For example, as Angrist and Krueger explained in 1991, quarter of birth is correlated with schooling because of compulsory education laws, but presumably uncorrelated with ability. Thus, an IV approach based on quarter of birth allows a consistent estimate of the effect of schooling on wage

that is not biased by the omission of a measure of ability. Obviously, this technique depends on the availability of suitable instruments.

If there is no way to add the omitted variable or to control for it implicitly, the best we can do is to try to evaluate the likely impact of the bias, as discussed previously.

Conclusion

Social phenomena are the results of complex multivariate processes in which the causal variables are often correlated. Ultimately, the best way to recognize a left-out variable problem is to use theory, prior empirical research, and common sense as guides to what variables ought to be included in the model. Given the near impossibility of measuring all the relevant variables, virtually all social science analyses are plagued by omitted variable bias to some degree. However, understanding the mechanics of omitted variable bias can suggest the probable size and direction of the bias. Perhaps more important, it can help the researcher to decide which left-out variables cause the most serious threat to the validity of research findings and therefore indicate where further time, money, and effort can be most usefully deployed.

Appendix: Expectation of the Bivariate Slope Coefficient with an Omitted Variable

Assume that the true model is:

$$Y_i = \beta_1 + \beta_2 X_{2i} + \beta_3 X_{3i} + u_i \quad u_i \sim N(0, \sigma^2) \quad (14)$$

However, the following model is estimated:

$$Y_i = \alpha_1 + \alpha_2 X_{2i} + \varepsilon_i \quad (15)$$

For ease of presentation, let lower-case letters represent deviations from the respective means. In other words:

$$\begin{aligned} y_i &= Y_i - \bar{Y} \\ x_{2i} &= X_{2i} - \bar{X}_2 \\ x_{3i} &= X_{3i} - \bar{X}_3. \end{aligned}$$

It is also useful to note the following relation:

$$\sum x_{2i} y_i = \sum x_{2i} (Y_i - \bar{Y}) = \sum x_{2i} Y_i - \bar{Y} \sum x_{2i} = \sum x_{2i} Y_i. \quad (16)$$

The second term disappears because the sum of deviations around a mean is always zero.

The expectation of the slope coefficient from the incorrect bivariate regression is:

$$E[\hat{\alpha}_2] = E \left[\frac{\sum x_{2i} y_i}{\sum x_{2i}^2} \right] = E \left[\frac{\sum x_{2i} Y_i}{\sum x_{2i}^2} \right]. \quad (17)$$

As shown, for example, by Gujarati in 2003, the first step is the standard solution for the bivariate slope coefficient. In the second step, we make use of Eq. (16). Now we substitute the true model, Eq. (14), simplify the expression, and take the expectation:

$$\begin{aligned} E[\hat{\alpha}_2] &= E \left[\frac{\sum x_{2i} (\beta_1 + \beta_2 X_{2i} + \beta_3 X_{3i} + u_i)}{\sum x_{2i}^2} \right] \\ &= E \left[\frac{\beta_1 \sum x_{2i} + \beta_2 \sum x_{2i} X_{2i} + \beta_3 \sum x_{2i} X_{3i} + \sum x_{2i} u_i}{\sum x_{2i}^2} \right] \\ &= E \left[0 + \beta_2 + \beta_3 \left(\frac{\sum x_{2i} x_{3i}}{\sum x_{2i}^2} \right) + \frac{\sum x_{2i} u_i}{\sum x_{2i}^2} \right] \\ &= \beta_2 + \beta_3 \gamma_{32}. \end{aligned} \quad (18)$$

This is the result noted in Eq. (4). The first term goes to zero because the sum of deviations around a mean is always zero, and the final term has an expectation of zero because the model assumes no covariance between the X s and the disturbance term. The raw values of X_2 and X_3 are replaced by their deviations (x_2 and x_3) in the third step by making use of the property demonstrated in Eq. (16).

Glossary

analytical hierarchy process A method for building a hierarchy of decision elements and comparing and ranking those elements.

branch and bound A search procedure in which relaxations of an integer linear program are organized in a tree structure and solved in order to bound the solution space of the root problem and converge on the optimal solution.

combinatorial complexity The measure of the size of or difficulty in solving a problem based on the number of possible combinations of decision variable values within the problem.

decision variables The elements of an operations research model that represent choices among possible alternative assignments of resources.

Delphi process A structured method for developing consensus among decision makers and experts regarding the significant factors to be included in a model.

enumeration procedure A method for examining all possible alternative solutions in order to identify an optimal solution.

heuristic solution method A “rule-of-thumb” algorithm that will rapidly produce high-quality (though not guaranteed optimal) solutions to a difficult problem.

interior point solution procedure An iterative procedure that identifies a solution within the boundary of the feasible region for a problem and improves on that solution until an optimal solution is found.

linear programming A method for modeling a complex problem as a set of linear functions, including an objective function and a set of constraints.

mathematical modeling The process of structuring complex systems as a set of mathematical functions.

objective function The mathematical expression of the goal of a complex system.

optimization An act, process, or methodology of making something (as a design, system, or decision) as fully perfect, functional, or effective as possible; specifically the mathematical procedures (as finding the maximum of a function) involved in this process.

resource constraint A mathematical representation of a limitation on reaching the objective for an optimization problem.

simplex method An iterative procedure for solving a system of linear equations given in a standardized form, representing constraints on a system.

Operations research is defined as the application of advanced analytical techniques in order to solve complex problems. Its dominant characteristic is the use of mathematical models to analyze problems. With origins in military strategic planning, operations research has found applicability in a wide range of industrial, commercial, and social contexts. Although many of the problems studied are highly combinatorially complex, advanced optimal and heuristic solution procedures have been developed to find alternative solutions for decision-making processes.

Operations Research Defined

The field of operations research (alternately termed operational research or management science) is defined as the application of advanced analytical techniques in order to solve complex problems. Operations research (OR) contains a set of tools used by those who must make organizational decisions. Often these problems involve the allocation of scarce resources in such a way as to achieve a goal maximally (such as profit or level of service) or to minimize some negative consequence of the operation of an organization (such as cost or environmental degradation). In order to solve a complex problem posed by the operation of an organization or system, this problem must be formulated in such a way that it can be efficiently analyzed.

The dominant characteristic of OR is that it constructs and uses mathematical representations, i.e., models, to analyze problems. These models commonly take the form of an objective function that defines the goal of the organization (or one of many goals), and a set of constraints representing the conditions within which the system must operate. Once the general version of problem is formulated, individual instances of that problem may be solved optimally in order to suggest specific allocations of the organization's resources. This solution will be the one that best satisfies the objective that is to be optimized. This distinctive approach is an adaptation of the scientific method used by other sciences.

History of Operations Research

The discipline of OR has its origins in the application of problem-solving techniques in a military context during World War II, when the practice was termed "military OR." In this context, the complex system was designed to wage war, and the components of that system were the enormous resources and requirements of military organizations. Examples of how OR was applied include the determination of the optimal fuse length for depth charges designed to combat submarines, the optimal deployment of radar stations and mining operations, and the optimal arrangement for convoys of ships.

Following the end of the war, two fundamental changes occurred in the practice of OR. First, the methods employed in the conduct of war were quickly adapted to a wide range of industrial applications. Rather than maximizing the efficiency of weapons systems, problems were formulated to increase the efficiency of manufacturing and transportation systems. Second, the development of the simplex method by G. B. Dantzig in 1947 revolutionized the practice of solving mathematical models. The simplex method is a procedure for solving a system of linear equations given in a standardized form, representing the constraints on a system. This iterative method can efficiently evaluate very large numbers of such constraints and associated variables. Due to the computational complexity of such problems and the potential for astronomically large numbers of possible solutions to evaluate, the simplex method effectively unlocked the solutions to a vast number of problems that could not otherwise have been solved.

The two changes in the practice of OR have brought about the steady growth in the development and application of OR techniques for over 50 years. Moreover, these techniques have demonstrated that the efficiencies gained by mathematically modeling a system and solving that model optimally are significant and can in some cases be extraordinary. Recent findings show that major corporations have realized savings in the hundreds of

millions of dollars attributable to the implementation of optimization techniques.

An Approach for Conducting Operations Research

Although the mathematical model provides both the message for decision makers and the structure for conveying that message, the model alone is only one part of a process for conducting OR. There are commonly five stages in this process.

Stage 1: Understand and State the Problem

As in any research project, the first step is to state the problem clearly. In the context of OR, such a statement involves an understanding of the system to be modeled and the environment within which the system operates. Understanding the system requires that there is a known goal (or set of goals). Examples of goals are to maximize profit in the context of a commercial enterprise, to minimize cost for a particular manufacturing process, or to minimize distance traveled in the case of transportation applications. Moreover, there may be many factors that influence the extent to which the goal can be met. In terms of commercial gain, there are limits on costs of acquiring goods and constraints imposed by both markets and regulations. In terms of manufacturing processes, there are set requirements for inputs and scheduling considerations. Transportation functions depend on the origin and destination locations, the locations of stops, mode choices, and a host of other factors. All of the pertinent factors must be determined in order to have a reasonable understanding of the problem. These factors can be determined through consultation with the managers of the system and others who are experts in the field, perhaps through a Delphi process. It may be appropriate to determine the importance of different factors through the use of an analytical hierarchy process or some other method of ranking these factors. With an understanding of the factors that influence the system, a clear statement of the problem can be generated.

Stage 2: Formulate the Problem Mathematically

In any research project, models are built in order to find a useful, albeit simplified, representation of a real-world situation. It is no different in OR. A mathematical model is generated from the understanding of the problem gained in stage 1 of the research process. The model often consists of a single objective function that reflects a simplified vision of the goal to be met. The objective

function also serves as the quantitative performance measure for the system being modeled. A series of mathematical constraint functions represent simplified versions of the limitations that must be met in the system.

Within these functions many different decisions must be made in order to evaluate the system. Examples of decisions include which roads to travel in order to minimize distance, which locations to choose for warehouses, or how many units of manufactured goods to ship from a particular warehouse to a retail store. These decisions are represented within the functions in the mathematical model with decision variables, and it is the value of these variables that must be determined in such a way as to optimize the system. Decision variables may be binary (e.g., either a road is traveled or it is not), integer (e.g., only whole units of manufactured goods may be shipped), or fractional (e.g., any number of gallons or fractions of gallons of water may be pumped in order to meet the needs of a community). Constants or weights may be associated with particular decision variables if relevant and accurate data exist.

Consider as an example the mathematical formulation for a common OR problem known as the “knapsack” problem. This problem arises when there is limited space to carry or include items (such as in a knapsack) and the objective is to select those items that will be most valuable for inclusion in the limited space. This could pertain to the loading of products for delivery into trucks with limited space or limited weight-carrying capacity. First, the notation used in the formulation is defined as follows: j is the index of item types, N is the number of types of items, c_j is the value of item type j (where $j = 1, 2, \dots, N$), a_j is the weight of item type j (where $j = 1, 2, \dots, N$), b is the limit on the total weight of the items that can be included, and x_j is the number of items of type j that are included in the knapsack. The objective or goal is to maximize the value of the items included in the backpack, and thus the objective function can be written as

$$\text{Maximize } Z = c_1x_1 + c_2x_2 + \dots + c_Nx_N,$$

or alternatively as

$$\text{Maximize } Z = \sum_{j=1}^N c_jx_j.$$

This objective function is subject to a constraint on the total amount of weight allowed (room in the knapsack or truck). This constraint can be written mathematically as

$$a_1x_1 + a_2x_2 + \dots + a_Nx_N \leq b,$$

or alternatively as

$$\sum_{j=1}^N a_jx_j \leq b.$$

The x_j variables are the decision variables for this formulation. It must be decided how many of each type of item (if any) ought to be included in the knapsack in order to maximize the objective function, while respecting the constraint. In practice, it is impossible to put negative numbers of items in a knapsack, thus a set of constraints is usually generated to ensure that the decision variables hold only non-negative numbers of items. These can be written as $x_1 \geq 0, x_2 \geq 0, \dots, x_N \geq 0$, or alternatively as $x_j \geq 0$ for all $j = 1, 2, \dots, N$. Depending on the nature of the items to be included in the knapsack, these decision variables may be further constrained. For example, if the items to be placed in the knapsack cannot be broken into smaller pieces, they must be constrained to be only integer values. Moreover, if only one item of each type may be included in the knapsack, then the decision variables are binary and $x_j = 1$ if an item of type j is included in the knapsack, and $x_j = 0$ otherwise.

Although the knapsack problem is only one of many different types of problems that are commonly solved in OR, the mathematical formulation is typical of many different problems: there is an objective function, a constraint on the available resources for the system, and a set of constraints on the values of the decision variables. This common type of formulation is called a linear programming formulation, and such formulations are perhaps the chief research area in OR. However, several other research areas command attention, including critical path analysis, dynamic programming, goal programming, nonlinear programming, decision analysis, game theory, Monte Carlo simulation, and queuing theory. Due to the limited space here, the focus remains on using linear programming to model complex systems.

Stage 3: Solve Instances of the Problem

Once an appropriate model formulation has been developed, it must be used to solve real-world instances of the problem. Although there is a fairly large toolbox of solution procedures and variants of such procedures, they can be grouped into five major categories: graphical solution procedures, enumeration methods, simplex-type solution methods, interior point methods, and heuristic solution methods.

Graphical solution methods depend on the fact that all of the parts of a typical mathematical formulation are linear functions. Those functions can therefore be graphed in Cartesian coordinate space in order to determine the optimal solution. Consider a problem instance with two decision variables (x_1 and x_2) and with two resource constraints ($3x_1 + 5x_2 \leq 20$ and $4x_1 + x_2 \leq 15$). The decision variables must be non-negative. The objective function is to Maximize $Z = 2x_1 + x_2$. These functions can be graphed as in Fig. 1. Each axis in the coordinate system represents one of the two decision

variables. Each of the constraints can be graphed as linear equalities, whereby one side of the line represents feasible values for the decision variables and the other represents values that would violate the constraint. Taken together, all of the constraints (including the non-negativity constraints) define the feasible region for the problem instance. This area is shaded in Fig. 1. The objective function cuts through the feasible region, and its exact placement depends on the values of the decision variables. With the graphical method, it is easy to see that the objective function value will be greatest when the decision variables have values that allow it to be drawn through the intersection of the two resource constraint lines. Although the graphical method for solving OR problems with linear functions is a very intuitive tool, its usefulness is limited to those cases in which there are only two or three decision variables, since it is difficult to represent four or more dimensions graphically in such a way that they can be easily interpreted. Therefore, other solution procedures must be employed for more complex problem instances.

When there are small numbers of constraints and decision variables in the problem instance, it is conceivable that a complete enumeration procedure could be used to find the optimal solution. That is, each possible combination of decision variable values is tested and the associated objective function value is found. One or more of those combinations will be optimal. It may be more efficient, however, to employ a search method such as “branch and bound” to eliminate some nonoptimal solutions from consideration. The branch and bound method divides the feasible region into partitions in a tree structure and uses the solutions to subproblems to bound the objective function and “prune” branches of the solution tree. In practice, however, many of the problem formulations that must be solved in OR belong to a large family of problems that have been proven to be “NP-complete” (where NP refers to nondeterministic polynomial time). Simply put, this means that there are no algorithmic solutions to such problems, and the size

of the problems (as measured by the number of decision variables and constraints) may grow exponentially. Due to the massive resources (in terms of computing time, memory, or storage) that such problems require in order to find a guaranteed optimal solution, it is effectively impossible to solve them through any enumeration procedure. Therefore, an appropriate solution procedure for a problem instance must be chosen based on an understanding of the combinatorial complexity of the problem.

To demonstrate the notion of combinatorial complexity in the context of common OR problems, consider the simple system present in a game of straight pool (billiards). There are 15 billiard balls numbered sequentially, and these must be arranged (in any order) in a rack with 15 places. In the general case, the number of alternatives will be as follows:

$$\text{Number of alternatives} = \binom{n}{p} = \frac{n!}{p!(n-p)!}$$

where n is the number of locations in the rack and p is the number of billiard balls to locate among those potential locations. In the special case of a billiard rack, n is equal to p , so there are 15! (15 factorial) possibilities, or 1,307,674,368,000 possible arrangements of the balls in the rack. In order to determine the optimal solution that describes the best way to arrange the balls through simple enumeration, the objective function must be evaluated for each of the possible arrangements. Depending on the complexity of the objective function chosen for the rack, and on the computing power available, this problem may be unsolvable through inspection. Even a solution protocol that can evaluate the objective function 10,000 times per second would need to run for over 4 years in order to guarantee that the optimal solution had been found. Recall that this problem represents a system with only 15 components! The problems of managing a complex industrial application dwarf this problem by comparison. Given such combinatorial complexity of even small instances of problems in OR, it is clear that enumerative solution procedures are insufficient for many applications.

The development of the simplex method revolutionized OR by providing a standard technique for solving even large optimization problems of the form just described. It is an iterative method that explores the boundary of the feasible region, improving the objective function value with each iteration until the optimal solution has been found. Often the simplex method is used in conjunction with a branch and bound procedure to obtain integer optimal solutions. In other cases, additional constraints (termed “cutting planes”) are included in the formulation in order to eliminate parts of the feasible region containing fractional solutions. The “transportation” problem, the “assignment” problem, and the “transshipment” problem are

Figure 1 Graphical solution to a two-dimensional problem.

examples of the common problems pertinent to the simplex method. Special versions of the simplex method have been developed to more efficiently solve some problems with particular structural characteristics. The “transportation,” “assignment,” and “transshipment” problems are among these. These special case solution procedures are sometimes termed “network flow” solution methods.

Interior point solution methods are an alternative to the family of simplex solution procedures. These are iterative methods that find feasible solutions inside the boundary of the feasible region (rather than on the boundary), and at each iteration they find a solution that provides a better objective function value, until the optimal solution is found on the boundary.

When the problem size proves too large for any of the enumeration or iterative methods, heuristic solution methods may be the only practical means of finding a solution. Many heuristics (or rules of thumb) have been developed and tested on problems for which the optimal solutions are known. It is presumed that if a heuristic works well on small problems, it will likely work well on larger instances of the same problem. Some of the most common heuristics include a family of interchange heuristics for which an initial solution is chosen and successive interchanges of the decision variable values are used to search for solutions that improve the objective function value. Interchange heuristics are susceptible to becoming trapped at local optima that may be far from the global optimal solution for the problem, and Tabu (as in “taboo,” referring to prohibition) versions of these heuristics have been developed to overcome this limitation. Simulated annealing heuristics use an analogy to the process of heating and cooling metal to harden it, in order to move toward the optimal solution. Lagrangian relaxation heuristics are used to find upper bounds on a problem, ideally narrowing the solution space such that the optimal solution is determined. Although heuristic solution procedures may be the only reasonable method for determining solutions to large problems, and although they may find the optimal solution, there is no guarantee that they will do so.

Stage 4: Validate and Interpret the Results of the Model

Once a general formulation for the model has been formulated and instances of the problem have been solved optimally or heuristically, the researcher must examine the solution and reexamine the model that generated it. Only through the processes of validation and interpretation of the solutions that are generated can the researcher determine whether the model accurately represents the problem environment. The quality of the optimal solution is a function of the suitability of the objective function, the constraints, and the parameters. The nature

of mathematical models guarantees that any objective function will be limited in its precision and open to interpretation.

There are several flaws from which models commonly suffer, and which ought to be considered in the validation process: extraneous variables, missing variables, misidentified parameter values, and structural problems. It is possible to use standard statistical analyses such as correlation, regression, and analysis of variance to test for the significance of the variables to the solution. If a variable is not significant to the solution, it may be appropriate to eliminate it and perhaps make the problem easier to solve. Conversely, measures of explained variance might suggest that relevant variables are missing, although they will not help to determine which ones. Sensitivity analysis is useful in determining the amount by which the parameters can be altered before the generated solution will no longer be optimal. The parameters that are varied can include economic and social characteristics such as prices, demands, or population figures, and positional variations in site locations or distance measurements in the case of location optimization problems. If the solution is very sensitive to changes in a particular parameter, then those values must be determined with greater care.

If the model appears to be valid, a critical interpretation of the model should be conducted in the light of the model results. Simply visualizing the solution or presenting it to decision makers can bring to light structural flaws in the model. The optimal solution may expose a missing constraint that would preclude the solution from ever being implemented. The interpretation must be conducted with awareness that the optimality of the solution is always relative to a carefully stated set of constraints, and these constraints are always surrogates for and simplifications of reality. Satisficing solutions that consider qualitative or subjective elements may be close to optimal, but more appropriate in terms of constraints that are well known but not easily expressed as a mathematical function.

Although validation and implementation are discussed here as a fifth step in a research methodology, elements of these processes may be conducted throughout the research program. This highlights the importance in stage 1 of the identification of decision makers and experts for determining objectives, constraints, and significant parameter values.

Stage 5: Implement the Model—Use the model to Explain, Predict, and Decide

The final stage in the OR process is the implementation of the model solutions. Implementation of the solution is the only test of the validity of the results of the research. Because the OR process is concerned largely with optimality, it is tempting to assume that after careful formulation, solution, and validation there could be no possible

reason to reject or delay implementation of that optimal solution. In practice, the generation of a valid optimal solution may be less than half the battle. The implementation of a new solution for a complex system may cause massive change in many different but related systems. Resistance to these changes may be substantial and can prevent the implementation of the optimal solution.

In order to ensure implementation of the results of the OR process, those in a position to authorize its implementation must believe that the model is a reasonable simplification of the system and its environment, and they must understand the structural assumptions built into the model. Such understanding can be gained only through clear communication of the model and the ways in which it was generated, and through the involvement of all interested parties. Because OR tries to improve the efficiency of the system under consideration, it implies a tacit criticism of the existing arrangement. Therefore, in order to avoid resentment among those who manage the current system, the results of the research must be considered to be an imaginative exercise in tactful communication and persuasion. Toward this end, decision makers must be presented with a range of alternative solutions, so that they can select the alternative that can be implemented at a reasonable cost. Although they may risk the loss of optimality, they will be able to weigh the cost and time of implementation versus the potential gains.

If the solutions are implemented, it must also be considered that the system is very likely not static, and it will need to be controlled and monitored over its useful life. Changes in the environment may invalidate the assumptions of the model. Additional constraints may be identified, parameter values may change substantially, or objectives may even change. The application of OR requires that all involved are prepared for changes that may have long-lasting implications for the all of the related systems.

Applications of Operations Research

In the few decades since its origin as a tool for military strategy, OR has become involved in an astounding number of applications areas. Due to the interdependence between the military and industrial activities, there was a quick acceptance of this body of methods in manufacturing. OR quickly proved to identify efficiencies in various production systems, including assembly processes, the blending of ingredients, inventory controls, optimal product mixes, trim loss applications, and job shop scheduling. Later, high-technology manufacturing was to use OR to assist in circuit layout design and multi-processor assignment applications.

Managers of commercial interests other than manufacturing also welcome the cost-effective organizational changes that OR can suggest. Personnel directors can more efficiently schedule a workforce, agricultural decisions under uncertainty can be better evaluated, purchasing decisions can be optimized, and cargo loading can be planned for the greatest efficiency. Those who are concerned with marketing issues can evaluate media mixes to maximize exposure, plan product introductions, arrange portfolios of assets, assess pricing strategies, and propose optimal sales allocations.

A subset of OR applications is concerned with the location of facilities. Examples include the location of warehouses or retail stores, the layout of workstations within a factory, and the placement of public services such as fire or police stations. Location problems will often contain a function of distance, which may be measured in a variety of ways. Some of the most common location problem structures include median problems, center problems, dispersion problems, covering problems, and layout problems. A smaller subset of location applications concerns problems that occur on networks or in systems that can be represented as networks. Such problems take advantage of network topology and the associated graph theoretic concepts of connectivity and adjacency. An enormous number of decisions related to transportation and physical distribution can be constructed and evaluated using these types of models. Other applications on networks involve things such as pipeline construction, highway patrol scheduling, and school bus routing.

Operations Research as a Decision Tool in Social Science

Although OR has proved its worth for practical applications in military, industrial, management, or commercial interests, there are many other applications for which the motivation is to understand social systems. Because many social systems are extraordinarily complex, the model structures and solution procedures designed in OR are capable of providing insights where other methods would be overwhelmed.

Some of the applications of OR in the social sciences are economic in nature, including research into labor costs and market demand under different conditions, capital budgeting and expansion for the public sector, and budget allocation. Other applications concern the distribution of limited common public resources. Others may give insight into the patterns of criminal activity through "hot-spot" analysis. Political campaign strategies and policy platforms can be designed or analyzed using OR methods. Appropriate candidates for committee

assignments or the selection of the most diverse set of applicants for acceptance to a graduate program can be modeled with the OR process. Ecological applications exist when the goal is to minimize the risk of natural hazards, optimize forest management, encourage environmental protection, select sites for natural reserves, or implement pollution controls. Still more applications are designed to increase the efficiency of public services, such as minimizing the response time for emergency personnel, or reduce inequities in access to services or workloads among public servants.

Generally speaking, OR offers a structure for modeling the complex relationships among humans or between humans and the environment. Even though these social systems can be highly complex, OR allows simplified versions of these systems to be modeled in such a way that their individual constraints and variables can be examined and used to generate alternative solutions.

Prospects and Opportunities

Although OR has matured quickly over the decades since its inception, its rapid growth and dissemination into a wide variety of applications areas have opened up new areas for fundamental research. Due to the complex nature and computational complexity of the systems being modeled in OR, there is an ongoing search for new methods (or modifications of existing methods) that will allow a greater number of problem instances to be solved optimally. Investigations into “integer-friendly” formulations—that is, formulations that will generate integer solutions without explicit integrality constraints—are one area of interest. New and variant heuristic solution procedures are developed on a regular basis. Of course, the search for an algorithmic solution to NP-complete OR problems or to special cases of such problems is of constant concern. Although the notions of optimality and fuzzy modeling may seem to be at odds with one another,

the notion of parameters that are dynamic has produced substantial interest. Perhaps most importantly, each incremental step in OR allows for a greater understanding of complex systems—often social systems—and the models chosen for these systems expose both our understanding of them and the limitations of our ability to capture and study them.

Optimal Test Construction

Bernard P. Veldkamp

University of Twente, Enschede, The Netherlands

Glossary

0-1 linear programming A method for solving optimal test construction problems.

algorithm A sequence of instructions that solves a computational problem.

constraint The mathematical representation of a test specification.

heuristic An approximation method for finding a near optimal solution.

infeasibility analysis The process of finding contradictions between constraints in the test construction model.

item pool The database of items and their attributes from which the test has to be constructed.

item response theory (IRT) Theory of measurement models with distinct person and item parameters.

linear programming model A model for optimal test construction.

objective function A function that represents the objective for which the test is constructed.

optimal solution A test that performs optimally with respect to the objective function and meets all the test specifications.

shadow test approach A model for constrained computerized adaptive testing.

test information A function that relates the amount of information in the test to the person parameter.

weighted deviation model A model for optimal test construction.

Optimal test construction deals with the selection of items from a pool to construct a test that performs optimally with respect to the objective of the test and simultaneously meets all test specifications. Optimal test construction problems can be formulated as mathematical decision models. Algorithms and heuristics have been developed to solve the models, which can be used to construct tests.

Introduction

In the area of educational and psychological measurement, tests are often used as data collection instruments. The data are used to assess the score of an examinee on an ability. To define the relation between the answers to a test and the ability, a measurement model is formulated. Based on the model and the data, the score of the candidate is estimated.

In the early days of testing, oral tests and interviews were used to assess the abilities. The measurement model was not formulated explicitly, and the score did not depend only on the answers but also on the mood of the rater. In some areas, standardized test forms, such as the Binet-Simon test, were introduced to make scores more comparable. These standardized test forms solved one problem, but introduced another. When items in the test became known, candidates might try to influence their scores by formulating answers in advance and learning them by heart. This is a potential problem especially in educational measurement, and teachers, or test committees, had to formulate new items for every new test administration.

The new items had to be written, pretested, calibrated, edited, and transported to the test location before they could actually be used to collect data. This process was quite expensive, and, because these items were used only once, it meant a waste of efforts and time. To increase efficiency, new items were collected in item pools. In educational measurement, these pools usually contain between a few hundred and a few thousands of items. From these pools, tests can be selected for several purposes. Item selection is based on the test specifications. For a large test construction problem, the number of specifications may easily run to a few hundred. When the number of items to choose from is also large, manual test construction becomes impractical and

a computer algorithm is used to construct the tests optimally.

Item Response Theory

The introduction of item response theory (IRT) into large-scale testing provided new opportunities for test assembly. In IRT measurement models, item parameters and person parameters are modeled separately. Apart from sampling variation, the item parameters do not depend on the population or on the other items in the test. For dichotomously scored items the Rasch model, the two-parameter logistic model (2PLM), and the three-parameter logistic model (3PLM) are most often applied. The relation between the item and the person parameters can be formulated by the following logistic expression:

$$P_i(\theta_j) = c_i + (1 - c_i) \frac{e^{a_i(\theta_j - b_i)}}{1 + e^{a_i(\theta_j - b_i)}}, \quad (1)$$

where $P_i(\theta_j)$ is defined as the probability of obtaining a correct answer to item i for person j . The person parameter θ_j denotes the latent ability and the item parameters a_i , b_i , and c_i denote the discrimination, the difficulty, and the guessing parameters. For the Rasch model and the 2PLM, the guessing parameter is supposed to be zero, and for the Rasch model also all discrimination parameters are supposed to be equal to 1. For polytomously scored items, polytomous IRT models have also been formulated, for example, the graded response model, the graded partial credit model, and the nominal response model.

When IRT models are applied, measurement precision is determined by the amount of information in the test. Test information, which is a function of the person parameter and the parameters of the items in the test, is defined by:

$$I(\theta) = \sum_{i \in \text{test}} I_i(\theta) = \sum_{i \in \text{test}} \frac{[P'_i(\theta)]^2}{P_i(\theta)Q_i(\theta)}, \quad (2)$$

where $P'_i(\theta)$ is the first derivative of $P_i(\theta)$, and $Q_i(\theta)$ is the probability of obtaining a wrong answer. The focus in optimal test construction is therefore to find a computer algorithm that selects items from the pool that maximize the amount of information in the test but that also meet the test specifications.

Knapsack Problem

To solve optimal test construction problem, all kinds of smart decision rules have been developed. In 1968, Birnbaum presented a rather general approach. His algorithm consists of the following steps.

1. Decide on the shape of the desired test information function.
2. Select items from the pool with information functions to fill areas under the target information function.
3. After each item has been added to the test, calculate the test information function.
4. Continue selecting items until the test information function approximates the desired shape.

However, if more and more test specifications have to be added to the construction problem, the approach becomes hard to adapt. In 1985, Theunissen made the observation that optimal test construction is just another example of a selection problem. Other well-known examples are flight scheduling, work scheduling, human resource planning, inventory management, and the traveling-salesman problem.

In the area of operations research or mathematical programming, algorithms were developed to solve such problems. To find the best algorithm for optimal test construction, algorithms from this area have been adapted and applied. One class of selection problems consists of those called knapsack problems. Before a traveler leaves, he has to fill his knapsack. All possible items he may wish to pack represent a certain value to him, but the volume of the knapsack is limited. The problem is how to maximize the value of all the items in the knapsack while meeting the volume restriction. More formally stated:

$$\max \sum_{i=1}^n c_i x_i \quad (3)$$

subject to:

$$\sum_{i=1}^n a_i x_i \leq b \quad (4)$$

$$x_i \in \{0, 1\} \quad (5)$$

where c_i denotes the value of item i , a_i denotes the volume of item i , and the volume of the knapsack is denoted by b . The decision variables x_i denote whether an item is selected ($x_i = 1$) or not ($x_i = 0$). In mathematical programming terms, the formula in Eq. (3) is called the objective function, and Eqs. (4) and (5) are called the constraints.

In optimal test construction, a problem can be described as a knapsack problem. The value of a test, that is the information in the test, has to be maximized in order to obtain optimal measurement precision. The volume can be interpreted as all possible tests that meet the constraints defined by the test attributes, and an item has to be either selected ($x_i = 1$) or not ($x_i = 0$) for the test.

Overview

In the remainder of this entry, how to model several kinds of optimal test construction problems is

demonstrated using mathematical programming and also some algorithms for solving the problems are described. First, the problem of constructing one linear test form is described. Several objective functions and different kinds of constraints are suggested. This section results in a general formulation of a test construction problem. Then we address models for several major test construction problems. Next, the algorithms and heuristics to solve the problems are described. Finally, we discuss the topic further and gives some recommendations about use.

Constructing a Single Linear Test Form

The traditional format in both educational and psychological testing is the linear test form. A linear test form is a paper-and-pencil (P&P) test that can be used for a population of candidates. To select a linear test form from an item pool, first the objective of the test has to be specified. Then, the test specifications have to be written as a set of constraints.

Objective Functions

How we specify the objective function in a test construction model depends on the goals or objectives of the test. Three examples of objective functions are given next.

A simple objective deals with the security of the item pool and the costs of testing. When more items are exposed to candidates, the item pool becomes known faster and the costs of maintaining the pool are higher. If the objective of the test is to maximize the security of the pool or to minimize costs of testing, a reasonable objective function is to minimize the number of items in a test. In this case, the objective function can be formulated as:

$$\min \sum_{i=1}^n x_i. \quad (6)$$

The objective of the test can also be chosen to depend on the decisions that have to be taken based on its scores. In criterion-referenced testing, a cut-off score θ^* is specified in advance. When the estimated ability $\hat{\theta}$ is larger than or equal to θ^* , the candidate passes, otherwise the candidate fails. For candidates who clearly pass or clearly fail, measurement precision need not be optimal. However, for candidates who are close to the cut-off score, measurement precision should be high. To construct a test that serves this purpose, the following objective function

can be used:

$$\max \sum_{i=1}^n I_i(\theta^*)x_i. \quad (7)$$

where $I_i(\theta^*)$ denotes the information item i provides for the cut-off score.

A third example is a broad ability test. The test should measure the abilities of a population of candidates, for example, diagnostic testing in school classes. Before the test is constructed, targets for the information in the test are defined. The objective of the test construction problem is to minimize the distance between the target information function and the test information function. A few points on the θ scale are chosen, and for these points the distance between the target and test function is minimized. This problem leads to the following objective function:

$$\min y \quad (8)$$

subject to:

$$\left| \sum_{i=1}^n I_i(\theta_k)x_i - T(\theta_k) \right| \leq y \quad \forall k, \quad (9)$$

where y is the maximum distance between the test information function and the target information function T for the k ability points. If no targets for the test information functions are defined a maximin approach can be applied:

$$\max y \quad (8')$$

subject to:

$$\sum_{i=1}^n I_i(\theta_k)x_i \geq y \quad \forall k, \quad (9')$$

In this approach the minimum value of the test information function over the k ability points is maximized.

These three objective functions are most commonly used in optimal test construction. The number of objective functions can easily be extended because almost every property of the test can be used to define an objective function. Also, in some optimal test construction problems, multiple objectives are necessary. Later, some other examples of objective functions are given, but first several possible constraints are introduced.

Constraints Based on Test Specifications

Test specifications can be categorized in several ways. Here they are categorized based on the properties of the test construction model. Three kinds of constraints are distinguished.

First, there are categorical constraints. Categorical item attributes partition the pool into a number of subsets.

Examples of categorical item attributes are item content, cognitive level, item format, author, and answer key. In a categorical constraint, the number of items in a category is specified:

$$\sum_{i \in V_c} x_i \leq n_c \quad c = 1, \dots, C \quad (10)$$

where V_c is the subset of items in category c , n_c is an upper bound to the number of items chosen from category c , and C denotes the number of categories.

Second, there are quantitative constraints. These constraints do not impose direct bounds on the numbers of items but instead on a function of the items. Examples of quantitative attributes are word count, exposure rates, expected response times, and also item parameters. To limit the expected response time for a test, the following constraint can be added:

$$\sum_{i=1}^n t_i x_i \leq T \quad (11)$$

The sum of the expected response times t_i , $i = 1, \dots, n$, is bounded from above by a time limit T . Quantitative constraints are usually indexed with the symbol q .

The third type of constraints deals with inter-item dependencies. They are also called logical constraints. If, for example, one item contains a clue to the solution to another, these items cannot be selected for the same test. Thus we use an exclusion constraint; if one item is chosen, the other one is excluded. An inclusion constraint deals with item sets; if one item in the set is chosen, all items in the set have to be chosen. These kinds of constraints can be formulated as:

$$x_i \leq y_l \quad \forall i \in V_l \quad (12)$$

$$\sum_{i \in V_l} x_i = n_l y_l \quad (13)$$

where V_l denotes a logical set l , and n_l defines the number of items to be chosen from the set. The variable y_l is equal to 1 if an item from the set is chosen. Equation (13) implies that if one item is chosen, all items will be chosen. For an exclusion constraint, $n_l = 1$; for an inclusion constraint, n_l is equal to the number of items to be chosen from the set.

General Model for Construction of Linear Test Forms

Now that the objective functions and constraints have been formulated, a general model for optimal test construction can be given. In this model, generic constraints will be used to denote the different kinds of constraints. For a typical high-stakes achievement test, such as the LSAT, GMAT, or TOEFL, the total number of

constraints easily runs into the hundreds. The general model can be formulated as:

$$\min y \quad (14a)$$

subject to:

$$\left| \sum_{i=1}^n I_i(\theta_k) x_i - T(\theta_k) \right| \leq y \quad \forall k, \quad (\text{target information}) \quad (14b)$$

$$\sum_{i \in V_c} x_i \leq n_c \quad c = 1, \dots, C \quad (\text{categorical constraints}) \quad (14c)$$

$$\sum_{i=1}^n f_q(x_i) \leq n_q \quad (\text{quantitative constraints}) \quad (14d)$$

$$\sum_{i \in V_l} x_i \leq n_l \quad (\text{logical constraints}) \quad (14e)$$

$$\sum_{i=1}^n x_i = n_t \quad (\text{total test length}) \quad (14f)$$

$$x_i \in \{0, 1\} \quad (\text{decision variables}) \quad (14g)$$

The constraint in Eq. (14g) guarantees that an item is either selected or not. In the remainder this entry, this model is used to formulate optimal test construction problems.

Weighted Deviations Model

In the general model, all test specifications are considered to be constraints that have to be met. For some test construction problems, the test specifications are considered to be desirable properties rather than constraints. As a result, they are allowed to be violated in the test construction process. When properties are considered to be desirable properties, a weighted deviation model can be formulated. In this model, targets are defined for all violations or deviations. This model can be formulated as:

$$\min \sum_j w_j d_j \quad (\text{minimize weighted deviation}) \quad (15a)$$

subject to:

$$\sum_{i \in V_c} x_i - n_c \leq d_1 \quad (\text{categorical constraints}) \quad (15b)$$

$$\sum_{i=1}^n f_d(x_i) - n_q \leq d_2 \quad (\text{quantitative constraints}) \quad (15c)$$

$$\left| \sum_{i \in V_l} x_i - n_l \right| = d_3 \quad (\text{logical constraints}) \quad (15d)$$

$$x_i \in \{0, 1\} \quad d_j \geq 0 \quad (\text{decision variables}) \quad (15e)$$

where the variables d_j denote the deviations of constraints j , $j = 1, \dots, J$, with J being the total number of

constraints, and w_j denotes the weight of deviation j . In this model, the difference between the target information function and the test information functions is formulated as a quantitative constraint. When some specifications are considered to be of paramount interest, their weights get high values. When other specifications are considered to be less important, the weights get low values. Because the specifications do not have to be met, the model is less restrictive. A less favorable feature of this model is that two different tests constructed by the same model might have different attributes.

Models for Construction of Other Testing Formats

In educational and psychological measurement, a wide variety of testing formats has been developed. Models for the majority of these formats can be formulated by slightly changing the general test construction model defined in the previous section. Next we present a number of testing formats and explain how they differ from the general test construction problem and how the model should be adapted to construct the desired test form.

Parallel Test Forms

In many applications, several linear test forms have to be constructed that meet the same set of specifications. Several versions of the same test might be needed for security reasons or so that the test can be offered to candidates on different occasions. When tests meet the same set of specifications, they are considered to be parallel. Several definitions of parallel tests are given in the literature, but the concept of weakly parallel tests is often applied. This means that the same set of constraints is met by the tests and the test information functions are identical. If a model is developed for constructing parallel tests, a few changes have to be made to the general model stated in Eqs. (14). First, the decision variables have to change. Whereas in the general model variable x_i indicates whether an item is selected for the test, for parallel tests an additional index j is needed to determine for which test the item is selected, where j runs from 1 to the number of parallel tests that have to be constructed. The new decision variables x_{ij} are defined as:

$$\begin{cases} x_{ij} = 1 & \text{item } i \text{ is selected for test } j, \\ x_{ij} = 0 & \text{otherwise.} \end{cases} \quad (16)$$

The same sets of constraints should hold for all parallel tests. However, the objective function has to change slightly. For all parallel tests, the maximum difference between the target information function and the test

information function should be minimized. It might also happen that no targets for the information functions have been defined. In that case, the maximum difference between the test information functions of the parallel test can be minimized.

Tests with Item Sets

Some items in the pool may be grouped around a common stimulus. The stimulus can be a text passage, a table, a figure, or a video or music fragment (sometimes called vignettes). Whenever stimulus is selected for the test, all items, or at least a minimum number of items, that belong to the stimulus have to be selected. Several ways of dealing with these inclusion constraints have been presented. One of them has already been discussed in the section on constraints on inter-item dependencies. However, when test specifications at the stimulus level have also been met, this approach does not work.

An alternative approach is to introduce decision variable z_s , where

$$\begin{cases} z_s = 1 & \text{if stimulus } s \text{ is selected,} \\ z_s = 0 & \text{otherwise.} \end{cases} \quad (17)$$

Categorical, quantitative, and logical constraints can be formulated both at the stimulus and item levels. To make sure that the relation of inclusion between the stimulus and the items is also met, the following constraint can be added to the model:

$$\sum_{i \in V_s} x_i = n_s z_s \quad (18)$$

Whenever stimulus s is selected, this constraint guarantees that n_s items from V_s , the set of items that belong to the stimulus, are selected.

Classical Test Construction

Even though classical item parameters depend on the population and the other items in the test, in practice classical test theory is often applied to construct tests. When the assumption can be made that the population for the test does hardly change, test construction may be possible for classical test forms. In general, the objective function for these tests is to optimize reliability of the test. The reliability of the test is hard to estimate, but Cronbach's α defines a lower bound for it. The objective function for maximizing Cronbach's α can be defined for a fixed length test as:

$$\max \frac{n}{(n-1)} \left[1 - \frac{\sum_{i=1}^n \sigma_i^2}{(\sum_{i=1}^n \sigma_i \rho_{iX})^2} \right], \quad (19)$$

where σ_i^2 is the observed score variance, and ρ_{iX} is the item test correlation of item i . These parameters are

based on earlier administrations of the items. The expression for Cronbach's α is a nonlinear function of the decision variables. In order to formulate the test construction problem as a linear programming problem the following modification is often made. Instead of maximizing the expression in Eq. (19), the denominator of the last term is maximized and its numerator is bounded from above:

$$\max \sum_{i=1}^n \sigma_i \rho_{ix} \quad (20)$$

subject to:

$$\sum_{i=1}^n \sigma_i \leq c. \quad (21)$$

Tests Measuring Multiple Abilities

For certain types of items, several abilities are involved in answering the item correctly. When taking a driving test, the candidate has to both master the car and show insight about traffic. In some cases, all abilities are intentional, but in other cases, some of them are considered nuisances. When multiple abilities are involved, optimizing the information in the test is more complicated. Fisher's information measure takes the form of a matrix instead of a function. From optimum design theory, several criteria for optimizing matrices are known, but they all result in nonlinear and complicated objective functions. An alternative approach is to use Kullback-Leibler information instead of Fisher information. Kullback-Leibler information is a linear expression in the decision variables even in the case of multiple abilities. The resulting test constructing model can be written as:

$$\max \sum_{i=1}^n \text{KL}_i(\theta) x_i, \quad (22)$$

where $\text{KL}_i(\theta)$ denotes the amount of Kullback-Leibler information of the item, and θ is a vector instead of a scalar.

Tests with Equated Observed-Score Distributions

In many large-scale test programs, observed scores are presented to the candidates. Expensive equating studies have to be carried out to make the observed scores of different test forms comparable. Adding constraints to the optimal test construction model that will guarantee equal observed-score distributions will decrease the costs of testing. It can be proven that the conditional distributions of observed scores given θ for two test forms

are identical if:

$$\sum_{i=1}^n P_i^r(\theta) = \sum_{j=1}^n P_j^r(\theta) \quad r = 1, \dots, n \quad (23)$$

where $P_i^r(\theta)$ is the r th power of $P_i(\theta)$. In practice, the impact of high powers of $P_i(\theta)$ vanishes quickly. To construct tests with equated observed scores, the constraints in Eq. (23) should be added for several values of θ .

Computerized Adaptive Testing

Computerized adaptive testing (CAT) can be compared to an oral exam. Instead of a teacher, in CAT a computer algorithm adapts the difficulty of the items to the answers of the candidate. After an item has been administered, the ability level of the candidate is estimated. Based on this estimate, the item that provides most information at the examinee's estimated ability level is selected to be presented next. Compared to P&P tests, CAT reduces the test length by almost 40%. An important dilemma in CAT is that optimal CAT construction requires sequential item selection to maximize the adaptivity of the test but simultaneous test construction to realize all the test specifications. In order to deal with this dilemma, the shadow test approach was developed.

The main idea in this approach is that, to maximize adaptivity, a shadow test is constructed in every iteration. This shadow test contains all previously administered items and meets the test specifications. From the unadministered items in this shadow test, the next item is then selected. Because of this, the complete CAT will also meet the test specifications.

For constructing the shadow test, the objective function is to maximize the information at the current ability estimate. This objective function can be compared with the objective function in Eq. (7). The difference is that the estimated ability is used instead of the cut-off score. The constraints are formulated by the test specifications. However, an additional constraint is needed to guarantee that all the items that are administered are contained in the test. For selecting the k th shadow test, the following constraint is added:

$$\sum_{i \in S_{k-1}} x_i = k - 1 \quad (24)$$

where the set S_{k-1} is the set of items that have been administered in the $k-1$ previous iterations.

Multistage Testing

A multistage test form consists of a network of item sets. The item sets are also called testlets. The path of a candidate through this network of testlets depends on

Figure 1 Multistage testing format.

the answers. So, after a testlet is finished, the next testlet is selected adaptively. An example of a network for a multistage test form is shown in Fig. 1. In the first two stages, all candidates answer the same items. At the third stage, the candidates are assigned to either the low-difficulty or high-difficulty testlet. From the fourth to the last stage, based on an estimate of their ability, the candidates are then assigned to the high-, medium-, or low difficulty testlet. The path through the network is chosen to maximize the information in the test as well as to meet the test specifications.

Constructing multistage tests is rather complicated. First, testlets have to be constructed from the item pool, and then they have to be assigned to slots in the network. A testlet can be viewed as a small linear test with its own target information function and a small set of constraints. Constructing one testlet is a straightforward application of the model in Eqs. (14). However, to assemble a multistage test, many testlets have to be constructed. Sequentially solving the model in Eq. (13) would result in high-quality testlets in the beginning and low-quality testlets at the end of the construction process because high-quality items would be selected first. For simultaneous selection, decision variables x_{ij} have to be introduced, which are defined as:

$$\begin{cases} x_{ij} = 1 & \text{item } j \text{ is selected for testlet } i \\ x_{ij} = 0 & \text{otherwise} \end{cases} \quad (25)$$

In addition, Eq. (14b) should be slightly changed because different target information functions are defined for different testlets. The large number of decision variables in this test construction problem makes it very hard to solve.

Algorithms and Heuristics for Solving Optimal Test Construction Problems

In the previous section, models for optimal test construction have been described. An important question is: How

do we solve the models? That is, how do we construct optimal tests? Several algorithms and heuristics have been proposed. In this section, 0-1 linear programming techniques, network-flow programming, and a number of heuristics are discussed.

0-1 Linear Programming Techniques

When a problem is formulated in mathematical programming terms, many algorithms are available for solving the model. For example, linear programming, 0-1 linear programming, quadratic programming, and interior point methods can be applied. Which algorithms perform best depends on the kind of decision variables and on the formulation of the constraints. In optimal test construction, the decision variables are 0-1 variables. For the general formulation of a test construction problem in Eqs. (14), all constraints consist of the sums of decision variables. Because the general test construction model only consists of linear constraints, 0-1 linear programming techniques can be applied. 0-1 linear programming problems are known to be non-polynomial (NP)-hard, which means that it is not guaranteed that the optimal solution can be found in polynomial time. However, this is only the worst-case performance.

To find optimal values for the decision variables, standard 0-1 linear programming software such as CPLEX can be used. CPLEX employs an efficient implementation of the branch-and-bound (B&B) algorithm. For most test construction problems, a solution can be found in a reasonable amount of time. Only such problems as multiple-stage testing problems are too time-consuming.

Some models described in the previous section have nonlinear objective functions or constraints. These have to be linearized before the 0-1 linear programming techniques can be applied.

Network-Flow Programming

For some special test construction problems a much faster 0-1 linear programming algorithm is available, the network-flow programming algorithm. In order to apply this algorithm, the model is allowed to have only categorical constraints. When this algorithm is applied, even large test construction problems with thousands of variables can be solved quickly.

Unfortunately, most optimal test construction problems also have to deal with quantitative constraints. To embed these constraints into a network-flow programming algorithm, they are added to the objective function as penalty terms times a Lagrangian multiplier. For example, if a time limit of 30 minutes is to be imposed on a test, the following term is added to the objective function:

$$\lambda \left(30 - \sum_{i=1}^n t_i x_i \right) \quad (27)$$

The remaining problem is to find appropriate values for the Lagrangian multipliers λ . These values are usually found iteratively. Even when this iterative process is needed to find the solution of the test construction problem, the algorithm is fast, but the solution might accidentally suffer from a constraint violation.

Logical constraints might also be part of the optimal test construction problem. Some of them can be incorporated in the same way as the quantitative constraints. When it is not possible to use Lagrangian multipliers, a heuristic is needed to calculate a solution under these constraints.

Heuristics

For some optimal test construction problems, 0-1 linear programming techniques cannot be applied because of the nonlinearity of the objective function or the constraints or because the techniques may need too much time. In addition, it might not be possible to formulate the problem as a network-flow model. In those cases, heuristical methods can be applied to find a solution. An heuristic is an approximation method that works fast but that tends to result in a good solution rather than in the optimal solution. In optimal test construction, the greedy algorithm, simulated annealing, and genetic algorithms have been applied successfully.

Greedy algorithms work very fast. They select items sequentially. At every iteration, the item is selected that contributes most to the objective function. The normalized weighted absolute deviation heuristic (NWADH) is a well-known application of a greedy heuristic. It has also been applied very successfully in combination with the weighted deviations model in Eqs. (15). However, because these heuristics operate sequentially, the greedy algorithm might run into infeasibility problems at the end of the test, when violations of constraints are not allowed.

Simulated annealing is a much more time-consuming method. First, an initial test is constructed that meets all the specifications. Then, one item is swapped with an item in the pool. If the new test performs better with respect to the objective function, it is accepted; otherwise it is accepted with a probability that decreases during the test assembly process. The method stops when the probability of accepting a worse test is smaller than a lower bound.

When genetic algorithms are applied, several tests are constructed that meet all the specifications. New tests are constructed by selecting one part from one test and another part from a second test. If the new test performs better with respect to the objective function, it is added to the set of candidate tests. At the end, the best candidate in the set is selected.

Infeasibility Analysis

Sometimes, 0-1 linear programming techniques, network-flow programming, and heuristical methods might not

be able to construct a test from the item pool that meets all the test specifications. When this occurs, the model is said to be infeasible. The reason might be that there is a logical contradiction between some of the specifications, a writing error may have occurred in the modeling process, or the item pool may be poor. The exact cause of infeasibility is often very hard to detect. A typical test construction model might consist of thousands of variables and hundreds of constraints.

Several methods have been developed to diagnose infeasibility. Because infeasibility is always caused by the specifications in combination with the item pool, the focus of the methods is on the interaction of individual specifications as well as on the interaction of specifications and the item pool. The main idea in most methods is to isolate a small group of specifications that have to be modified in order to construct a test from the pool. A closer investigation of such a group of specifications has to reveal the exact reasons of infeasibility.

Conclusion and Discussion

The main issue in optimal test construction is how to formulate a test assembly model. Models for a number of optimal test construction problems have been introduced. However, all these models are based on the general test construction model in Eqs. (14). They may need a different objective function, some additional constraints, or different definitions of the decision variables, but the structure of the model remains the same. When different optimal test construction problems have to be solved, the question is not how to find a new method but how to define an appropriate objective function and a set of constraints.

The weighted deviations model is an alternative to the linear programming model. All the models presented in the third section could also be written as weighted deviation models. Whether linear programming models or weighted deviation models should be applied depends on the nature of the specifications. When the specifications have to be met, linear programming models are more suitable, but when the specifications are less strict, the weighted deviations model can be used. In practical testing situations, it may even happen that a combination of the two models can be applied if only some of the specifications have to be met. The same algorithms and heuristics can solve both the linear programming models and the weighted deviation models.

Finally, some remarks have to be made about the quality of optimal test construction methods. The models, algorithms, and heuristics presented here are very effective in constructing optimal tests. Additional gains are possible by improving the quality of the item pool. Some efforts have already been made to develop an

optimal blueprint for item pool design that would combine test specifications and optimal test construction methods to develop better item pools. This will further increase measurement precision.

Glossary

assumptions Mathematical conditions used in the derivation of an estimator that are critical for determining the statistical properties of the estimator.

dependent variable The outcome variable on the left-hand side of the equation, which is being explained as a linear function of the independent or explanatory variables.

efficient estimator An unbiased estimator whose sampling distribution has the smallest variance.

error term The population-level difference between an observed value of the dependent variable Y_i and the expected value of the statistical model $E(Y_i)$.

estimator A mathematical method or formula used to calculate a numerical estimate of a population parameter from sample data.

fitting criterion A numerical or scalar index used in the minimization phase of estimation that determines when the residuals of a model are as small as possible.

Gauss–Markov theorem A mathematical theorem that proves that the ordinary least squares (OLS) estimator is the best linear unbiased estimator (BLUE) when the assumptions of the OLS estimator are met.

homoskedasticity The condition whereby the variance of the error terms is constant over the entire range of values of the independent variables. Data with a nonconstant (e.g., increasing or decreasing) variance of the error terms are said to be heteroskedastic.

independent/explanatory variables The variables on the right-hand side of the equation, which are hypothesized to influence or predict the dependent variable.

population parameter A usually unknown characteristic of a population that is estimated using sample data.

residual The sample-based estimate of the true random error term.

serial correlation The amount of correlation between the error terms of any two given observations. Serial correlation is also often referred to as autocorrelation.

unbiased estimator An estimator whose expected value of its sampling distribution equals the true value of the population parameter.

Ordinary least squares (OLS) is a mathematical method often used to numerically estimate a linear relationship between a continuous dependent variable and one or more independent or explanatory variables using sample data. From a statistical point of view, an estimator is a mathematical method or formula used to produce a numerical estimate of an unknown population parameter based on the extractable information contained in a sample of data. The OLS estimator produces the best linear unbiased estimate of the relationship between each independent/explanatory variable (also known as a regressor or predictor) and a continuous dependent variable (also known as the regressand or response variable) while simultaneously eliminating the linear effects of the other included independent variables. The principle of OLS was first published by A. Legendre in 1805, and the theoretical presentation and derivation of its statistical properties was undertaken shortly thereafter by C. Gauss (who claimed to have already been using OLS years prior to Legendre's publication). Even today OLS remains a popular analytical tool in the analysis of social data. Yet, even though the OLS estimator has enjoyed long-standing popularity due to its relative simplicity, ease of computation, and statistical properties,

the resulting estimates can be justified only on the basis of whether the assumptions underlying the OLS estimator can be empirically or theoretically satisfied. Herein, we describe the OLS estimator, including its assumptions, its statistical properties, and the consequences of violating the assumptions on which this estimator is based. In an effort to emphasize the substantive principles behind the OLS estimator, we primarily use simple numerical or scalar algebra notation. But, where necessary and relevant, we employ matrix algebra.

Introduction

A common undertaking in the analysis of social science data is to employ the use of a mathematical model to represent a substantive or theoretical social process or issue. This often necessitates formulating a model in which one variable is hypothesized to depend on one or more independent variables. The purpose of this formulation usually is to estimate the effect of each independent variable on the dependent variable while simultaneously adjusting or controlling for the effects of the other relevant independent variables. To quantitatively describe the relationship between a continuous dependent variable, Y , and one or more independent variables, X_k , the population linear regression model is often specified as:

$$Y_i = \beta_0 + \beta_1 X_{i1} + \cdots + \beta_k X_{ik} + \varepsilon_i \quad (1)$$

where β_0 is a constant term (which, geometrically, represents the Y intercept), β_k is the regression parameter characterizing the linear relationship between the k th independent variable and Y , and ε_i is the error or disturbance term for the i th individual ($i = 1, \dots, n$, where n denotes the sample size). Corresponding to the population linear regression model in Eq. (1) is the sample linear regression model:

$$Y_i = b_0 + b_1 X_{i1} + \cdots + b_k X_{ik} + e_i \quad (2)$$

where b_0 and b_k indicate sample estimates of the unknown population parameters β_0 and β_k , and e_i denotes the error of estimation or residual for the i th observation (corresponding to ε_i). The b_k regression coefficients of this linear function represent the expected change in the continuous dependent variable associated with a one-unit change in the k th independent variable while holding constant the effect of all other independent variables included in the model specification.

From a statistical perspective, the goal is to estimate the population parameter using values that best describe the linear relationship between each of the k regressor variables and the Y regressand variable. This entails generating estimates of the dependent variable, denoted \hat{Y} ,

that best predict the observed values of the dependent variable. Equation (2) can be rewritten as:

$$e_i = Y_i - (b_0 + b_1 X_{i1} + \cdots + b_k X_{ik}) = Y_i - \hat{Y}_i \quad (3)$$

to highlight that the difference between the observed value (Y) and the model's predicted value (\hat{Y}) is reflected in the value of the residual term, e_i . Substantively, the residual terms are best thought of as the representation of both the combined effects of all variables not included in the model as specified and any remaining random elements or noise (e.g., measurement error) in the dependent variable. Mathematically, the residuals represent the amount by which an observed value deviates from the predicted conditional mean value (conditional on the values of the regressors). Important for our discussion is that the residuals are estimates of how accurately the model predicts the dependent variable; the smaller the residuals, the better the model fits the observed data, and vice versa. The statistical estimation problem, then, is one of determining how to generate estimates of the population parameters such that the residuals are as small as possible. This is accomplished by using an appropriate fitting criterion that uniquely and objectively determines when such a condition is satisfied.

The linear regression model in Eq. (2) involves fitting a regression surface to the sampled data. In the case of the simple regression model [a regression model involving one regressor or where $k = 1$ in Eq. (1)], we can graphically show the linear dependence of Y on X by fitting a straight line to the scatter plot of the data. Consider Fig. 1, which is a scatter plot of the variables labeled X and Y . Each circle on the graph represents a particular (X_i, Y_i) pair ($n = 8$). The figure also exhibits three lines that have been fitted to these data: a horizontal line equal to the mean of the dependent variable (line A in Fig. 1), a line representing a reasonable eyeball guess at the best-fitting line that was generated by making the line dissect the data points exactly in half (line B), and the OLS regression line itself. The vertical distance between any of the lines and the observed value is each case's residual for that particular line.

As is evident in Fig. 1, a different set of regression coefficients (b_0 and b_1) creates a different estimated line and, therefore, a different set of residuals. Given that each line produces a different set of residuals, there is an important need for a fitting criterion that both selects one particular set of estimates over all other sets of estimates and also can be used when the regression surface is multidimensional. That is, we need a criterion that can be used to determine estimates of the population parameters that best describe the linear relationship between the X_k values and Y for the given sample data. Figure 1 shows that each line fits some observations better than others, which indicates

Figure 1 Three lines fitted to eight data points.

that the fitting criterion must simultaneously take into account all the residuals for the sampled data as a whole. In other words, we need to mathematically accumulate the residuals into an overall numerical or scalar index that can be objectively used to generate the best estimates of the population parameters. In the next section we discuss the nature of the fitting criterion used in ordinary least squares (OLS).

Fitting Criterion

In selecting the set of estimates that makes the errors as small as possible, we consider three possible fitting criteria that appear to be useful for this purpose. One possible criterion is the sum of deviations of the observed and predicted Y values, or $\sum_{i=1}^n (Y_i - \hat{Y}_i)$. This criterion method, however, is problematic for several reasons. First, there is no unique solution for this fitting criterion. For example, one way to minimize this sum (to 0) is to simply set the b_0 parameter equal to the mean of the dependent variable and set each of the b_k parameters equal to zero. However, any line that passes through both the mean of X and the mean of Y will generate a sum of the residuals that is equal to 0; this is true regardless of the direction of the line. In Fig. 1, all three lines pass through the means of both X and Y and, as a result, the sum of the residuals from all three lines sum to 0. Second, the residual term for any given individual may be quite large (e.g., large positive and negative residuals can cancel one another), and thus the fit of any model satisfying this criterion may be incredibly poor. This fitting criterion clearly is not suitable.

A second fitting criterion that might be advocated is to minimize the sum of the absolute value of the deviations,

or $\sum_{i=1}^n |Y_i - \hat{Y}_i|$. Applying the absolute value function avoids the potential problem of large positive and negative residuals canceling one another because all residuals enter this sum as positive values. However, this method does not differentially weight observations on the basis of the size of the residual, and thus large residuals are equal in weight to small residuals. Further, from a computational perspective, this fitting criterion is quite algebraically intractable (due to its nonlinearities) and requires the use of an iterative numerical optimization algorithm.

A final fitting criterion considered here is the sum of squared errors (SSE):

$$\begin{aligned} \text{SSE} &= \sum_{i=1}^n e_i^2 = \sum_{i=1}^n (Y_i - b_0 - b_1X_{i1} - b_2X_{i2} - \cdots - b_kX_{ik})^2 \\ &= \sum_{i=1}^n (Y_i - \hat{Y}_i)^2 \end{aligned} \quad (4)$$

By squaring the deviations of \hat{Y} from Y , this fitting criterion simultaneously satisfies both the need for positive values of the residuals and the differential weighting of residuals (i.e., the squaring makes all values positive and weights larger residuals more heavily). Given that it is desirable to avoid larger residuals, this fitting criterion accords more weight to larger residuals than smaller residuals in order to shift the regression surface toward the cases with larger residuals in an effort to reduce the size of their residuals. Computationally, the SSE can be minimized using a simple algebraic equation.

The estimator that minimizes the sum of squared errors in Eq. (4) is the OLS estimator. The statement that the OLS estimator minimizes the SSE implies that no other linear estimator will produce a smaller SSE than

the OLS estimator. Consider Fig. 1 again. As shown in the table in the lower part of the figure, all three lines produce prediction errors that sum to 0. The OLS line, however, produces a sum of squared errors that is the lowest of all three lines. For these data, there is no other linear estimator that will produce a SSE value less than 549.0.

The data used in Fig. 1 were specifically generated to emphasize two important points regarding the OLS estimator. First, the fundamental principle behind the OLS estimator is that it uniquely minimizes the sum of the squared residuals. Second, as a consequence of minimizing the sum of squared errors, the OLS regression surface is pulled toward cases farther from the means of the independent and dependent variables. For example, notice that in Fig. 1 the regression line is pulled in the direction of the two cases farthest from the means of both X and Y , and that in fact the OLS regression line nearly passes right through those two data points. Observations that markedly deviate from the typical pattern of the variables are sometimes referred to as extreme cases or outliers. Extreme cases can have a large disproportionate influence on the regression estimates, and thus the results of any OLS estimation should always be checked to ensure that no sample member (or subsets of sample members) exerts significant influence on the values of the parameters.

The Ordinary Least Squares Estimator

Having chosen a fitting criterion, the statistical estimation problem is to find the sample estimates of model parameters that minimize the sum of squared errors. This can be accomplished using differential calculus because Eq. (4) is a quadratic equation and quadratic equations attain a minimum when the first derivative equals 0. Thus, we can find the OLS estimator by taking the partial derivative of the SSE with respect to each of the regression coefficients:

$$\frac{\partial \text{SSE}}{\partial b_0} = 2 \cdot \sum_{i=1}^n (Y_i - b_0 - b_1 X_{i1} - b_2 X_{i2} - \cdots - b_k X_{ik}) \cdot (-1) \quad (5)$$

$$\frac{\partial \text{SSE}}{\partial b_1} = 2 \cdot \sum_{i=1}^n (Y_i - b_0 - b_1 X_{i1} - b_2 X_{i2} - \cdots - b_k X_{ik}) \cdot (-X_{i1}) \quad (6)$$

$$\vdots$$

$$\frac{\partial \text{SSE}}{\partial b_k} = 2 \cdot \sum_{i=1}^n (Y_i - b_0 - b_1 X_{i1} - b_2 X_{i2} - \cdots - b_k X_{ik}) \cdot (-X_{ik}) \quad (7)$$

Setting Eqs. (5)–(7) equal to zero and then multiplying and summing through each of the $k+1$ expressions results in the system of linear equations known as the normal equations:

$$\sum_{i=1}^n Y_i = \sum_{i=1}^n b_0 + b_1 \sum_{i=1}^n X_{i1} + \cdots + b_k \sum_{i=1}^n X_{ik} \quad (8)$$

$$\sum_{i=1}^n Y_i X_{i1} = b_0 \sum_{i=1}^n X_{i1} + b_1 \sum_{i=1}^n X_{i1} X_{i1} + \cdots + b_k \sum_{i=1}^n X_{ik} X_{i1} \quad (9)$$

\vdots

$$\sum_{i=1}^n Y_i X_{ik} = b_0 \sum_{i=1}^n X_{ik} + b_1 \sum_{i=1}^n X_{i1} X_{ik} + \cdots + b_k \sum_{i=1}^n X_{ik} X_{ik} \quad (10)$$

Before proceeding, note that these equations can be reexpressed as:

$$\sum_{i=1}^n e_i = 0 \quad (11)$$

$$\sum_{i=1}^n e_i X_{i1} = 0 \quad (12)$$

\vdots

$$\sum_{i=1}^n e_i X_{ik} = 0 \quad (13)$$

which highlights that the OLS estimator forces *both* the sum of the residuals to equal zero and the covariance between each of the independent variables and the residuals to be zero.

Given that $\sum_{i=1}^n b_0 = n \cdot b_0$, solving Eq. (8) yields:

$$b_0 = \bar{Y} - b_1 \bar{X}_1 - \cdots - b_k \bar{X}_k \quad (14)$$

The solution in Eq. (14) can then be substituted into the remaining k normal equations, which themselves can then be simultaneously solved. Consider, for example, a regression model that contains two independent variables ($k=2$). For this model, the normal equations for the independent variables X_1 and X_2 , after substituting Eq. (14) for the constant, simplify to:

$$\begin{aligned} \sum_{i=1}^n (Y_i - \bar{Y}) \cdot X_{i1} - b_1 \sum_{i=1}^n (X_{i1} - \bar{X}_1) \cdot X_{i1} \\ - b_2 \sum_{i=1}^n (X_{i2} - \bar{X}_2) \cdot X_{i1} = 0 \end{aligned} \quad (15)$$

$$\begin{aligned} \sum_{i=1}^n (Y_i - \bar{Y}) \cdot X_{i2} - b_1 \sum_{i=1}^n (X_{i1} - \bar{X}_1) \cdot X_{i2} - b_2 \\ \times \sum_{i=1}^n (X_{i2} - \bar{X}_2) \cdot X_{i2} = 0 \end{aligned} \quad (16)$$

Equations (15) and (16) can be rewritten as:

$$\sum_{i=1}^n y_i x_{i1} - b_1 \sum_{i=1}^n x_{i1}^2 - b_2 \sum_{i=1}^n x_{i2} x_{i1} = 0 \quad (17)$$

$$\sum_{i=1}^n y_i x_{i2} - b_1 \sum_{i=1}^n x_{i1} x_{i2} - b_2 \sum_{i=1}^n x_{i2}^2 = 0 \quad (18)$$

where $x_{ik} = (X_{ik} - \bar{X}_k)$ and $y_i = (Y_i - \bar{Y})$. Simultaneously solving Eqs. (17) and (18) yields the solutions for the regression slopes for X_1 and X_2 :

$$b_1 = \frac{\sum_{i=1}^n x_{i2}^2 \sum_{i=1}^n x_{i1} y_i - \sum_{i=1}^n x_{i1} x_{i2} \sum_{i=1}^n x_{i2} y_i}{\sum_{i=1}^n x_{i1}^2 \sum_{i=1}^n x_{i2}^2 - \left(\sum_{i=1}^n x_{i1} x_{i2} \right)^2} \quad (19)$$

$$b_2 = \frac{\sum_{i=1}^n x_{i1}^2 \sum_{i=1}^n x_{i2} y_i - \sum_{i=1}^n x_{i1} x_{i2} \sum_{i=1}^n x_{i1} y_i}{\sum_{i=1}^n x_{i1}^2 \sum_{i=1}^n x_{i2}^2 - \left(\sum_{i=1}^n x_{i1} x_{i2} \right)^2} \quad (20)$$

In the case of the simple regression model ($k=1$), the regression slope coefficient for each of the independent variables is found by dropping the terms in Eqs. (19) and (20) that involve the other independent variables, or more specifically:

$$b_1 = \frac{\sum_{i=1}^n x_{i1} y_i}{\sum_{i=1}^n x_{i1}^2} \quad (21)$$

With each additional independent variable, the OLS solutions for the regression coefficients become increasingly more difficult to derive algebraically due to the rapidly increasing number of terms involved. For example, compare Eq. (21) to Eq. (19).

The OLS estimator, however, can be compactly and conveniently described using matrix algebra, and the OLS solution in matrix terms can be applied regardless of the number of independent variables included in the specification. In matrix notation, Eq. (2) can be written as:

$$\mathbf{Y} = \mathbf{X}\mathbf{b} + \mathbf{e} \quad (22)$$

where

$$\begin{aligned} \mathbf{Y}_{n \times 1} &= \begin{bmatrix} Y_1 \\ Y_2 \\ \vdots \\ Y_n \end{bmatrix}, \quad \mathbf{X}_{n \times p} = \begin{bmatrix} 1 & X_{11} & \cdots & X_{1k} \\ 1 & X_{21} & \cdots & X_{2k} \\ \vdots & \vdots & & \vdots \\ 1 & X_{n1} & \cdots & X_{nk} \end{bmatrix}, \\ \mathbf{b}_{p \times 1} &= \begin{bmatrix} b_0 \\ b_1 \\ \vdots \\ b_k \end{bmatrix}, \quad \mathbf{e}_{n \times 1} = \begin{bmatrix} e_1 \\ e_2 \\ \vdots \\ e_n \end{bmatrix} \end{aligned}$$

and $p = k + 1$. The column of 1s in the \mathbf{X} matrix is required for the constant term b_0 . In matrix terms, the normal equations are expressed as:

$$(\mathbf{X}'\mathbf{X})\mathbf{b} = \mathbf{X}'\mathbf{Y} \quad (23)$$

Solving Eq. (23) yields the general matrix solution for the OLS estimator:

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{Y} \quad (24)$$

where $(\mathbf{X}'\mathbf{X})^{-1}$ denotes the inverse matrix of $\mathbf{X}'\mathbf{X}$.

Assumptions of Ordinary Least Squares

In statistics, precise mathematical conditions are required for the derivation of statistical estimators. These mathematical conditions are referred to as the assumptions of an estimator and are critical for determining the statistical properties of a given estimator. The OLS estimator in Eq. (24) is derived under five assumptions. It should be noted that these assumptions are distinct from the conditions necessary for model identification, which include (1) that there be at least p ($= k + 1$) observations in the sample ($n \geq p$) and (2) that none of the independent variables is an exact linear combination of the other independent variables. These conditions are required for the computation of unique OLS estimates because they ensure the \mathbf{X} matrix is of full rank, a necessary condition for inverting the $\mathbf{X}'\mathbf{X}$ component of Eq. (24).

If the following five mathematical assumptions about the process through which the data were generated can be satisfied, then the OLS estimator will have several desirable statistical properties.

Assumption 1. The model is specified correctly, which implies that Eq. (2),

$$Y_i = b_0 + b_1 X_{i1} + \cdots + b_k X_{ik} + e_i$$

is the correct specification of the regression function such that on average, or by taking the expected value of the estimated regression equation, we obtain the corresponding population or model regression function:

$$\begin{aligned} E(Y_i) &= E(b_0 + b_1X_{i1} + \cdots + b_kX_{ik} + e_i) \\ &= E(b_0 + b_1X_{i1} + \cdots + b_kX_{ik}) + E(e_i) \\ &= \beta_0 + \beta_1X_{i1} + \cdots + \beta_kX_{ik} + 0 \\ &= \beta_0 + \beta_1X_{i1} + \cdots + \beta_kX_{ik} \end{aligned} \quad (25)$$

This assumption implies that there are no relevant independent variables omitted from the specification, that no irrelevant predictors are included, that the relationship between X_k and Y is linear in the parameters, and that the regression coefficients are additive in nature (e.g., the effects are not multiplicative).

Assumption 2. The conditional expected value of the error term is 0, or:

$$E(\varepsilon_i | X_{i1}, \dots, X_{ik}) = 0 \quad (26)$$

In other words, knowledge of X_k provides no information about the error term.

Assumption 3. The independent variables are uncorrelated with the error term:

$$\text{cov}(\varepsilon_i, X_{ik}) = 0 \quad (27)$$

The importance of this assumption is that if they are correlated, it is impossible to separate the true effect of X_k on Y from the effect of ε on Y . In other words, this assumption is necessary in order to identify the $k + 1$ unknowns in the \mathbf{b} vector.

Assumption 4. The errors have constant variance:

$$\text{var}(\varepsilon_i | X_{i1}, \dots, X_{ik}) = \sigma^2 \quad (28)$$

This assumption is often referred to as the assumption of homoskedasticity and implies that the errors of the predictions or are no more or less variable for some observations than others.

Assumption 5. For any two observations i and j , their corresponding error terms are uncorrelated (i.e., there is no serial correlation among the errors):

$$\text{cov}(\varepsilon_i | X_{i1}, \dots, X_{ik}, \varepsilon_j | X_{j1}, \dots, X_{jk}) = 0 \quad (29)$$

Assumptions 4 and 5, Eqs. (28) and (29), taken together are often referred to as the assumption of spherical errors or the assumption that the errors are independently and identically distributed (i.i.d.). These two assumptions

imply that the variance–covariance matrix of the error terms can be described as:

$$\begin{bmatrix} \sigma^2 & 0 & \cdots & 0 \\ 0 & \sigma^2 & \cdots & 0 \\ & & \ddots & \\ 0 & 0 & \cdots & \sigma^2 \end{bmatrix} = \sigma^2 \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & 1 & \cdots & 0 \\ & & \ddots & \\ 0 & 0 & \cdots & 1 \end{bmatrix} = \sigma^2 \mathbf{I} \quad (30)$$

where \mathbf{I} is an $n \times n$ identity matrix with 1s on the diagonal and 0s in the off-diagonals.

The Gauss–Markov Theorem

In statistics, estimators are usually adopted because of their statistical properties, most notably unbiasedness and efficiency. The statistical property of unbiasedness refers to whether the expected value of the sampling distribution of an estimator is equal to the unknown true value of the population parameter. For example, the OLS estimator b_k is unbiased if the mean of the sampling distribution of b_k is equal to β_k . That is, if we repeatedly sampled the population by taking samples of some finite size n , calculated b_k for each sample, and then calculated the mean of the b_k estimates, the mean would be equal to the population parameter i.e., $E(b_k) = \beta_k$.

However, simply knowing that an estimator is unbiased *on average* is not very advantageous if the values of b vary greatly from sample to sample. That is, estimators are adopted not only based on whether they are unbiased, but also based on whether the estimates vary widely from sample to sample. In statistical terminology, an unbiased estimator is maximally efficient when the variance of its sampling distribution is smaller than the variances of the sampling distributions of all other unbiased estimators. For example, consider Fig. 2, which is a graph of the sampling distribution of the two unbiased estimators,

Figure 2 Sampling distributions of two unbiased estimators.

b_1 and b_2 (i.e., the mean of each distribution is equal to the true population parameter β). The variance of the estimator b_1 is much greater than the variance of the estimator b_2 . In other words, b_2 is a more efficient estimator than b_1 . If either of these distributions were biased, the mean of the distribution would not be equal to the true population parameter value.

The linear estimator with the smallest variance (or highest precision) is said to be the best linear estimator. Under the conditions specified in Eqs. (25)–(29), the OLS estimator is the best linear unbiased estimator (BLUE). This means that among all unbiased linear estimators, the OLS estimator has the smallest variance. This theorem (that the OLS estimator is BLUE) is commonly referred to as the Gauss–Markov theorem after mathematicians C. Gauss and A. Markov. The BLUE property is arguably one of the main reasons why the OLS estimator has been a mainstay of statistical analysis since its derivation, but it is important to emphasize both that the Gauss–Markov theorem applies to the OLS estimator rather than a particular estimate from a given sample and that it is possible that there exists a *biased* estimator that has a sampling distribution with a smaller variance.

By now, some readers are probably wondering why we have not discussed any assumption regarding a particular statistical distribution for the error terms. The reason we have not discussed this issue is that the OLS estimator is BLUE without specifying a particular statistical distribution for the error terms. However, if the error terms can be assumed to be normally distributed, then the OLS estimator becomes the best unbiased estimator. This means that the OLS estimator is the estimator with the smallest variance among *all* unbiased estimators, not just among the linear unbiased estimators. It also can be shown that, under the assumption of normally distributed errors, the OLS estimator is the maximum likelihood estimator (MLE) of β . Thus, minimizing the sum of squared errors is identical to maximizing the likelihood function, or $b_{OLS} = b_{MLE}$. This congruence between the least squares approach and the maximum likelihood approach is another compelling theoretical justification of the OLS estimator. A final crucial item to note about the assumption of normality of the errors is that this assumption also provides the theoretical justification for statistical inference regarding the regression coefficients.

Consequences of Violating the Assumptions of Ordinary Least Squares

We now briefly discuss the consequences of violating the assumptions of the OLS estimator; a complete discussion of these consequences is beyond the scope of this entry.

The first three OLS assumptions are fundamentally critical for proving the unbiasedness of the OLS estimator. These assumptions can be violated in a number of ways, including via nonlinearity in the relationship between the independent and dependent variables, via measurement error in the independent variables, via simultaneity or joint dependence between the independent and dependent variables (e.g., Y is a cause of X), or via the model specification's excluding a relevant independent variable that is correlated with both the included independent variables and the dependent variable. If any of these three assumptions is violated, the OLS estimator will be biased. Although violations of either assumptions 4 or 5 will not bias the OLS estimator, the violation of either of these two assumptions will cause the OLS estimator to be inefficient (i.e., no longer the best estimator). Further, violations of assumptions 4 and 5 also will bias the estimator of the variance–covariance matrix of the OLS estimator (which will bias the standard errors of the OLS estimates). Thus, the conventional t tests and F tests used in statistical inference regarding the OLS estimates can no longer be trusted. The important point to remember about the assumptions is that, although OLS estimates can be computed regardless of whether the assumptions can be justified, the statistical properties of the Gauss–Markov theorem *require* that all these assumptions be met.

The violation of the assumptions of OLS is perhaps best viewed on a continuum from “very mild” to “very severe” rather than as a dichotomy of “yes” or “no.” In other words, sample data can rarely be assumed to perfectly satisfy all the assumptions, and thus there will usually be some degree of violation. The critical question of when the violation of an assumption can be considered severe enough to be detrimental to the conclusions has been an ongoing debate among statisticians for decades. This question concerns the robustness of the OLS estimator to violations of its assumptions. The OLS estimator has been argued to be quite robust to moderate violations of some of the assumptions (e.g., heteroskedasticity), and our point here is not to argue for absolute strict adherence to these assumptions in order to use the OLS estimator. Rather we wish to emphasize that the principle of least squares and the Gauss–Markov theorem should not be used as a blanket justification for the application of the OLS estimator without giving due consideration to the assumptions of the model. The user should think critically about the assumptions and be prepared to either empirically or theoretically justify the application of the OLS estimator.

Arguably, the detection of violated assumptions is as much art as science because determining the degree to which the assumptions are satisfied can be a difficult analytical task. For example, as a consequence of the normal equations, the second and third assumptions

are guaranteed to be true in the sampled data by the definition of the OLS estimator [see Eqs. (11) and (13)]. Whether these are true in the population from which a sample has been obtained is a much more difficult question that can only be adequately answered with substantive theory about the social issue under consideration. Nonetheless, the user should be aware of the possible consequences of violations of the assumptions on the conclusions of a study, and, if the violation(s) cannot be corrected, the user should make the reading audience keenly aware of the possible consequences.

If the violation of a particular assumption is detected (whether theoretically or empirically), some type of remedial action can usually be taken. Often, violations necessitate the use of a more advanced statistical estimator (e.g., generalized least squares, two-stage least squares), but occasionally a correction can be made to the data (e.g., using a transformation to induce linearity) or the estimator (e.g., applying a heteroskedastic consistent variance-covariance estimator). Recent advances in computing power and the incorporation of advanced statistical estimators in standard statistical software packages have made remedies for data not suitable for the method of OLS much more feasible.

Glossary

construct validity Empirical evidence that a measure is an acceptable indicator of a particular theoretical concept.

content validity The extent to which the items making up a measure are logical representations of the concepts being measured.

interrater agreement A quantitative indicator of the level of agreement among two or more informants concerning the same measurement.

item A question or a statement that describes a measurable aspect of the concept being measured.

key informant A person with knowledge about the nature of an organization or work group adequate to respond to items describing the collective unit.

latent variable A nonobservable characteristic of people, presumed to underlie observed variables.

multiple-item measure A composite measure, composed of the sum or average of responses to multiple statements or questions about various aspects of the concept being measured.

reliability The extent to which the items of a composite measure of a concept consistently capture various aspects of the concept.

Organizational behavior is the study of humans at work within organizations. It seeks to understand individual workers, work groups, and entire organizations. Measurement in organizational behavior often seeks to assess employee perceptions about work within an organization by quantitatively describing employee attitudes, beliefs, intentions, and behaviors. Organizational behavior is often concerned with which of the variables present within groups and/or organizations positively or negatively affect

the attitudes and behaviors of workers. Measurements in organizational behavior may also determine analytical and structural properties of groups or organizations. Global properties of groups or organizations are best detected through measurement of the characteristics of the collective units. However, in some cases, the viewpoints of individuals are aggregated to represent properties of groups and organizations.

Introduction

Organizational behavior research draws on multiple disciplines, including psychology, sociology, and anthropology, but predominantly examines workers within actual organizational settings, rather than in experimental or quasi-experimental settings. Organizational behavior researchers are primarily concerned with measuring the presence of employee motivation, job alienation, organizational commitment, or similar work-related variables in order to understand how these attributes explain employee work behaviors and how they are affected by other variables, such as working conditions, company policies, human resource programs, or pay plans.

Individuals regularly behave in various ways at work, and these behaviors are described in various ways: someone putting forth a great deal of effort might be described as “motivated”; a person who approaches his or her job in a resigned fashion, putting forth only the minimum effort required, might be described as “alienated”; an employee who stays late to help a customer might be described as “committed.” In each case, there are alternative possible explanations for the observed behaviors. Plausible

alternatives could be that the employee putting forth lots of effort has knowledge about a possible layoff, that the person putting forth the minimum required may be ill or preoccupied with family problems, and that the person staying late may be hoping to secure a job with the customer. Many of the variables of interest in organizational behavior reflect employee perceptions. In fact, many researchers consider the perceptions of organizational members to be the reality within work settings. Perceptions and other similar phenomena on which people may vary are not directly observable as attributes (such as hair color, height, and size), but are nonobservable aspects, or latent variables. Nonobservable variables are latent in that they are assumed to be underlying causes for observable behaviors and actions. Examples of individual latent variables include intelligence, creativity, job satisfaction, and, from the examples previously provided, motivation, job alienation, and organizational commitment. Not all latent variables studied in organizational behavior are individual in nature. Some latent variables apply to groups and organizations. These include variables reflecting aggregate characteristics of the group, such as intragroup communication, group cohesion, and group goal orientation. Furthermore, organizations may be globally described as centralized, flexible, or actively learning, also representing latent variables.

Although some theories in organizational behavior (OB) include manifest variables that are directly observable, such as age, gender, and race of workers or the age and location of a work facility, many OB theories are concerned with relationships among latent variables. For example, job satisfaction is a variable that has been studied extensively over the history of organizational behavior. In particular, researchers (and practitioners) are frequently concerned with which variables are related to higher levels of job satisfaction. Generally, an employee's perceptions of the nature his or her work (interesting, boring, repetitive, difficult, demanding, skill intensive, autonomous) greatly influence job satisfaction. These perceptions are all latent variables. Some researchers have measured these aspects of a worker's job using estimations by trained observers. The agreement between the observer estimations and the worker self-assessments of perceptions is often low, and the observations have a weaker relationship with job satisfaction. Thus, measurement in organizational behavior often deals with how to obtain the specific beliefs, attitudes, and behaviors of individuals that appropriately represent, or operationalize, a latent variable. An example of one way to measure a latent variable, intelligence, is to sum the scores of an individual on tests of verbal, numerical, and spatial abilities. The assumption is that the latent variable, intelligence, underlies a person's ability in these three areas. Thus, if a person has a high score across these three areas, that person is inferred to be intelligent.

A central issue in measurement in organizational behavior is which specific perceptions should be assembled to form adequate measures of latent variables such as job satisfaction and organizational commitment. Because satisfied and committed employees are valued, managers are very interested in what policies, jobs, or pay plans will help promote such states in workers. Researchers, in turn, want to be sure that the things they use to represent satisfaction and commitment are in fact good indicators of the unseen variables. Because latent variables such as satisfaction may be based on different aspects of a job or an organization, it is necessary for an indicator of job satisfaction to include all these aspects—as many as is necessary. The result is that indicators of job satisfaction and other latent variables important in organizational behavior are based on multiple items representing statements or questions addressing measurable aspects of the concept being measured.

Examples of Measures Used in Organizational Behavior

Table I presents examples of multiple item scales capturing various types of employee attitudes, beliefs, intentions, and behaviors that are widely used in measuring employee perceptions concerning organizational commitment, job satisfaction, organizational justice, job stress, and workplace behaviors. These particular measures have been used in multiple research studies that were published in the 1990s in 15 peer-reviewed organizational behavior research journals.

The measures illustrated in **Table I** describe employee perceptions that are frequently of interest in the field of organizational behavior. For example, organizational commitment has been defined as a strong belief in and acceptance of the organization's goals and values, willingness to exert considerable effort on behalf of the organization, and a strong desire to maintain membership in an organization. Other various definitions reflect three broad themes: (1) commitment reflecting an affective orientation toward the organization, (2) recognition of costs associated with leaving the organization, and (3) the moral obligation to remain with an organization. The concept of job satisfaction is defined as an employee's affective reactions to her or his job based on comparing actual outcomes with desired outcomes. Job satisfaction is generally recognized as a multifaceted construct covering both intrinsic and extrinsic job elements. Organizational justice is measured through a process by which employees judge fairness in the workplace by comparing the equity of their inputs and outcomes to the perceived inputs and outcomes of their co-workers. One aspect of organizational justice is the distributive justice, a summary

Table I Examples of Organizational Behavior Measures

<i>Concept</i>	<i>Measure</i>	<i>Number of items</i>	<i>Example items</i>	<i>Response scale</i>
Organizational commitment	Organizational Commitment Questionnaire (OCQ)	15	I am willing to put in a great deal of effort beyond that normally expected in order to help this organization be successful I find that my values and the organization's values are very similar	1, Strongly disagree; 2, moderately disagree; 3, slightly disagree; 4, neither disagree nor agree; 5, slightly agree; 6, moderately agree; 7, strongly agree
Job satisfaction	Minnesota Satisfaction Questionnaire	20 (short form)	The chance to do different things from time to time Being able to do things that don't go against my conscience The feeling of accomplishment I get from the job	1, Very dissatisfied with this aspect of my job; 2, dissatisfied with this aspect of my job; 3, can't decide if I am satisfied or not with this aspect of my job; 4, satisfied with this aspect of my job; 5, very satisfied with this aspect of my job
Organizational justice	Distributive and Procedural Justice	24 (11 for distributive justice and 13 for procedural justice)	I am told promptly when there is a change in policy, rules, or regulations that affect me (procedural) In general, disciplinary actions taken in this organization are fair and justified (procedural) Promotions or unscheduled pay increases here usually depend on how well a person performs on his or her job (distributive) My performance rating presents a fair and accurate picture of my actual job performance (distributive)	Responses are obtained using a five-point scale (1, strongly disagree to 5, strongly agree)
Job stress	Job-Related Tension Index	15	How frequently do you feel bothered by each of these? Feeling that you have too little authority to carry out the responsibilities assigned to you Being unclear on just what the scope and responsibilities of your job are Feeling that you have too heavy a work load, one that you can't possibly finish during an ordinary workday	1, Never; 2, rarely; 3, sometimes; 4, rather often; 5, nearly all the time
Workplace behaviors	Organizational Citizenship Behavior	24	Willingly helps others who have work-related problems Obeys company rules and regulations even when no one is watching Considers the impact of his or her actions on co-workers Attends meetings that are not mandatory, but are considered important	Responses are obtained using a seven-point Likert-type scale (1, strongly disagree to 7, strongly agree); the item wording provided is for supervisor or peer description of a focal employee, and can be modified for self-reporting

judgment about the fairness in distribution of pay, promotions, and other incentives. Another is procedural justice, focused on the process of how reward decisions are made.

Measures of job stress tend to recognize the fact that stress does not reside solely in the environment or solely in the individual, but is established when the interactions between the two are appraised as demanding enough to threaten personal well being. Employee workplace behavior can be generally characterized as either contributing to organizational goals or contributing to the employee's occupational control. A good deal of attention has been devoted to work behavior that is sometimes beyond the reach of traditional definitions of job performance, because these "organizational citizenship behaviors" may contribute to organizational innovation, flexibility, and responsiveness to changing external conditions.

An example of an organization level measure is a three-item measure of the tendency for an organization to be innovative. The items making up the measure were originally designed for a study of hospitals, but are presented here as general statements. The statements are formatted as follows: "(a) This [type of organization] is a little behind in utilizing the most adequate equipment and medicines. (b) This [type of organization] has not introduced any new methods and techniques. (c) This [type of organization] is very behind in the application of new administrative techniques." The responses from organizational members are collected using a five-point scale ranging from 1, strongly agree, to 5, strongly disagree. The use of this type of measure within an organization or group requires identification of an appropriate set of respondents who have been working in the organization long enough to have adequate information about innovative tendencies. These individuals are referred to as "key informants" about the organization. Once collected, the responses from these informants are evaluated in terms of the level of agreement. High levels of agreement and small variations in the responses to the three items would suggest that the measure provides a reliable assessment of the organization's innovativeness. Several different measures can be used to assess agreement among raters. These include the percentage of raters whose responses are the same value (using a Likert-type response with limited choices of responses), the average interitem correlation across raters and the intraclass correlation produced in the analysis of variance (ANOVA) procedure.

The measures described here are designed to be completed as part of a questionnaire or survey, or administered as part of an interview. Measures of this sort can be "closed end," whereby the respondent must choose one of several predefined response options. It is also possible to measure variables in organizational behavior using "open-ended" questions, whereby a respondent can compose an

answer using their own words. These types of measures are somewhat difficult to interpret and cannot be evaluated from a reliability point of view because each person's response may be unique.

Response Scales, Reliability, and Validity

The topic of reliability and validity of measures is mentioned here because it is a critical concern in organizational behavior, in part because many of the variables are perceptual in nature. It is important to remember that many organizational behavior measures ask employees to describe aspects of their job or work environment by choosing preselected responses to a series of questions or statements. These measures attempt to capture meaningful aspects of individual perceptions as well as an employee's evaluation of these perceptions. The use of multiple items to attempt to capture employee perceptions and related evaluations is tacit recognition of the difficulty of the task at hand. That is, if a large percentage of workers would all agree on the concept of organizational commitment, much as they would agree about the color red, then a single question or statement could measure commitment in nearly all situations. However, the reality is that organizational commitment is the result of an employee evaluating numerous aspects of the work situation. Attitudes such as commitment to an organization may have affective and cognitive aspects, thus comprehensive measures of commitment must attempt to capture multiple aspects of how employees feel about the organization and how they think about the organization.

Many alternative types of scales can be used to convert human perceptions to numbers based on the statements or questions used in organizational behavior measures. Choice of the type, nature, and anchor values in response scales can be a critical choice in measurements in organizational behavior. For example, to assess the extent to which a sample of students considered a robot to imitate a duck, a list of characteristics such as sound, appearance, walk, flight, and swim could be selected for obtaining assessments from the students. Ratings on each characteristic would be used to compute a score representing how well each student believes that the robot is like a duck. The ratings could be obtained via YES/NO responses, where each YES response is assigned the value 1 and each NO response is assigned the value 0. This approach, however, does not capture much of the variation in the ratings of each characteristic. That is, some students may have voted YES for some characteristics of the robot even if the resemblance to a duck were very limited. In other cases, characteristics may have received a YES vote because they were almost identical to those of a real duck. If

the overall score was intended to improve certain aspects of the robot, it would be more informative to know which duck-like characteristics scored high and which scored low. To get such ratings, the students could be asked to rate each characteristic of the robot as “not at all” like a duck, “somewhat” like a duck, “pretty much” like a duck, “a good deal” like a duck, and “very much” like a duck. The values 1 through 7 could then be assigned to these responses and to obtain considerably more information about how the respondents rated the extent to which each of the characteristics were characteristic of a duck.

After getting the responses to the items, a common approach in organizational behavior measurement would be to average the ratings across the characteristics and get a summary score that showed how well the robot approximates a duck overall. The latter approach, using a range of values to collect the ratings, is a commonly used method for obtaining responses from employees in measures of organizational behavior. These Likert-type response scales used in measures of latent variables in organizational behavior often provide respondents with five or seven alternative choices (see [Table I](#) for examples of Likert-type response scales frequently used).

Some variation in the extent to which different people see a collection of items as related is expected. However, if the variation is too great, confidence in the stability of the measurement is lessened. The consistency with which a group of statements of questions measure the same concept is referred to as the internal consistency reliability of a measure. There are two commonly used indicators of internal consistency reliability for items for which responses are obtained using a Likert-type scale. These are both readily calculated when using SPSS (Statistical Package for the Social Sciences) or other similar statistical software programs for analyzing organizational behavior data. The most commonly used indicator of internal reliability used for measures in organizational behavior is Chronbach's alpha. An alternative is the Spearman–Brown prophecy. Assessment of the internal consistency reliability is based on a single administration of that measure. Prior to using a measure for research or practice, it is generally wise to consult a reference to determine if the measure's internal consistency reliability has been assessed in multiple samples. It is also relevant to consider whether the responses to the items in a measure are consistent across time periods. This type of reliability, referred to as test–retest reliability, is assessed by examining the correlation of the responses to the items from the same sample of people obtained at two different times. The time between the two measurements should be long enough to limit the likelihood that people will remember their first response, but not so long that there have been substantial changes in jobs or business conditions that could cause legitimately different responses to the items.

The validity of a measure is concerned with the extent to which it actually gauges what it is thought to measure. In other words, validity shows the magnitude of the direct effect of the latent variable on its corresponding observed variables. For example, in the previous example of assessment of the robot duck, the goal was to collect ratings of how well the robot mimics several characteristics of real ducks. The hope is that a measure of the similarity of the robot to a real duck will be obtained. However, it is possible that the measure might actually be of student reactions to a possible robot pet, or an indicator of awe at the technology represented by the robot “quacker.” Because many of the concepts measured in organizational behavior are intangible (e.g., motivation, job satisfaction, and organizational justice), the question of a measure's validity is addressed in both direct and indirect ways.

The direct method is called content validity and involves examination of each of the statements or questions used to obtain responses and asking “are these items part of the pool of items that should be used to describe the concept of interest?” Generally, this assessment is made using a panel of judges as a way of approximating the variation that may be found among respondents to the questions or statements. For example, a panel of five judges might have high levels of agreement that five items measure similarity with a duck, but may have low levels of agreement on two other items. The measure with the five items would then have greater content validity than would the measure using all seven.

The indirect approach to validation of organizational behavior measures involves searching for evidence of convergence and discrimination. The idea of convergence is that different versions of measuring the same concept should converge. That is, one measure of a latent variable should produce similar values to other measures of the same latent variable obtained using different techniques. Discrimination in this case means that it should also be possible to show that the measure of a latent variable is distinct from other measures of similar but different latent constructs, and that the measure is not correlated with a set of other latent variables with which it should not be correlated. As an example, the objective might be to validate a measure of the extent to which a person's work interferes with family life. The convergent validity can be examined by comparing a person's reported work/family conflict with independent reports of the frequency that work interferes with a person's planned family activities, as provided by a spouse, children, and co-workers. The discrimination of the measure can be assessed by examining its correlation with pay level, expected to be negative, and the number of pets in the household, expected to be insignificant. Discrimination among measures of similar concepts, e.g., job satisfaction and organizational justice, is often tested empirically using confirmatory factor analysis. This statistical technique evaluates the extent to which

the items of the measures of two similar concepts are more strongly related to each of the measures than they are to each other.

Considerations in Organizational Behavior Measurement

There are some issues with which organizational behavior researchers must be particularly concerned in using perceptual measures about work. First, measurement should be made at the appropriate level. For example, the work climate in an organization can affect employee job satisfaction and commitment. However, climate is a property of the organization. It should be measured at the organizational level either by assembling key informants and asking them to provide a consensus response to questions about the organization or aggregating the individual responses of key informants to questions about the organization after assuring there is an acceptable level of interrater agreement. Aggregating responses to statements or questions about an individual's work experience on the job would not provide a valid measure of organizational climate.

Second, self-reports about jobs and related work environments provided by employees do not describe objective job conditions, as might be reported by observers. In general, perceptions of a worker may not agree well with observations by others. In addition, self-reports of behaviors tend to reflect self-serving bias, which is a tendency to describe the self as conforming to some ideal image. Generally, reports by others describing an employee's behaviors do not have high levels of agreement with self-reports. Self-reports can also be contaminated by other forms of bias. For example, it is likely that an employee's descriptions of the autonomy and variety present in his or her job may be influenced by the nature of the employee's relationship with his or her supervisor or by recent events in the work unit, such as promotions or terminations. Self-reports about jobs and work environments provide very meaningful and valuable insights, but do have limitations that are worth keeping in mind. In many cases, the measurement errors introduced by these biases can be controlled in the analysis if data about the biasing condition is collected at the time of the study.

It is also common practice in organizational behavior studies to collect multiple measures within a single questionnaire in order to examine the relationship among concepts. The relationships among variables may be inflated because the measures are all collected within a single instrument. Several alternative statistical methods are available for assessing the degree of impact of method variance. Finally, users of measures in organizational behavior should be aware that the use of English language instruments in other cultures may be fraught with problems. One study used four versions of a measure, each version

varying according to the language and the response scale used. There were two reasons for adopting the four versions. First, by comparing the responses of the two language versions, the researchers were able to determine whether respondents were interpreting the Chinese and English questions in a similar way. Second, they could examine the response bias of the Chinese research participants induced by different scales. That is, past studies have found that Chinese respondents may be reluctant to make known their opinion on politically sensitive matters. It is important to examine whether this effect is present when using English language measures in other cultures.

Glossary

computer adaptive rating scale (CARS) An item response theory-based measure of job performance; the respondent is presented with items consisting of pairs of behavioral statements, representing the same dimension, but different levels of performance.

empirical keying A method of scoring responses to situational judgment tests in which a sample of high-performing employees is assessed and the most frequently endorsed option for each item is keyed as “correct.”

faking Intentional distortion of responses to self-report items measuring personality or other noncognitive constructs.

job performance An aggregate of employee behaviors having some expected value to organizations (positive or negative).

personnel selection The process of matching an applicant's qualifications (knowledge, skills, abilities, and other) to job requirements in such a way that job performance is maximized.

Measurement technology is used in the research and practice of organizational psychologists, who specialize in workplace personnel selection and performance management. The focus here is on how measurement technology is used in the workplace and on identifying the main constructs of interest and how they are measured and assessed. Results concerning construct and predictive validity and recent psychometric innovations and avenues for future research are discussed. Measurement equivalence, which is especially important for researchers interested in cross-cultural/national comparisons, is also examined.

Challenges in Measuring Individuals in Contemporary Organizations

The workplace environment has changed dramatically in the past two decades. Development of new technologies, increased globalization, and workforce diversification have transformed “manufacturing style” organizations, characterized by hierarchical structures and well-defined jobs, into “service style” organizations with flat structures, fluid jobs, and the extensive use of teams. The survival of such contemporary organizations is increasingly dependent on their ability to attract, select, and retain workers capable of performing in highly complex, ever-changing, and progressively more social situations. That can be difficult to accomplish without deliberate and continual measurement of workers' abilities, skills, attitudes, and performance. As a result, measurement applications are an important part of organizational efforts to achieve and maintain a competitive advantage.

Measurement in organizations poses numerous challenges for researchers. For example, high test scores usually lead to desirable outcomes, such as job offers, pay raises, and promotions; low test scores, on the other hand, may result in not being selected, being censured, or, possibly, being terminated. Consequently, there are strong incentives for test takers to perform well, if necessary, by manipulating their answers to present themselves in the best light possible. Not surprisingly, this can create difficulties for score use and interpretation, particularly in noncognitive assessment, which often

depends on self-report data and subjective performance ratings to select individuals and allocate rewards.

Another challenge for contemporary organizational researchers is to develop measures that assess skills related to the popular concept of “social intelligence.” For example, managers usually want to select people with good interpersonal, teamwork, and conflict resolution skills. However, scores on most paper-and-pencil social intelligence measures correlate highly with scores on cognitive ability and personality tests. This raises issues concerning construct and incremental validity (i.e., that which is gained by including social intelligence measures in a selection battery). Hence, the immediate challenge for researchers is to explore alternative methods of assessment and demonstrate discriminant validity.

Measurement Applications for Selection

The use of tests for selection decisions is perhaps the most widely scrutinized and well-researched topic in industrial/organizational psychology. The main purpose of selection is to match an applicant’s qualifications, commonly framed as knowledge, skills, abilities, and “other” (KSAOs), to job requirements in such a way that job performance is enhanced. Because the success of selection decisions largely depends on the quality of measures used to assess applicants’ KSAOs, organizational psychologists exert a great deal of effort to ensure the reliability and validity of the assessment tools. Overall, the cumulative body of research indicates that measures of cognitive ability, personality, and social skills can be effectively used to predict different aspects of performance, both on the job and in training.

Measurement of Cognitive Ability

Among all the individual difference measures used in organizations, cognitive ability tests (also called intelligence tests) are perhaps the most widely used. Their popularity stems from meta-analytic research indicating that general cognitive ability is the best predictor of performance across thousands of occupations, and the correlations increase as a function of job complexity. For example, the overall meta-analytic estimate of the correlation (corrected for range restriction and unreliability) between general cognitive ability and job performance is 0.51, and the correlation with training performance is 0.53. Years of education, interests, job experience, and biographical data measures provide very little in terms of incremental validity, although the results concerning personality measures, structured interviews, and work samples are more encouraging.

In general, psychometric approaches to measuring cognitive ability in organizational settings are pragmatic, but relatively unexciting. Most organizational researchers are aware of item response theory (IRT) methods of test construction and scoring, but, due to sample size requirements or other practical concerns, they rely on classical test theory methods to develop short tests of general ability; these are scored using “number correct” and are administered via paper-and-pencil or computer programs that act as electronic “page turners.” Computerized adaptive testing is far less common in industrial/organizational (I/O) settings than in educational contexts, perhaps because paper-and-pencil measures have traditionally worked well and, possibly, because of competition among organizations. Provided that validity can be demonstrated, organizations are free to develop and purchase tests that best suit their individual needs, in an effort to maximize outcomes with respect to their competitors. A good selection battery is viewed as a competitive advantage or a product that can be licensed for profit, so there is little incentive to cooperate with other companies on research and development or to disclose publicly how scores are obtained. On the other hand, in educational testing, the assessment of college-bound seniors, for example, is relegated to large-scale testing corporations. Rather than developing or purchasing their own tests, universities have agreed to use standardized measures, such as the Scholastic Aptitude Test (SAT), for selection decisions. Development, administration, scoring, and reporting costs are thus absorbed initially by the testing corporation and, ultimately, passed on to applicants, of which there are literally tens of thousands each year. Obviously, there is no analogous situation for job selection; candidates expected to pay for the opportunity to apply would likely seek employment with a different organization. Consequently, organization researchers must be more practical when it comes to evaluating new technology.

There are some recent exceptions, however, involving large organizations. For example, U.S. military psychologists have developed and implemented a computerized adaptive version of the Armed Services Vocational Aptitude Battery (ASVAB), which is used for screening and classifying recruits. In a similar vein, IRT has been recently used to develop parallel forms of several cognitive ability tests for a large telecommunications organization. Both initiatives were motivated by a need for continuous testing and classification of large numbers of applicants, as well as by long-term goals for reducing testing time and costs. In short, given that computer technology is increasing rapidly, which is reducing once prohibitive start-up costs, and there is a growing impetus for workplace globalization, it is likely that IRT-based computer adaptive assessments will become more prevalent in I/O research and practice in the not-too-distant future.

Measurement of Personality

The five-factor structure of personality (extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience) has emerged in the past decade as the predominant framework for describing the basic dimensions of normal personality. Based on this framework, selection researchers have conducted several meta-analyses to examine which “big-five” dimensions are useful for predicting work performance. These studies have shown consistently that conscientiousness is a valid predictor of job performance across all occupations included in the meta-analyses, whereas the other four dimensions predict success in specific occupations, or relate to specific performance criteria. More recently, results of a number of studies have suggested that measures of narrow traits may have higher predictive validity, compared to measures of broad factors. For example, several big-five factor measures, as well as narrow trait measures, were correlated with several performance criteria and it was found that the latter were more effective predictors. Similarly, other studies have shown that narrow facets of a broad factor can have marked but opposite relationships with a performance criterion. Consequently, if measures of the narrow facets are aggregated to assess a broad personality factor, the relationship with an external criterion may fall to zero. In sum, these results suggest that using lower order facets of the big five might increase the validity of personality measures in selection contexts.

There is currently no shortage of personality inventories measuring both broad and narrow big-five traits. Among the most widely used measures for selection are the NEO (neuroticism, extraversion, openness) Personality Inventory (NEO-PI), the Sixteen Personality Factor Questionnaire (16PF), and the California Personality Inventory (CPI). All of these inventories were developed using classical test theory (CTT) methods. They are composed of scales having 10 to 15 self-report items that ask about a respondent's typical behavior. Most measures also contain a lie or social desirability scale to identify respondents who may engage in impression management. Though these scales might work well in research settings, when respondents are motivated to answer honestly, their efficacy in selection contexts is still a matter of concern. Recent research comparing responses to traditional personality items across testing situations has clearly shown that applicants can and will increase their scores, with respect to nonapplicants, when there are incentives to fake “good.” In fact, it is not uncommon for applicants to score 1 SD higher compared to respondents in research settings. The main problem, however, is that not all individuals fake, and certainly not to the same extent, so faking affects the rank order of high-scoring individuals and, thus, the quality of hiring decisions. Moreover, because approaches to detect and correct for faking *post hoc*, using

social desirability/impression management scores, are generally ineffective, interest may be shifting toward preventing faking by using veiled items, threats of sanctions, or alternative items formats. An example of the latter approach involves the construction of multidimensional forced-choice items that are designed to be fake resistant. By pairing statements on different dimensions that are similar in social desirability and asking a respondent to choose the statement in each pair that is “most like me,” items are more difficult to fake. However, important concerns have been raised about the legitimacy of inter-individual comparisons due to ipsativity. In an effort to address that concern, a mathematical model for calibrating statements has been proposed, constructing multidimensional forced-choice tests and scoring respondents. In simulation studies conducted to date, this approach has shown to recover known latent trait scores, representing different personality dimensions, with a reasonable degree of accuracy. But more research is needed to examine the construct and predictive validity of such personality measures in applied settings.

Aside from concerns about faking, there is a basic question that should be examined in the area of personality assessment. Namely, studies are needed to explore the way in which persons respond to personality items. Many measures have been developed and a great deal of research has been conducted, assuming that a dominance process underlies item responding; that is, a person will tend to endorse a positively worded item when his/her standing on the latent dimension is more positive than that of the item. However, some recent studies suggest that an ideal point response process may be better suited for personality items; i.e., respondents tend to agree with items that are located near them on the latent continuum and to disagree with those that are distant in either direction. In IRT terms, this means that some personality items may exhibit nonmonotonic, folded item response functions (IRFs). In the case of neutral items, the IRFs may be bell-shaped when computed based on an ideal point model.

The possibility of using nonmonotone items in personality questionnaires opens new avenues for theoretical and applied research. First, there is a need to determine what features of items can yield nonmonotone response functions and whether some personality dimensions tend to have more such items than others have. Second, the effects on construct and predictive validity due to eliminating or retaining items of neutral standing during personality test construction have not been investigated. If truly nonmonotone items are scored using dominance models (i.e., number right or summated ratings), the rank order of high/low-scoring individuals may be affected by the choice of scoring model; so that the accuracy of hiring decisions could suffer. More research is needed to determine whether these results indeed exert measurable influences on validity and utility in organizations.

Measurement of Social/Emotional Intelligence

Because organizations are sociotechnical systems, successful interaction with others can be a critical competency for any employee. That fact is further recognized by contemporary models of job performance, which now explicitly view helping and cooperating with others as components of performance that contribute to overall organizational effectiveness. Consequently, organizations are increasingly interested in selecting individuals who have good social skills and are able to appraise, express, and regulate emotions in themselves and others. In other words, they want to hire and retain persons having a high degree of social/emotional "intelligence." Many measures of social/emotional intelligence have been designed since the term was first introduced in the 1920s. However most of these measures have been either unreliable or have shown poor discriminant validity. For example, measures that rely on self-reports (e.g., respondents recall typical social behavior) typically correlate highly with personality scales. Others, such as paper-and-pencil situational judgment tests (e.g., respondents are given written scenarios and asked how they would react in that situation) do not correlate with personality measures, but, instead, correlate highly with cognitive ability scores. In sum, though the concept of social/emotional intelligence is intuitively appealing, attempts to measure it have been largely unsuccessful.

Despite the checkered history of social intelligence assessment, considerable progress, in terms of validity, seems to have been made in the past several years. For example, a study using video as a medium of administration for situational judgment tests (SJTs) showed that video-based SJT scores did not correlate with either cognitive ability or personality measures, but the same scenarios were highly correlated with cognitive ability when presented using a paper-and-pencil format. Another study used video-based SJT to assess conflict resolution skills. The measure predicted work performance, and, similar to other SJT findings, this SJT was uncorrelated with cognitive ability and personality. Therefore, the medium of administration seems to play an integral role in SJT validity. At this stage, more research is needed to understand how and why video-based assessment changes the nature of the construct that is assessed. Perhaps the answers here lie in perceptual or cognitive psychology information-processing models.

Scoring video-based SJTs poses a formidable challenge from a psychometric standpoint. Usually, each SJT scenario has several response options (actions) that are derived from interviews with subject matter experts. Because so many reactions to a scenario are possible, those selected and presented as response options in the context of an item often vary widely; i.e., they do not

represent a single behavioral dimension. Consequently, unidimensional scoring procedures cannot be applied and alternative approaches must be developed. The most widely used approach to scoring is "empirical keying," wherein a sample of high-performing employees is assessed and most the frequently endorsed option for each item is keyed as "correct." In the end, applicants who earn high scores on empirically keyed SJTs are those that exhibit response patterns similar to high performers. Unfortunately, empirical keying has a number of limitations. First, not all scenarios (items) can be keyed, because high performers sometimes disagree about which response action is better. Second, organization-specific keys are often needed, because there are different preferences and norms for teamwork, leadership, and conflict resolution styles across organizations. A third concern is that empirically derived keys do not cross-validate well, particularly if the sample used for calibration is small; in that case, bootstrap approaches or alternatives to empirically derived keys might be required. And, fourth, empirical keying is not very informative with regard to designing training programs to improve social/emotional skills. In short, despite these limitations, empirical keying of SJTs seems to be more effective than either subject matter/expert-opinion-based scoring methods or rational approaches. More research is needed to explore alternative scoring procedures, medium of administration effects, and incremental validity in job selection.

Performance Measurement

Helping to manage workers' performance is the central task of organizational psychologists. Virtually all organizational interventions target this area. Personnel selection procedures seek to identify applicants who are likely to perform better in the future. Training programs, feedback interventions, and merit pay systems are designed to maintain and improve current performance. Promotion and termination decisions essentially reward (or punish) past performance. None of these interventions is possible without first defining the dimensions of performance and developing valid assessments of the construct.

Dimensions of Job Performance

Job performance is defined as an aggregate of employee behaviors that have some expected value to organizations (positive or negative). These behaviors can be classified into three broad classes: task performance, contextual performance, and counterproductivity. Task performance is composed of behaviors that either (1) directly transform raw materials into products and services or (2) service and maintain the successful transformation of raw materials. Task performance behaviors are role

prescribed; that is, they are explicitly written in an employee's job description. In contrast, contextual performance is not role prescribed, but rather includes discretionary behaviors that shape the organizational, social, and psychological context of the workplace. Examples of contextual performance include volunteering to carry out task activities that are not formally part of the job, helping and cooperating with others, and following organizational rules and procedures. In the business literature, these behaviors are also known as organizational citizenship behaviors (OCBs). The third broad dimension of job performance is counterproductivity. It is composed of intentional behaviors that are viewed by the organization as contrary to its interests. Counterproductive behaviors can range from blatantly damaging (i.e., theft, destruction of property) to somewhat less destructive (i.e., poor attendance, misuse of information, intentionally poor work); all of these are detrimental to overall organizational effectiveness.

For many years, task performance was the focus of most applied and research efforts, because it was believed to be the most salient component of job performance. However, recent studies have shown that overall job performance is influenced nearly as much by contextual performance, so there has been an upsurge of research on its antecedents and consequences. Counterproductive behaviors, on the other hand, have been studied primarily in the context of employee attitude surveys, because they tend to correlate highly with job satisfaction. More recently, counterproductivity and contextual performance have been studied together as organizational psychologists attempt to develop more general models of extra-role work behaviors. In summary, research suggests that adequate evaluation of work performance requires assessment of task performance, OCBs, and counterproductive behaviors. Organizations seek to design interventions that discourage counterproductivity, but encourage the task and contextual behaviors.

Psychometric Approaches to Performance Ratings

Assessing job performance is difficult. Often, relatively few "objective," numerical, or easily quantified performance data are available, so organizations must rely on subjective performance ratings obtained from immediate supervisors, co-workers, customers, or even employees. Subjective ratings, however, are often unreliable and prone to a number of rating errors (e.g., halo, leniency, or central tendency). To combat these errors, organizational psychologists have explored many ratings formats over the past 60 years.

The earliest performance ratings were obtained using graphic rating scales (GRSs). These were typically one-item measures, containing a rulerlike response scale. GRSs were quick and easy to administer, but had poor

psychometric properties and were susceptible to many rating errors. Manipulations of the GRS format, such as the placement of the scale on the page or the number of response categories on the scale, had little salutary effect on the quality of ratings. In the 1960s, behaviorally anchored rating scales (BARSs) were introduced, wherein behavioral statements representing different levels of job performance are ordered along a scale in terms of effectiveness; the rater's task is to mark the statement that best describes the typical behavior of the ratee. The idea of BARS was to help raters make more objective evaluations by listing prototypical job behaviors, but, like the GRS, the BARS was susceptible to rating errors and exhibited low interrater reliability. Later, other formats, such as behavior observation scales and mixed-standard scales, were developed. These approaches were more complicated, but showed little improvement in terms of rater errors, reliability, and validity. As a result, the quest for improving performance rating formats came to a standstill and organizational psychologists turned, instead, to training raters to more accurately and consistently evaluate employees.

The hope for a better rating format was revived in 2001 using a paired-comparison rating format to measure contextual performance via a computer adaptive ratings scale (CARS). The idea is to present raters with items consisting of pairs of behavioral statements, representing the same dimension, but different levels of performance; the rater's task is to choose the statement in each pair that better describes the performance of the ratee. The novel feature of this approach is the use of a computer adaptive algorithm for composing items and scoring responses, based on an ideal point IRT model. Computer adaptive testing helps raters make more precise estimates of ratees' performance, while simultaneously decreasing the number of items administered per ratee. The results indicate that the CARS format yields more reliable ratings and significantly greater validity and accuracy compared to the GRS or BARS formats. In addition, raters prefer the CARS format to other formats and perceive it to be more accurate. Overall, these findings suggest that improvements in methodology can help raters improve the accuracy of performance assessments. More applications of CARS methodology are likely to appear in the near future.

Emerging Issues in Test Score Use

Measurement Equivalence in Cross-Cultural Research

Industrial/organizational researchers are increasingly interested in comparing test scores across cultural/national groups. The goal of these comparisons can be, for example, to ensure that a test used for selection and promotion

decisions is not biased. Alternatively, some researchers may want to identify items and scales that function differently across cultures as a means of generating hypotheses for future experimental research or understanding cultural differences. Others may simply want to know the magnitude of score differences across groups so that appropriate norms can be created. To achieve any of these objectives, measurement equivalence analyses are needed.

Measurement equivalence exists when the relations between observed test scores and a latent attribute measured by a test or scale are identical across groups. Essentially, measurement equivalence refers to the comparability of a scale's internal psychometric properties across subpopulations. It should be distinguished from relational equivalence, which refers to the similarity of a scale's external relationships (i.e., those with other constructs) across subgroups. To date, a majority of measurement equivalence studies have been conducted using either factor analytic or IRT methods. Factor analytic methods, such as confirmatory factor analysis (CFA) and mean and covariance structure (MACS) analysis, involve comparisons of a full model, whereby item parameters are estimated separately for each group, and a series of restricted models, whereby parameters are constrained to be invariant (equal) across groups. Significant change in fit when going from a full to a more constrained model is interpreted as a lack of some form of measurement equivalence (e.g., scalar invariance); the type depends on the specifics of the constrained model.

IRT methods, on the other hand, typically involve comparisons of item/test characteristics curves. For example, Lord's chi-square method compares item parameters estimated for a focal group (e.g., Americans) and a reference group (e.g., Asians), under a particular IRT model, after they have been placed on a common metric. The primary advantage of IRT methods over factor analytic methods is that IRT methods do not confound measurement bias with mean score differences across groups, and they make no assumptions about normality or linearity. Although the number of measurement equivalence studies continue to grow, results from these studies are often difficult to interpret. First, experience shows that CFA and IRT measurement equivalence methods rarely agree when applied to the same data set. That may not be particularly surprising, because the two approaches make somewhat different assumptions about item responding (i.e., linearity or multivariate normality). However, divergent results can obfuscate the interpretation of findings, because it is not apparent which set of results should be trusted. Psychologists therefore need to conduct simulation studies comparing the performance of factor analytic and IRT methods under controlled conditions and

examine the relative robustness of these procedures to violations of model assumptions. The second important issue is that a majority of the methods rely on significance testing to detect measurement nonequivalence—i.e., differential item/test functioning (DIF/DTF). However, measurement equivalence analyses typically involve large samples, so small differences in item loadings, item response probabilities, or expected total test scores are often identified as statistically significant, even if they have little practical importance. Furthermore, *p*-values regarding the tenability of the null hypothesis of no DIF/DTF provide no clue as to what action should be taken when nonequivalence is found. Thus, practical guidelines for interpreting measurement equivalence results are needed.

An effort to improve interpretability of measurement equivalence studies is underway. It involves development of two IRT-based methods to translate findings of test bias into quantities that are easily understood by test users. The first method translates bias into raw score points, so that values can be compared readily to the magnitudes of observed mean differences across groups. If desired, the values can also be transformed to obtain effect size measures similar to those reported in experimental studies. The second method evaluates how bias affects the proportions of reference and focal group members selected using various cut scores, which are commonly used in personnel selection, licensing, and college admissions. More methods, similar to these, should be developed to aid the interpretation of results from measurement equivalence studies.

Summary

There are three areas of burgeoning interest concerning measurement in organizations. As in professional licensing and educational testing, there is a trend in I/O research and practice toward more realistic assessments that can be administered adaptively and delivered, perhaps, over the Internet. Computer simulations and video-based assessments will become more common as technology improves and organizations explore new ways of assessing constructs, such as job performance, personality, and situational judgment. However, the proliferation of new measurement technology from quantitative circles to mainstream research and practice is expected to occur slowly. After all, new technology can only influence mainstream research and practice if results are communicated in a way that is understandable to a general audience, programs are made easier to use, examples and guidelines for interpreting results are provided, and, ultimately, new methods of test construction and evaluation

lead to appreciable gains in validity that will offset development and maintenance costs.
