A second shortcoming of earlier research is that most studies have investigated direct linear relationships between Internet use and social connectedness. There is hardly any research that has studied the mechanisms that underlie the relationship between Internet use and social connectedness. In other words, little research has hypothesized about possible variables that may explain a stimulating effect of Internet communication on social connectedness. As discussed previously, there is growing evidence that intimate online self-disclosure may account for a positive relationship between online communication and social connectedness. However, it is possible that other communication or psychological processes, such as uncertainty management, breadth of interaction, and perceived similarity, shape or account for potential social effects of the Internet. Future research should identify and hypothesize on potential mechanisms that underlie the effects of Internet use. We need to know not only that Internet use affects social connectedness, but also more precisely how this influence works.

A final shortcoming of existing research refers to the fact that most conclusions about the effects of online communication on the quality of friendships are based on correlational studies. These studies cannot give a decisive answer about the direction of the relationship between online communication and social connectedness. It may be that Internet use indeed increases social connectedness. However, research has not decisively refuted the causally reversed hypothesis that people who are socially more connected more often turn to the Internet. Future research needs to invest in designs that allow more rigorous causal explanations. Only if we address this issue can we assess the role of Internet use for people's social connectedness in an encompassing fashion.

INTERNET DATING

The term *online dating* is a slight misnomer because this term actually refers to the formal process of matchmaking via the Internet. Online sites have been set up where individuals locate a potential partner and then the dating process takes place offline. This entry examines the process of online dating and the reasons that people elect to use this matchmaking method. In addition, it considers the best types of presentations of self on these sites and the future of online dating.

During the early days of the Internet, given the restricted technology capabilities and bandwidth, online dating sites looked more like newspaper personal ads. Individuals would read a profile and contact people on the site to learn more about them and to gauge whether the other person was also interested. Men were much more likely to subscribe to these sites than women, and companies allowed women onto these sites for free to ensure men had an adequate selection. Compared with the early days of the Internet, today the amount of information and detail people can add to their profile is obviously less restrictive due to increased bandwidth. Most sites attract about equal numbers of

men and women. Online dating sites across the globe continue to increase in popularity.

Given the number of people seeking others online for love and sex, it is little wonder that companies have tried to formalize this process, as well as to make money from people who are prepared to seek out romance on the Internet. These sites are typically set up to have their users construct a personal ad for themselves. Clients can, and generally do, show at least one photograph of themselves and can also add video and voice to their profiles. Online daters can rate themselves or check boxes indicating attributes such as their age, gender, location, job, and physique (e.g., a choice ranging from slim to overweight). In addition, clients are usually given an opportunity to add to and expand on this information. For example, they may elaborate on their hobbies and musical interests or the type of person they are attempting to attract.

Some sites do the matching for the client. For example, some online dating sites ask the client to fill out descriptive details and a personality scale. The site then applies a formula to match like-minded individuals and presents their clients with options from which to select. In contrast, other sites provide a more flexible approach, whereby clients can opt to fill out such tests and be presented with profiles of clients deduced to be suitable matches, or instead the client can wade through the sea of possibilities and select for themselves (i.e., a profile-searching approach).

Once a potential match is identified on the site, individuals make contact. This might be via a subtle flirtatious note or via a more detailed e-mail. Individuals might elect to get to know one another via e-mail or an instant message (IM) program. If all goes well, then a face-to-face meeting is organized. Typically this meeting is organized within a couple of weeks of initial contact via the site.

In addition to the general online dating sites such as eHarmony, True.com, Match.com, and so forth, there are also more specialized online dating sites that gather like-minded individuals together. For example, there are sites designed specifically for Christians, Jews, Vegans, Goths, or spiritual people.

Motivations for Using the Sites

Research has reported social and personality reasons for choosing online dating as a way to find a match:

- Given that career and time pressures are increasing, people are looking for more efficient ways of meeting others for intimate relationships;
- Single people are more mobile due to demands of the job market, so it is more difficult for them to meet people face to face for dating;
- Workplace romance is on the decline due to growing sensitivity about sexual harassment—hence, alternative dating approaches are needed; and
- Shy people and people over the age of 35 (compared with non-shy people and those under the age of 35) are more likely to have tried online dating and consider using it in the future.

Successful Presentation Strategies

Researchers have begun to consider, at least qualitatively, the types of profiles individuals are more attracted to and are more likely to lead to successful budding relationships. Many people lie or exaggerate aspects about themselves in their profiles (e.g., some men lie about their height, whereas women lie more about their body shape). These people are usually judged as untrustworthy and do not usually get a second date. The Balance Between Attractive and Real Self theory argues that a more successful profile is one that presents a balance between an attractive presentation of self and a “real” depiction of self (i.e., a presentation that individuals can match up to during the first face-to-face date).

Future of Online Dating

Online dating sites are here to stay; however, their structure and form will change as the technology becomes more sophisticated and companies find ways to deal with some of the problems that online daters encounter with using these sites. For example, the sites’ and clients’ trustworthiness need to be strengthened. Perhaps also adding more playful applications, such as those used in social networking sites, will make the online dating experience more playful and flirtatious.

INTERPERSONAL ATTRACTION

Interpersonal attraction is the broad process by which we come to prefer some potential relationship partners to others. It involves all of the influences in the initial stages of a relationship that lead us to notice particular people, consider them appealing, prioritize our interest in them, and to wish to approach them. Attraction to others is obviously influenced by their personal characteristics; some people are appealing to almost anyone they meet. However, attraction also depends on the aims and goals of the perceiver and the idiosyncratic pairing of the two people involved. It also emerges from impersonal influences that—because they are frequently overlooked—can be surprisingly potent. That is where this entry’s survey of various determinants of attraction begins.

Impersonal Influences

Attraction depends in part on one’s current desire to affiliate with others, and potential partners who would ordinarily be desirable may seem less appealing when one wishes to be alone. Alternatively, *any* partner is sometimes better than no partner at all, and we may occasionally pursue the company of others who would not be highly sought after in better circumstances.

Adverse conditions that induce confusion or fear make the presence of others more comforting, whereas embarrassing circumstances have the opposite effect—and any of us may encounter such conditions from time to time.

In fact, any event that gets a rise out of us may influence our attraction to others. Anything that “turns us on”—that is, that causes physical activation and arousal—seems to intensify our evaluative reactions to the people we encounter. When our hearts are racing and we are breathing hard, whether as a result of robust laughter, strong trepidation, or simply strenuous exercise, we find lovely people to be more desirable than they seem when we are at rest. Unattractive people seem more *undesirable* when we are aroused, as well. Thus, diverse experiences that have nothing to do with a particular partner can influence our attraction to him or her.

One of the most striking examples of impersonal influences on attraction, however, is the role of physical proximity in encouraging new relationships. Obviously, in order to be attracted to others, we have to meet them, and that is more likely to happen if they are often nearby. Various Web sites may provide ways of making contact with others in remote locations, but—everything else being equal—we tend to like those who live and work near us more than those who are larger distances away. This pattern is so striking that when college students are assigned seats in their classrooms, they are much more likely to become friends with the people who end up sitting near them than with others sitting just a few feet farther away.

There appear to be two major reasons that proximity is important: *familiarity* and *convenience*. The more often we encounter others, the more familiar they become, and that usually leads us to like them better. If they are pleasant people, familiarity does *not* breed contempt; people we recognize trigger fonder feelings than strangers do. Partners who are close at hand are also more convenient than are those who are far away, offering richer rewards that are more easily obtained. Long-distance relationships are typically less rewarding than they would be closer to home, so absence does *not* ordinarily make the heart grow fonder.

Finally, the number of potential partners we have available to us also influences our attraction to them. People become less picky when partners

become scarce. Thus, when closing time approaches, bar patrons who are still looking for a date come to consider the other people remaining in the bar to be more attractive than they seemed to be when the night was young. (This does not occur when people are not seeking a partner, so such attraction is multifaceted, depending both on the goals of the patrons and the situation they face.)

Others' Personal Characteristics

Still, no matter the circumstances, some people are more attractive than others. Everybody likes warmth, loyalty, kindness, and trustworthiness in a potential partner—including women, who prefer men who are both assertive *and* tender to those who are stonily macho—but personality traits like these are less evident than is one's appearance. When interaction begins, looks count. Many people hold the stereotype that *what is beautiful is good*: They assume that people who are physically attractive also possess desirable personalities. People also sometimes confuse beauty with talent: Good-looking professors get better teaching evaluations, and physically attractive employees receive higher salaries than less attractive people do.

Judgments of physical beauty carry special weight because we all tend to agree on who's hot and who's not. There is some idiosyncrasy in judgments of beauty—for instance, some of us prefer blondes to brunettes, whereas others do not—but beauty is “in the eye of the beholder” only to a limited extent. Instead, there is remarkable consensus around the world about the facial and physical features that make someone attractive. Appealing faces tend to be *symmetrical*, with the left and right sides of the face being mirror images of one another—so, the cheeks are the same width, the eyes the same size, and so on. Gorgeous faces also have *average* proportions that do not much differ in any dimension from human norms. This does not mean that they are ordinary or mundane. To the contrary, they are beautiful because there is nothing about them that is odd or exaggerated; their noses and chins are neither too big nor too small, their lips neither too full nor too thin. Remarkably, we seem to be born liking such lovely faces: Babies exhibit visual preferences for the same faces that adults consider to be attractive.

There is also notable agreement around the world regarding the shapes of attractive bodies. Women are most attractive when they are of average weight and have curvy figures in which their waists are noticeably narrower than their hips. A waist-to-hip ratio (WHR) of 0.7, in which the circumference of a woman's waist is only 70 percent of that of her hips and buttocks, is ideal. In fact, *Playboy* Playmates and Miss America beauty pageant contestants are now thinner, on average, than they used to be, but their typical WHRs—which hover around .67—have not changed over the last 50 years.

Men are more attractive with WHRs around 0.9. These patterns are noteworthy because the distribution of fat in the body is influenced by sex hormones, and an appropriate WHR is associated with better health in both sexes. Women with curvy shapes also get pregnant more easily than stocky women do. Thus, both sexes are attracted to the physical shapes in the other sex that suggest one is healthy and fit.

Indeed, all of these standards of beauty—symmetrical faces with average dimensions and bodies of the proper shape—are associated with healthy well-being (and the absence of harmful mutations). The cross-cultural appeal of these features leads some theorists to assert that our desires for them are evolved inclinations; they have become universal preferences because the early humans who pursued them obtained healthier mates and thereby reproduced more successfully than did those with other tastes.

Norms of fashion do vary from culture to culture. In particular, heavier weights tend to be attractive when a culture is going through hard times, but thinner bodies are more desirable when a culture is prosperous. Nevertheless, the same facial and bodily features are attractive around the world, and it is possible that these fundamental preferences are not just norms that are learned in each culture. Despite some idiosyncrasy here and there, we may have all inherited the same basic tastes.

In any case, when they are pursuing new romances, both men and women say that they want partners who have good earning prospects and who are physically attractive, warm, personable, and loyal. In practice, however, one of these characteristics clearly matters more than the rest. When they are choosing among several potential partners—as in a “speed-dating” situation, in which they have

brief conversations with 10 to 20 different possible dates—both men and women are influenced more by physical attractiveness than by anything else. If they stay together, people usually value dependability and agreeableness in their partners to a greater extent as time goes by. At first meeting, however, it is looks that count.

Aims and Goals of the Perceiver

Men and women generally seek the same attributes in a potential partner, but when they are seeking a lover for an enduring romance, their preferences differ in two particulars: looks and money. Men value physical attractiveness more than women do; they consider a moderate level of good looks to be indispensable in a mate. Women want handsome partners, too, but they first insist that their mates have acceptable prospects and incomes. Most women will be less interested in a potential husband who is handsome but poor than in one who is only moderately good looking but well to do. Men care less about a potential mate's money.

This pattern is also found around the world, and some theorists suggest that it, too, fits an evolutionary perspective. Our female forebears may have reproduced more successfully if they sought mates who could provide resources to shelter and protect their fragile children than if they were heedless of such concerns. In contrast, our male ancestors may have had more children if they pursued young, physically attractive—and therefore fertile—mates. Men's greater interest in looks and women's greater interest in resources in potential mates may thus be evolved motivations that have more to do with human nature than with our cultural heritage. (Not all relationship scientists agree with this conclusion, but it has been widely influential, stimulating a great deal of research.)

What we want in a partner also depends on whether we are seeking a lasting commitment or a short-term fling. When men want a one-night stand or a brief affair, they eagerly pursue promiscuous partners who will allow them such liaisons. However, they want potential wives to be more monogamous. When women seek a short-term fling, they prefer charismatic, masculine, physically attractive men who—because they are less likely to settle down—are less desirable as husbands.

Remarkably, women's specific tastes also fluctuate with their menstrual cycles. Women become fertile for the few days just before they ovulate each month, and during that period, their inclinations shift. Compared to the friendly, baby-faced features they typically like during the rest of the month, they prefer more masculine faces; they also become more partial to the cocky arrogance of dominant men, deeper voices, and the scents of men with more symmetrical bodies. They also dress to impress, choosing more provocative clothing, and are more flirtatious. If they already have long-term partners, they are also more likely to have affairs. None of this is necessarily intentional; indeed, most women have no idea when they are about to ovulate. Nevertheless, it is clear that many women who usually prefer kind, committed, nice men may find charismatic, untrustworthy “bad boys” to be strangely alluring when they are fertile each month.

Pair Influences

Other important influences on attraction emerge from processes that make some people more attractive to particular perceivers than to others. For one thing, the old saying that “birds of a feather flock together” is true; we do tend to like those who have similar personalities and who share our backgrounds, interests, attitudes, and values. The more similar to us others are, the more we tend to like them.

This pattern is plain in established friendships and romances; for example, in general, spouses who have a lot in common are happier with each other than are spouses who are less similar. However, there are various subtleties in the way similarity operates in beginning relationships that may mislead people into sometimes thinking, wrongly, that “opposites attract.” When we are attracted to others for any reason (such as their good looks), we tend to assume that we have much in common with them; thus, not only does similarity lead to attraction, but attraction leads to (assumed) similarity. People often think that they are more similar to the others they meet than they really are. Then discovering the truth can take time. The partners' assumed similarity may keep them together for a while until they recognize their differences—and during that

period it may superficially seem to outside observers that opposites attract. Moreover, the longer the partners stay together, sharing formative experiences, the more similar they may actually become. So, similarity is more attractive than opposition is, but opposites may take time to detect, and they may gradually fade if a couple stays together for some other reason.

We also generally like those who like us in return. Rejection is painful, but acceptance is pleasing, so—everything else being equal—we are attracted to others who reciprocate our interest. In fact, most people preferentially pursue potential partners from whom they expect a welcome, and they do not approach others whose acceptance is improbable. As a result, we tend to pair off with others of similar levels of *mate value* or global desirability as romantic partners.

This is a phenomenon called *matching*, and it seems to occur because people typically want the most desirable partners who will have them in return. Following such a rule, we may all want gorgeous mates, but (unless there are other potent attractions at work) only those of us who are also physically attractive will get them. In practice, beautiful people do tend to pair off with others of similar beauty, moderately attractive people end up with partners like them, and so on. Matching can be a broad process that includes other assets such as wealth, power, and fame, so that rich people with ordinary looks sometimes acquire “trophy” partners much more becoming than they. However, for most of us, the major attribute with which we find our match is physical attractiveness.

The Fundamental Basis of Attraction

Collectively, the various topics we have covered in this entry may have their effects on attraction in several different ways. For instance, finding that someone shares our attitudes and values may be reassuring, making the world seem a more coherent and predictable place. Similar partners may simply be more fun, happily encouraging us to do the things we like to do. A number of specific mechanisms are possible. At bottom, however, attraction seems to boil down to a matter of rewards and costs: We are attracted to those whose companionship promises to be rewarding to us.

We may not always be conscious of just what it is about someone that we find appealing, and we may not notice when our tastes shift over time. We may also make mistakes, thinking that something about a potential partner will be gratifying when in fact it will not; in quite a few relationships, a characteristic of a new partner that initially seems attractive proves, with time, familiarity, and experience, to be one of the most annoying and frustrating things about him or her. Researchers call such characteristics *fatal attractions*, and their prevalence demonstrates that attraction is sometimes complex and perplexing. Nevertheless, from the moment they begin (as well as thereafter), relationships hinge on what is, and what we think will be, rewarding to us.

INTERPERSONAL DEPENDENCY

Interpersonal dependency—the tendency to rely on other people for nurturance, guidance, protection, and support even in situations where autonomous functioning is possible—is one of the more widely studied personality traits in the field of human relationships. Individual differences in interpersonal dependency not only predict important features of social behavior (e.g., help-seeking, conformity, compliance, and suggestibility), but also have implications for illness risk, health service use, compliance with medical and psychotherapeutic regimens, and success in adjusting to the physical and emotional challenges of aging. Because dependent people are typically insecure and clingy, and have difficulty reaching decisions without a great deal of advice and reassurance from others, high levels of interpersonal dependency can have a significant negative impact on friendships, romantic relationships, and work relationships.

This entry discusses the role of interpersonal dependency in human relationships. As the ensuing review shows, this trait is more complex than psychologists initially thought. Consistent with the beliefs of many mental health professionals, dependent adults often exhibit acquiescent, compliant behavior in social situations. However, contrary to expectations, studies suggest that in certain contexts dependent people may actually behave quite actively—even downright aggressively. Moreover,

although high levels of interpersonal dependency are associated with social and psychological impairment in a variety of contexts, in certain settings, high levels of dependency may actually enhance adjustment and functioning.

Conceptualizing Dependency

The first influential theoretical model of interpersonal dependency came from Sigmund Freud's psychoanalytic theory, wherein a dependent personality orientation was conceptualized as the product of "oral fixation"—continued preoccupation during adulthood with the events and developmental challenges of the infantile, oral stage. Thus, classical psychoanalytic theory postulated that the orally fixated (or *oral dependent*) person would: (a) continue to rely on others for nurturance, protection, and support; and (b) exhibit behaviors in adulthood that mirror those of the oral stage (e.g., preoccupation with activities of the mouth, reliance on food and eating as a strategy for coping with anxiety).

Over the years, empirical support for Freud's classical psychoanalytic model of dependency was mixed, and gradually this perspective was supplanted by an *object relations model*, wherein dependency is conceptualized as resulting from the internalization of a mental image (sometimes called a *mental representation* or *schema*) of the self as weak and ineffectual. Retrospective and prospective studies of parent-child interactions confirm that overprotective and authoritarian parenting, alone or in combination, are associated with the development of a dependent personality in part because of the impact these two parenting styles have on the child's sense of self. Overprotective parenting teaches children that they are fragile and weak, and that they must look outward to others for protection from a harsh and threatening environment. Authoritarian (i.e., rigid, inflexible) parenting teaches children that the way to get by in life is to accede passively to others' demands and expectations. Both lead to the construction of a "helpless self-concept," which is the core element of a dependent personality style.

During the 1960s and 1970s, behavioral and social learning models called psychologists' attention to the role that learning—including observational

learning—may play in the etiology and dynamics of dependency. As social learning theorists noted, intermittent reinforcement of dependency-related behavior will propagate this behavior over time and across situation, and modeling—including symbolic modeling—can facilitate this learning/reinforcement process. Building on these initial social learning models, later researchers showed that traditional gender role socialization practices may help account for the higher levels of overt dependent behavior exhibited by women relative to men insofar as dependent responding is discouraged more strongly in boys than in girls in most Western societies. In both women and men, high levels of femininity are associated with elevated levels of self-reported interpersonal dependency, whereas high levels of masculinity are linked with low scores on a broad array of self-report dependency measures.

Analyses of cultural variations in dependency supported the hypothesis that gender role norms help shape the expression of underlying dependency needs and further indicated that traditionally *sociocentric cultures* (e.g., India, Japan) tend to be more tolerant of dependency in adults than are more *individualistic cultures* (e.g., America, Great Britain), wherein dependency is associated with immaturity, frailty, and dysfunction. Not surprisingly, adults raised in sociocentric societies report higher levels of interpersonal dependency than do adults raised in more individualistic societies. When traditionally sociocentric cultures begin to adopt Western norms and values, members of those cultures show a decrease in self-report dependency scores.

Today researchers conceptualize dependency in terms of four primary components: (1) *cognitive* (i.e., a perception of oneself as powerless and ineffectual coupled with the belief that others are comparatively powerful and potent), (2) *motivational* (i.e., a strong desire to obtain and maintain relationships with potential protectors and caregivers), (3) *affective* (i.e., fear of abandonment, fear of negative evaluation by figures of authority), and (4) *behavioral* (i.e., use of relationship-facilitating self-presentation strategies to strengthen ties to others and preclude abandonment and rejection). The cognitive component of dependency—the “helpless self-concept” discussed earlier—is the linchpin of a dependent personality orientation and the psychological mechanism from which all

other manifestations of dependency originate via a predictable sequence of steps. First, a perception of oneself as powerless and ineffectual helps create the motivational component of dependency: If one views oneself as weak and ineffectual, then one’s desire to curry favor with potential caregivers and protectors will increase. These dependency-related motivations in turn give rise to dependency-related behaviors (e.g., ingratiation and supplication) designed to strengthen ties to others, especially potential nurturers and caregivers. These dependency-related motivations also give rise to affective responses (e.g., fear of abandonment and fear of negative evaluation), which reflect the dependent person’s core beliefs and anxiety regarding the possibility that they might have to fend for themselves without the protection of a powerful other.

Dependency as a Social Construct: From Passivity to Activity, From Deficit to Strength

Early psychiatric diagnosticians such as Emil Kraepelin and Kurt Schneider were among the first to discuss the link between dependency and passivity, but the notion that high levels of dependency are associated with a compliant, acquiescent stance in interpersonal interactions was popularized primarily by psychoanalytic theorists such as Karl Abraham and Karen Horney, who wrote extensively on this topic during the 1920s and 1930s. Given this historical context, it is not surprising that, throughout much of the 20th century, social research emphasized the passive aspects of dependency, documenting links among dependency and suggestibility, conformity, help-seeking, interpersonal yielding, and compliance with the perceived expectations of others.

In recent years, researchers have become increasingly interested in identifying contextual cues that help shape dependency-related behavior, and studies confirm that observed variability in dependency-related responding is largely a function of the dependent person’s perceptions of interpersonal risks and opportunities. Typically (and quite understandably), dependent people tend to focus their efforts on currying favor with the person best able to offer protection and support over the long term. Thus, they will work harder to please a professor than a peer and, when forced to choose between

the two, may actually attempt to undermine the peer to impress the professor (e.g., competing aggressively, denigrating the peer's competence and commitment). Dependent college students put forth greater effort than do nondependent students when offered an opportunity to meet with a professor whom they believe can offer future help and support. However, when told that the professor will soon be leaving the university (and therefore will not be available in the future), dependent-nondependent differences in behavior disappear.

These and other findings confirm that dependency-related responding is proactive, goal-driven, and guided by beliefs and expectations regarding the self, other people, and self-other interactions. Although the behavior of dependent persons varies considerably from situation to situation, the dependent person's underlying cognitions (a perception of oneself as powerless and ineffectual) and motives (a desire to obtain and maintain relationships with potential protectors and caregivers) remain constant.

Other examples of goal-driven "active dependency" emerge in the medical and academic arenas. For example, studies indicate that dependent women show shorter latencies than nondependent women in seeking medical help following detection of a serious medical symptom (e.g., a possible lump in the breast) in part because dependent women are more comfortable than nondependent women seeking help from physicians. Dependent patients also adhere more conscientiously than nondependent patients to medical and psychotherapeutic treatment regimens. Other investigations indicate that dependent college students are more willing than nondependent students to seek advice from professors and advisors when they are having difficulty with class material; as a result, dependent college students have significantly higher grade-point averages than nondependent college students with similar demographic backgrounds and comparable Scholastic Aptitude Test scores. All these examples not only represent active dependency-related behavior, but also represent instances of *adaptive dependency* (sometimes called *healthy dependency*)—dependency-related responding that enhances health, academic achievement, and social adjustment.

These findings should not be taken to suggest that all active manifestations of dependency lead to positive outcomes. On the contrary, dependent

elementary school students who make frequent contact with the teacher are perceived by classmates as being clingy and demanding, and these students tend to score low on peer ratings of sociometric status and high on self-report measures of loneliness. Other studies suggest that dependency-related insecurity can lead to difficulties in romantic relationships and increased conflict with college roommates. Dependent psychiatric patients tend to have a higher number of "pseudo-emergencies" than nondependent patients with similar diagnostic profiles and to overuse medical and consultative services when hospitalized, a pattern also displayed by dependent nursing home residents.

In addition—and perhaps most surprisingly—studies consistently show that highly dependent men are at significantly increased risk for perpetrating domestic partner abuse in part because these men are extremely fearful of being abandoned by their partner. As a result, they become hypervigilant, overperceiving abandonment risk and becoming jealous of even casual contacts between their partner and other men. When more appropriate and adaptive social influence strategies (e.g., ingratiation, flattery) are ineffective in drawing the partner closer and persuading her to sever ties with potential rivals, some dependent men may, as a last resort, become emotionally and physically abusive.

Conclusion

In certain ways, the evolution of research on interpersonal dependency has paralleled the broader changes taking place in the study of human relationships during the past 80 years. What was once conceptualized as a personality pattern that manifested itself consistently across contexts and settings has come to be seen in a more nuanced way as a set of beliefs and behavioral predispositions that may be expressed differently depending on the opportunities and constraints characterizing different situations. What was once conceptualized primarily in terms of expressed behavior has come to be understood in terms of the complex interplay of underlying cognitive, motivational, and affective processes. Like many personality traits that were initially conceptualized as reflecting flaws or deficits in functioning, interpersonal

dependency has come to be seen as a personality style that can impair adjustment in certain ways, but enhance it in others.

INTERPERSONAL INFLUENCE

Interpersonal influence (also known as social influence) has occurred whenever the actions of one or more individuals influence the behavior or beliefs of one or more other individuals. Relationships thrive or decay according to how well the participants agree with one another about important decisions. Some agreements just luckily happen, but many of them are the result of the participants influencing one another. Knowing the

principles described next will make one a better practitioner of influence and also more aware of how one is being influenced. This entry discusses the two major forms of interpersonal influence, followed by an examination of tactics used by compliance professions, such as salespeople.

Informational and Normative Influence

Imagine a long line of people walking down a road toward a crossroad where they must go either left or right. You are standing on a hill watching as every single person goes to the left. You can see no reason for this because the road to the left does not look any more promising than the road to the right. You would probably assume that all these people had information that you didn't have—perhaps a concert is to take place on the road to the left. If you joined the line of people, you would probably also go to the left, making you the target of an instance of interpersonal influence known as *informational social influence*. In this type of social influence, you assume that the behaviors, beliefs, and opinions of others are based on some sort of correct information, and so you go along unless you have information to the contrary or some reason to doubt the motives of the other people. This type of influence is pervasive and is necessary for survival. To not take cues from others would be to ignore much of the information that is available about the world. When you seek the views of experts, such as movie critics or religious leaders, you are also seeking informational social influence, as you are when asking the advice of a trusted friend.

Sometimes, however, there is a conflict between what other people do or believe and what we see as correct or appropriate for ourselves. In the example of the crossroad, you may discover that the group playing the concert is one you don't like very much, and you start to turn right to look for a restaurant rather than go to the concert. Your friends, however, urge you to join them at the concert, implying that they may not value you as a friend as much if you don't go with them. If you go along with them to maintain the friendship, you have been the target of *normative social influence*, or conforming to the expectations of others in

order to be socially accepted. As the late Speaker of the U.S. House of Representatives, Sam Rayburn, used to tell new members of the House, you have to “go along to get along.”

Influence Tactics of Compliance Professionals

Robert Cialdini, a social psychologist, immersed himself for nearly 3 years in the world of compliance professionals, such as salespeople, fundraisers, and advertisers to discover what they were taught to do to influence people. He found that the majority of tactics fall into six categories, each governed by a psychological principle. Each of these principles—reciprocation, consistency and commitment, social proof, liking, authority, and scarcity—is discussed in the following sections.

Reciprocation

We are taught from childhood that we should give something back to people who give us something. This rule of reciprocation is important for society because it allows us to help people who need it and to expect that they will help us when we need it. However, the rule also permits deliberate interpersonal influence. For example, if a husband wants his wife to do something for him, he can give her a small gift or a compliment, or he can perform some task that is normally her responsibility. Before she has forgotten his benevolence, he can ask her whether she would mind cooking dinner for his poker group. The favor makes it more likely that she will acquiesce.

Reciprocation can also apply to concessions. If a wife refuses to cook dinner for her husband’s poker group, he can gracefully accept this refusal. This is his concession, and now she owes him one. When the husband asks whether she will serve drinks and appetizers, she is more likely to concede to this request. Not only did she “owe” him a concession, but the serving of drinks and appetizers is a small effort compared with serving dinner. Salespeople will often offer their most expensive model first to make the other models seem less expensive.

Consistency and Commitment

People want to be consistent from one time to another and from one situation to another. Thus,

if a person agrees to a small request to pick up a friend’s mother from the airport, that person is subsequently more likely to agree to a larger request to provide housing for the mother for a month. Agreeing to the small request has caused the person to change her self-image to that of a person who takes care of the mothers of friends. This is known as the “foot-in-the-door technique” (after which the door can be opened all the way). The initial commitment will have a greater effect if it is public, effortful, and freely chosen. If it is public, a person needs to prove to the world that he is consistent; if it is effortful, a person needs to justify that effort by believing that being nice to mothers is important; if it is freely chosen, a person must have been committed all along to motherhood.

Salespeople sometimes use a technique called “throwing a low-ball,” in which they agree to sell a product such as a car for an excellent low price. After forms are signed and financing is arranged, someone discovers that a mistake has been made and that the cost is actually several hundred dollars more than agreed. The buyer has become sufficiently committed to buying the car that he usually will pay the extra money to complete the purchase.

Social Proof

This is the same as the informational social influence discussed earlier—the tendency to see a behavior in a particular situation as the best behavior if we see other people performing it. People turn left at the crossroad because they assume that other people turning left know what they are doing. This is most likely to occur when these other people are similar and when the situation is ambiguous. A particularly interesting example of this is bystander intervention in emergencies. Suppose that you are turning left at the crossroad when someone in front of you suddenly slumps to the side of the road. It isn’t clear whether the person is resting, slightly ill, or seriously in trouble. Because it is ambiguous, you look to the other people to determine the appropriate course of action, just as they are looking at you for cues about what to do. If nobody moves to help the person, a belief grows that the person doesn’t need help, and thus no one helps. If you were alone on the road and saw the

person slump down, you would probably at least ask him whether he needed help. The presence of other people has actually made it less likely that anyone will help.

Liking

People are more likely to be influenced by others they know and like, and there are several factors that help determine liking for another person. People like those who are physically attractive. They imbue attractive people with all sorts of positive traits, from intelligence to morality, that make them seem trustworthy, and in addition they want to please attractive people. People like those who are similar to them in any possible way, whether it is having the same birthday, voting for the same political party, or rooting for the same sports team. People like those who compliment them or say they like them. People like others more as they become more familiar perhaps just because they ride the same bus. People like those with whom they have to cooperate with to get a job done. Of course people also like others for their particular personal qualities, such as having a good sense of humor, a questing mind, or a kind disposition.

Regardless of the basis of liking, individuals are more likely to go along with others they like (in order to get along), and they are more likely to trust these liked others' view of the world. In short, those who are liked can exert both more normative and more informational social influence.

Authority

In one of the most dramatic experiments in psychology, conducted by Stanley Milgram, participants were told that they were the teachers in a learning experiment and that they had to deliver what they were told were increasingly painful electrical shocks to the learner whenever he made a mistake. As the shocks grew more and more dangerous, the learner (actually a confederate) screamed with apparent pain, complained of a heart condition, and finally stopped responding altogether. If the "teacher" protested and tried to stop delivering the shock, he was told by the experimenter in a white lab coat that he had no choice; he had to continue administering the shocks. Astonishingly, many of the teachers continued to

administer shocks on command even after the learner had apparently passed out or had a heart attack. Actually there was nothing to stop the teacher from simply walking away, except the great power that apparent authority has on us. There are many real-life examples of destructive obedience to authority. Nurses will sometimes give what they know to be a dangerous dose of a drug if so ordered by a doctor, soldiers will kill innocent women and children, and individuals will even kill themselves when ordered to by a charismatic cult leader.

Yet society values obedience. Obedience keeps society running smoothly, with drivers staying within the speed limit, not taking the belongings of others, and doing all the other orderly things that society expects people to do. Children are praised for being obedient, but seldom are praised for disobeying destructive authority, creating a dangerous tendency not to question authority at all.

Scarcity

This principle is that opportunities seem more valuable when they are less available. To persuade shoppers to buy now, retailers will limit the apparent number of units available for sale or limit the amount of time a sale will go on. People will pay vast amounts of money for objects that are rare. Jack Brehm's theory of psychological reactance states that when people's free choice to do something is threatened, they react against this by trying to exercise their choice or increasing their desire for the threatened object. For example, Romeo and Juliet's love was doomed and therefore more intense because of the feud between their families. Riots and civil disturbances often occur when a group's position is improving but suffers a momentary reversal; the improvement makes the reversal more painful because of the loss of freedom. The singer Mickey Gilley wrote that "all the girls get prettier at closing time" because time is running out and freedom to make a connection is threatened. When a book or movie is censored, demand rises because the freedom to read the book or see the movie is being threatened. An interesting exercise for the reader would be to think of an influence situation in which all of these six compliance tactics could be used in combination. Is there an order in which they would work best?

INTERPERSONAL PROCESS MODEL OF INTIMACY

The Interpersonal process model of intimacy, initially proposed by Harry Reis and Phillip Shaver, describes the transactional process by which intimacy between two individuals is developed and maintained over the course of interactions. The interpretation, assimilation, and expectation of repeated intimate interactions give rise to more global judgments about the relationship, such as satisfaction, commitment, and trust. The model conceptualizes intimacy as a personal, subjective (and often momentary) sense of connectedness that is the outcome of a dynamic, interpersonal process. This entry first provides a description of the specific components of the Interpersonal process model of intimacy, describes factors that may interact with the various components, and then briefly discusses the benefits of thinking of intimacy in this way.

Components of the Interpersonal Process Model

Self-disclosure, partner responsiveness, and perceived partner responsiveness are the key elements that foster the development of intimacy. According to this model, the intimacy process is typically initiated with *self-disclosure*, whereby one partner, “the discloser,” shares personal information

that reveals core aspects of the self to their partner, “the listener.” This information can be verbal or nonverbal and affective/evaluative (e.g., “When we spend time together, I feel more and more connected to you”) or more factual (e.g., “My longest lasting relationship was 2 years”) in nature. Research suggests that disclosures of emotional information lead to greater feelings of intimacy than disclosures of factual information. This could be because emotional information serves to communicate specific needs and vulnerabilities to one’s partner, and by revealing this information, those needs and vulnerabilities are more likely to be perceived, acknowledged, and/or met. The process of self-disclosure is an integral part of the intimacy process because it provides an opportunity for one’s partner to respond and convey caring and understanding.

The second part of the model, in which the listener responds to the self-disclosure, is termed *partner responsiveness*. Once the discloser has revealed personal information, the listener then addresses the communications of the discloser. For the intimacy process to continue, the listener must emit behaviors and expressions that convey acceptance, understanding, validation, and caring toward his or her partner. Partner responses are most effective in contributing to intimacy when they are sincere and immediate and show a genuine understanding of and respect for the discloser’s needs. These partner behaviors and expressions are attempts at responsiveness.

An important element in the development of intimacy depends on the discloser’s perception of responsiveness from their partner. In the ideal case, the discloser will interpret his or her partner as responsive and feel that his or her needs have been met. Judgments about the degree of understanding, validation, and care in a partner’s response constitute the discloser’s view of *perceived partner responsiveness*. It is possible that, although the listener may intend to be responsive, the discloser may not feel like the partner was responsive to him or her. The discloser’s interpretation of their partner’s response is therefore a critical component in the development of intimacy. Occasionally the reverse—the listener’s response is not intended to be responsive, yet is perceived as such—may be true as well, although this is less common. The perception of partner responsiveness acts as a

mediating variable by which self-disclosure and partner responsiveness influence intimacy. Perceived partner responsiveness is theorized to be a central component both among interpersonal relational processes (e.g., trust, love, commitment) and intrapersonal processes (e.g., self-esteem, personal goal pursuit).

Individual and Contextual Factors

Each step of the Interpersonal process model is affected by a variety of individual and contextual factors. For example, individual differences, such as personality traits, goals, needs, and fears, may influence the degree to which one chooses to self-disclose, as well as how much and what type of information an individual chooses to share. Similarly, partner responsiveness has been shown to be influenced by extraversion, as well as the degree of motivation in developing intimacy with one's partner. In addition, the extent to which one construes one's partner's response as appropriately meeting one's needs and reflecting the disclosed information will vary from person to person. Individuals high in rejection sensitivity anxiously expect and readily perceive rejection from their partners, leading them to perceive unresponsiveness from their partners in interactions where a more objective observer may detect responsiveness. The attachment style of the discloser will also affect whether the listener's response is interpreted as responsive to his or her needs. For example, individuals with an insecure attachment style, particularly those high in anxiety and avoidance, have been found to interpret responses from their partner as more negative than would be judged by objective observers.

There are selected gender differences in intimacy across types of personal relationships. Some studies show that, although men and women tend to agree that conversations including personal self-disclosure lead to intimacy in same-sex friendships, men enact these behaviors less often than women. Other studies have found that gender differences do exist in the way intimacy is thought of by men and women in romantic relationships. When describing intimate experiences, men more often report sex or physical contact as a key feature of intimacy. Women tend not to refer to sex in describing their

intimate experiences, and, in fact, some report the absence of sex as contributing to an intimate interaction. The magnitude of identified gender differences tend to be small to moderate, suggesting that there may be more overlap than difference between men and women when it comes to intimacy and its related component processes.

There are also cultural variations in defining and operationalizing intimacy based on differences in constructions of self and social realities. The interpersonal process model of intimacy, which primarily assumes a Western cultural context for intimacy, emphasizes the self and describes the key ingredient of intimacy development as an individual being understood, validated, and cared for by his or her partner. Other cultures that focus less on independent, individual identities and more on interdependent, communal identities may consider relationship- or group-fulfilling obligations to be linked to intimacy, rather than perceived partner responsiveness. For example, partners in West African communities emphasize fulfilling mutual familial obligations and deemphasize individual romantic intimacy. However, the divide between individualistic and communal societies in relational intimacy is not always clear cut; in some individualistic cultures, individualism may not be conducive to building intimacy in romantic relationships. Russian entrepreneurs, who were characterized as individualistic, reported sex and love as being taboo topics of discussion even within the context of romantic relationships.

The Interpersonal process model provides several benefits for understanding intimacy in personal relationships. Rather than conceptualizing intimacy as a unitary construct, the Interpersonal process model breaks down the various components that lead to intimacy. This is particularly useful because it allows for intimacy to be examined as a process and not simply as an outcome. Understanding the process that leads to the development of intimacy enables researchers to view this interpersonal experience as it unfolds over time. The process model also allows intimacy to be distinguished from related but different constructs, such as satisfaction and love. By examining the individual components of intimacy development, not only can the field gain a better understanding of the process, but, by breaking it down, researchers and clinicians are also better

able to locate problems or collapses in the process and attend to them. Although there are other ways of conceptualizing intimacy, the Interpersonal process model offers a unique window into the underlying process by which relationship partners feel connected.

INTERPERSONAL PSYCHOTHERAPY

Interpersonal psychotherapy (IPT) is a time-limited, structured psychotherapy originally developed by Gerald Klerman and colleagues in the 1970s for the treatment of depression. IPT aims to reduce patients' psychological distress and symptoms by improving their interpersonal functioning. This entry provides an overview of IPT, a description of the treatment structure, and a review of the clinical populations that appear to benefit from interpersonally focused treatment.

IPT's Fundamental Premise

IPT is based on a biopsychosocial model of psychiatric illness. The biopsychosocial model identifies converging biological, psychological, and social factors that over time have contributed to the patient's current functioning and distress. Although IPT acknowledges the influence of the biological and psychological domains, the primary focus of IPT is on identifying the patient's current interpersonal difficulties. The basic premise underlying IPT is that there is a bidirectional association between an individual's interpersonal functioning and his or her psychological well-being. For example, when individuals become depressed, they may have feelings of low self-worth and may isolate themselves from others. This social withdrawal, in turn, can have negative effects on their mood. The IPT therapist helps patients to break out of this cycle by reconnecting with others and effectively communicating their interpersonal needs.

IPT Treatment Structure

IPT consists, on average, of 12 to 16 weekly 1-hour sessions. Typically, IPT is conducted in outpatient settings with individuals. However, IPT may also be conducted with couples and groups. The primary objectives of IPT sessions are to improve patients' interpersonal functioning and alleviate their symptoms. The treatment consists of various phases, including an *assessment phase* (that determines whether IPT is appropriate for the patient), an *initial phase* (that focuses on identifying the patient's interpersonal landscape and primary problem area), a *working phase* (that employs therapeutic strategies directly related to the identified problem area), and a *concluding phase* (in which the patient's treatment progress is reviewed and plans are made for coping with future problems that may arise). At the conclusion of treatment, the patient and therapist discuss whether a *maintenance phase* of IPT would be beneficial.

Assessment Phase

In the *assessment phase*, the therapist conducts a thorough diagnostic interview, identifies the patient's current interpersonal relationships, and

explores the degree to which the patient perceives a connection between his or her interpersonal functioning and psychological problems. The assessment phase concludes when the therapist and patient agree to proceed with a specified course of IPT.

Initial Phase

The initial phase of IPT usually occurs during the first three sessions. In this phase, the therapist gathers specific information about the patient's interpersonal landscape by conducting an Interpersonal Inventory. The Interpersonal Inventory includes a detailed review of the patient's key relationships and the strengths and shortcomings of those relationships from the patient's perspective. Using this information, the patient and therapist determine which of the patient's current interpersonal problems appear to be most relevant to the patient's current psychological problems.

The Four IPT Problem Areas

IPT encourages the selection of one treatment target from among four interpersonal problem areas: role transition, interpersonal conflict, loss/grief, and interpersonal sensitivity. When *role transition* is selected, the therapist helps the patient to identify the changing social role, such as parenthood or retirement; acknowledges the distress that can accompany the transition, and problem solves strategies to increase the patient's likelihood of success in adopting the new role. When the therapeutic focus is on *interpersonal conflicts*, the therapist uses IPT techniques, such as role-play and communication analysis, to facilitate the patient's understanding of how his or her communication patterns may contribute to his or her relationship difficulties. Once maladaptive patterns have been identified, the therapist helps the patient to resolve his or her interpersonal disputes by clearly expressing his or her interpersonal needs to others and responding productively to significant others' unmet needs in return. *Loss and grief* are also salient problem areas. Identifying and addressing losses in treatment reduce the likelihood that they will serve as triggers for a psychiatric relapse. Finally, some patients suffer from *interpersonal sensitivity*, or chronic problems relating to others, that can hinder

their interpersonal functioning and lay the foundation for pervasive relationship difficulties. When interpersonal sensitivity is selected, the therapist's main objectives are to modify the patient's dysfunctional expectations about relationships, establish and maintain close relationships with others, and develop a network of support that can adequately address the patient's interpersonal needs.

Working Phase

The selected IPT problem area focuses the treatment during the working phase. In the working phase (Sessions 4–12), the therapist and patient work collaboratively to improve the patient's ability to communicate his or her needs to others, modify distorted relationship expectations, and build or better utilize social supports.

Concluding Phase

During the *concluding or termination phase* of IPT (Sessions 13–16), the focus is on preventing relapse of the patient's psychiatric symptoms by maintaining positive interpersonal relationships. In these final sessions, the therapist reinforces the skills acquired during treatment and discusses a relapse plan that highlights how interpersonal crises and insufficient social support can trigger relapse.

Maintenance Phase

When a *maintenance phase* is indicated, the patient and therapist contract for an additional series of IPT sessions that focus on the patient's original problem area or that identify a new interpersonal problem that the patient wants to address in therapy.

Applications

IPT is a well-established treatment for depression with a strong body of evidence spanning decades of research. Findings from controlled clinical trials suggest that IPT is an effective treatment for individuals with major depression, postpartum depression, dysthymia, and bulimia. Perhaps one of IPT's most notable strengths has been its adaptability across a wide range of ages (from adolescence to

later life) and psychiatric disorders. In recent years, IPT has been modified to treat bipolar disorder, social anxiety, and post-traumatic stress disorder. Although additional research is required to establish IPT's efficacy with these diverse disorders, findings to date have been promising. In contrast, preliminary investigations indicate that IPT may not be as effective as traditional substance abuse treatment for patients with cocaine or opiate dependence. Further studies are needed to establish for whom and in what settings IPT is most appropriate.

INTERPERSONAL SENSITIVITY

Interpersonal sensitivity (IS) can refer to both how well one "reads" other people and how appropriately one responds. Thus, it might be said that it is interpersonally sensitive to both recognize when one's spouse is sad and respond sympathetically. This entry, however, limits the definition to the "reading" aspect—in other words, accuracy in processing or decoding another's behavior or appearance. IS has been studied for many years in a variety of different ways. This entry describes different kinds of IS, how IS is measured, and how IS correlates with other variables, especially those that are relevant to interpersonal relationships.

Definition and Measurement of IS

In daily life, people constantly notice the behavior and appearance of others. Behaviors may be

verbal or nonverbal. Nonverbal behaviors include facial expressions, direction of gaze, head shaking and nodding, body movements and postures, hand and arm gestures, vocal qualities (such as pitch or rhythm), and interpersonal distance, among others. Appearance can refer to physiognomic features, such as facial features or body shape, or to details of dress, hair, jewelry, and so forth. As examples of this kind of accuracy, one might notice that one's spouse is not speaking much at breakfast, one might recognize an acquaintance at a distance from the way he walks, or one might remember that a particular friend likes to wear hoop earrings. This kind of IS is typically measured by having the test taker interact with someone or watch a videotape of people interacting and then testing the accuracy (without forewarning) of what he or she recalls about the others' behaviors or appearance.

Of course, people also draw conclusions based on what they have noticed, and they do this countless times per day, often without much conscious awareness. Is this car salesman telling the truth? Does my mother really like her Christmas gift? Is that stranger going to attack me? Is that cute person across the room interested in me? Inferences based on the cues a person perceives might or might not be correct. Most research on IS is concerned with accuracy in recognizing emotions or other affective states, accuracy in judging personality, and accuracy in distinguishing truth from deception. Accuracy for judging many other kinds of content has been, or could be, measured as well, including status and dominance, intelligence, mental and physical health, age, geographic origin, ethnicity, and sexual orientation.

Accuracy of interpersonal judgment is measured by researchers in a variety of ways, but all methods have in common that they require a criterion against which judgments can be scored as right or wrong. Thus, for example, on a test of judging the extraversion of a set of persons (targets) shown on videotape, the researcher must have a good measure of the targets' actual extraversion. IS tests vary in how many target persons are shown, how many different kinds of content are represented, and what cue channels are included. As an example, such a test might present six targets, each expressing four different emotions using facial expressions, for a total of 24 test items. On some IS tests

perceivers judge a full audiovisual stimulus, whereas on others they judge single channels such as face only or voice only. IS test stimuli are typically short, ranging from less than a second to a few minutes in duration. Sometimes accuracy can be high, even when exposure to the stimulus is brief, although this depends on what is being judged. Accuracy levels depend on many factors and are notably low for judging deceptiveness and high for judging prototypical facial expressions of emotion (e.g., happy, sad, fearful).

Most IS research is based on administering tests using recorded stimuli such as described earlier, but some research is based on judgments made during or right after a live interaction. In one such method, known as the empathic accuracy paradigm, a person watches a video replay of one's interaction with a partner and makes inferences about the partner's thoughts and feelings, which are scored against the partner's self-described thoughts and feelings. Partners may be previously unacquainted or acquainted. Some research has examined accuracy of husbands' and wives' perceptions of each other while deliberately trying to convey different emotions. However, this research paradigm is often complicated by the fact that a person's decoding ability is often confounded with his or her partner's encoding (expression) ability. Going back to the spouse scenario, if you notice that your spouse is sad when he or she comes home from work, it could be for one of three possible reasons: (1) you have high IS and accurately picked up on your spouse's nonverbal cues even if they were subtle; (2) your spouse's cues were obvious and easy to interpret, so credit for your accuracy goes to the expression, not to your skill in decoding; or (3) some combination of skilled encoding and decoding. For this reason, most IS tests are standardized to solely focus on the decoding portion of IS.

Although in daily life people often exercise their IS with others whom they already know, in the testing literature, perceivers are typically unfamiliar with the targets, and therefore the research literature is mainly concerned with accuracy of drawing first impressions of strangers. However, to the extent that IS is a skill possessed by an individual, it is likely that skill in judging strangers is related to skill in judging people with whom one has a relationship. Some research suggests that

IS may be slightly enhanced by greater familiarity with the person being judged.

Psychosocial Correlates of IS

Researchers have generally considered IS to be a valuable skill and have hypothesized that the ability to make accurate inferences about other people based on minimal information is advantageous. What does research tell us about other traits and attributes that are correlated with IS? The following summary is based on meta-analyses as well as individual studies.

Personality Correlates

Research shows IS to be positively associated with a number of personality traits, some of which have clear implications for interpersonal relationships—empathy, affiliation, extraversion, dominance, conscientiousness, openness, tolerance for ambiguity, need to belong, and internal locus of control. IS is negatively related to the personality traits of neuroticism, shyness, depression, and an insecure attachment style. Individuals high in IS are also less likely to be prejudiced against minority groups. The high-IS individual thus possesses personality characteristics suggestive of healthy intra- and interpersonal functioning.

Social Competencies

IS is also connected to various social competencies that would assumedly lead individuals to develop and maintain healthy relationships with others. IS seems to be apparent to others in one's environment because individuals higher in IS are rated by acquaintances as more interpersonally sensitive. Higher IS also is associated with a better ability to judge the IS of a friend. Higher self- and acquaintance ratings of social and emotional competence are also positively related to IS, and IS predicts competence in workplace and clinical settings.

Relationship-Specific Correlates

There has also been research that specifically examines the relation between IS and relationship quality. Individuals higher in IS report having

higher relationship well-being, more positive relations with their roommate(s), better marital adjustment (especially among men), and an overall more positive rating of the quality and quantity of their same- and other-sex relationships. In all likelihood, failures of IS contribute to problems between relationship partners.

Gender, Knowledge, and Motivation

Many studies have found that women are better at judging the meanings of interpersonal cues than men are, especially when the test measures accuracy in recognizing emotions and other affective cues. Women are also better at remembering another person's appearance and nonverbal behavior, and they possess more explicit knowledge about the meanings of nonverbal cues, as measured with a paper-and-pencil test. These findings have implications for relationships, although further research is needed to understand the impact of these sex differences on communication processes and relationship outcomes. The sex differences in IS, and one's level of IS in general, could be related to both motivation (how hard one tries when taking an IS test) and knowledge (how much one knows about the meanings of cues). It is not yet clear what the relative contributions of these factors are.

Ambiguities About Causation

The literature reviewed previously confirms the hypothesis that IS is associated with valuable aspects of personality and social functioning. However, because the research is based on correlations, it is not clear what theoretical account should be made. So, for example, the finding that high-IS people tend to choose more people-oriented careers could mean that IS leads a person to choose such a career or that experience in such a career improves a person's IS, or both. Furthermore, a third variable that is correlated with both variables could account for such a correlation. For example, if extraverted people score higher on IS and also choose more people-oriented careers, then controlling for it might eliminate the association between IS and career choice. Such a demonstration would not, however, settle questions about causation; it would merely add insight into possible processes.

The possibility that experiences influence the development of IS is suggested by studies showing higher IS in individuals who have a prelinguistic toddler (compared with matched individuals without such a toddler) are athletes or dancers, have prior musical training, come from less emotionally expressive families, and have traveled abroad more. A longitudinal study by Holly Hodgins and Richard Koestner suggests that optimal development of IS may depend on a combination of both the temperament of an individual as well as the situation, or environment, to which the person is exposed.

The possibility that a person's level of IS may produce consequences in addition to being a consequence of earlier experiences is suggested by research showing that individuals higher in IS receive higher salary raises due to salesmanship, receive higher evaluations by superiors in several different occupations, learn nonsense words faster from a partner, achieve more advantageous negotiation outcomes, earn higher satisfaction ratings from patients (among physicians), and experience better adjustment to U.S. culture (among foreign students).

INTERRACIAL AND INTERETHNIC RELATIONSHIPS

An interethnic relationship is a relationship in which the partners differ in their presumed biological and/or cultural heritage. An interracial relationship is a relationship in which the partners differ specifically in their presumed biological heritage. Thus, an interracial relationship is one type of interethnic relationship. Other types of interethnic relationships include, but are not necessarily limited to, interreligious and international relationships.

Like many other topics within the field of personal relationships, the topic of interethnic relationships has been researched most heavily within the United States. Given the problematic nature of race relations throughout the history of the United States, it may not be surprising that interracial relationships have received far more coverage in the field of personal relationships than have interreligious or international relationships. This disparity of coverage is all the more evident when one considers that, among all interethnic marriages in the United States, interracial marriages are least frequent.

Among the general public in America, romantic interethnic relationships tend to be stigmatized to a greater extent than do platonic interethnic relationships. In turn, romantic interracial relationships tend to be stigmatized to a greater extent than do romantic interreligious relationships or romantic international relationships. At one time in their histories, three quarters of all American states enacted laws banning interracial marriage. It was not until 1967, in *Loving v. Virginia*, that the U.S. Supreme Court struck down all remaining state anti miscegenation or anti-“race-mixing” laws as unconstitutional.

From 1970 to 2000, the percentage of interracial marriages in the United States rose from 1 to 5 percent. Despite the increase in the proportion of interracial marriages, the fact remains that, as a whole, individuals overwhelmingly marry within their racial groups. The only major racial group among whom a majority of persons intermarry is Native Americans (among both sexes, more than 55 percent of Native Americans intermarry).

Popular and academic discussions of interracial marriage often focus on African American–European American intermarriage, especially African American male–European American female intermarriage. However, the most common type of interracial marriage is European American–Asian American (and especially European American male–Asian American female) intermarriage. In fact, European American–Asian American intermarriages outnumber African American–European American marriages by nearly a 2:1 ratio (14 percent vs. 8 percent). The prevalence of European American–Asian American marriages over African American–European American marriages has been consistent since the 1970s.

Despite the attention that scholars and laypersons alike have given to African American male–European American female marriages, African American female–European American male marriages outnumbered African American male–European American female marriages until the 1960s. Prior to the civil rights movement, anti-miscegenation laws tended to be enforced more rigorously against African American male–European American female unions than against African American female–European American male unions, especially in the South. It was not until the 1970s that African American male–European American female marriages outnumbered African American female–European American male marriages.

The best-known studies of interracial marriage in the United States are (a) a study of approximately 40 African American–European American couples in Chicago by Ernest Porterfield during the 1970s, and (b) a study of approximately 20 African American–European American couples in Minneapolis by Paul Rosenblatt, Terri Karis, and Richard Powell during the 1990s. Results of both studies contradicted the once-dominant view, expressed by Robert Merton in the 1940s, that exchanges involving different types of social status

accounts for patterns of African American–European American marriage (e.g., affluent African-American men are in a position to exchange their high-achieved status with European American women’s high ascribed status). Instead, results of the Porterfield and Rosenblatt et al. studies indicates that exchanges involving the same type of love (i.e., romantic love) account for patterns of African American–European American intermarriage.

The studies by Porterfield and by Rosenblatt et al. were primarily qualitative and involved relatively small samples, whereas a subsequent study by Stanley Gaines and his colleagues during the 1990s was primarily quantitative and involved a relatively large sample of approximately 100 couples (roughly half of which involved African American–European American pairs) from the United States and beyond. Three quarters of the Gaines et al. sample consisted of interracial cohabiting (and primarily married) couples. Results of the Gaines et al. research suggested that exchanges involving love, as well as exchanges involving esteem, promote the maintenance of interracial relationships. Moreover, results of the Gaines et al. research contradict popular and academic stereotypes concerning relationship dynamics among interracial couples (e.g., interracial couples are stereotyped as involving a one-way flow of esteem from wives to husbands).

Despite the stereotype-challenging results reported by Porterfield, by Rosenblatt et al., and by Gaines et al. regarding relatively happy interracial couples, a glance at divorce statistics (i.e., 50 percent divorce rate for couples in general vs. 67 percent divorce rate for interracial couples in particular) indicates that interracial couples face special struggles in trying to maintain their relationships. With regard to African American–European American marriages, parents of European American wives are especially likely to ostracize the wives, husbands, and offspring alike. This hostility from family members often occurs in addition to hostility from friends, acquaintances, and strangers. In some instances, interracially married spouses have only each other as support persons; and if spouses fail to support each other, then the marriages may be left in a precarious position.

One confound regarding the link between interracial marriage and increased likelihood of divorce is that interracial marriages are more likely to be

second marriages than are intraracial marriages. Regardless of racial pairing, second marriages are more likely to end in divorce than are first marriages. It is not clear whether interracial marriages would remain at higher risk for divorce if spouses’ number of previous marriages were taken into account.

Lost in the discourse regarding divorce statistics is the fact that many interracial marriages persist over time; the field of personal relationships could benefit from more systematic study of the factors that distinguish successful from unsuccessful interracial marriages. Published studies of interracial marriages have not tended to follow couples across time; longitudinal research is needed for relationship scholars to understand how interracial couples can defy the odds and maintain stable and satisfying marriages. The number of relationships studies on interracial marriages has not kept pace with the incidence of interracial marriages.

Just as the question “Would you want your daughter to marry one?” (typically limited to African American male–European American female relationships) implicitly suggests that parents of European American women should not encourage their daughters to marry African-American men, so too does the question “But what about the children?” implicitly suggests that interracially married spouses should not have children of their own. Unfortunately, the few studies that have examined relationship processes between interracially married spouses rarely, if ever, have examined relationship processes between the spouses and their offspring. Mixed-race children have long been stereotyped as biologically, socially, and psychologically ill adapted. However, virtually no evidence exists to support those stereotypes, and virtually nothing is known about the ways that parents can or do help mixed-race offspring cope with the often hostile society in which they live.

Throughout the present entry, the term *race* has been used uncritically. However, early in the 20th century, anthropologists had begun to question the utility of race as a social-scientific construct. By the end of the 20th century, psychologists similarly had begun to question the utility of race. For example, in a series of papers during the 1990s, Halford Fairchild and his colleagues called for an end to the use of the term *race* in psychology. Although the details of the controversy over the

utility of race are beyond the scope of the present entry, it is nonetheless worth noting that scholars' and laypersons' casual use of the term *race* has not helped (and, one might argue, has inhibited) academic and popular understanding of the dynamics regarding interracial relationships. Biological differences in spouses' skin color, hair color, and/or facial features, in and of themselves, do not explain the difficulties that interracial couples experience in trying to survive in the post-Civil Rights Era United States.

More research is needed regarding interracial relationships outside the United States. For example, even in the post-Civil Rights Era, the United States has posted some of the lowest interracial marriage rates among Western nations. It is not clear whether interracial marriages are more likely to survive in those Western nations whose histories of race relations have been less problematic than in the United States.

Also, more research is needed regarding interethnic relationships in general, within as well as outside the United States. For example, within the United States, Kozue Shibazaki and Kelly Brennan found that individuals who were in interethnic (and not necessarily interracial) dating relationships scored lower on self-esteem and ethnic identity than did individuals who were in intraethnic relationships; yet individuals in interethnic relationships scored as high on relationship expectations and relationship satisfaction as did individuals in intraethnic relationships. In a separate study within the United States, Regan Gurung and Tenor Duong found that individuals who were in interethnic (and, again, not necessarily interracial) dating relationships scored as high on self-esteem, ethnic identity, relationship expectations, and relationship satisfaction as did individuals in intraethnic relationships. The dissimilar results with regard to certain personality variables, in contrast to the similar results with regard to certain relationship variables, warrant further examination.

Finally, more research is needed on the prevalence of dating, as distinct from marital, interethnic relationships. Data from the 2000 U.S. Census reveal that approximately 10 percent of all unmarried cohabiting couples are interracial. Given that interracial couples constitute a higher proportion of unmarried cohabiting couples than of married

couples, one might reasonably assume that interracial couples constitute a still higher proportion of dating couples than of married couples. However, definitive statistics regarding the prevalence of interracial and other interethnic dating relationships are not readily available.

In conclusion, as interracial and other interethnic relationships continue to grow at a faster rate than do intraethnic and other intraracial relationships (at least in the United States), the quantity and quality of research on interethnic relationships ideally will grow as well. The theoretical fragmentation and, in some instances, lack of theory that characterizes research on interethnic relationships might contribute to the marginalized status of interethnic relationships within the larger field of personal relationships. Clearly, the ethnic diversity that is part and parcel of research on interethnic relationships is valuable in its own right. By the same token, a coherent theoretical foundation is likely to enhance the value of research on interethnic relationships.

INTERRACIAL FRIENDSHIPS IN ADOLESCENCE

Scholars have long viewed contact (or lack thereof) between different groups as an indicator of the social and geographic distance between them. They have also considered contact between different groups to be an important source of influence on attitudes and behavior. *Brown v. Board of Education*, which ended the legal segregation of schools, was based on the assumption that interracial contact is beneficial to the self-esteem and achievement of Black youth. This 1954 Supreme Court decision, and the decline in school and residential segregation that followed it, have motivated a number of studies on the causes and consequences of interracial friendship in adolescence. This entry summarizes the findings of recent studies on this topic and points to important directions for future research.

Adults and adolescents alike tend to befriend same-race others due to opportunities for same-race contact (propinquity) and preferences for contact with those who are similar to them (homophily). Studies typically assess preferences for same-race contact indirectly by examining patterns of interracial friendship after taking into account propinquity. Such an approach requires researchers to have information on the race of individuals who befriend each other, in addition to the racial composition of their social contexts, such as schools and workplaces.

Research focusing on friendships between adolescents of different racial groups has proliferated in the past decade largely due to the advent of the National Longitudinal Study of Adolescent Health (Add Health). Add Health is an ongoing school-based study that was initiated by affiliates of the Carolina Population Center in the mid-1990s; the project has already interviewed a subset of respondents from its original sampling frame at three different points in time and is currently in the field collecting a fourth wave of data. Many of the Add Health studies on interracial friendship (and interracial romantic relationships) were conducted by Grace Kao and her colleagues with funding from the National Institute of Child Health and Human Development.

Importantly, Add Health administered a questionnaire to the student bodies of more than

100 schools in the United States. Including school rosters, the questionnaire asked students to identify their five best friends of each sex and to distinguish their very best friend. This design allows researchers to identify the characteristics of any friends nominated who attended the same school and also completed the questionnaire. Specifically, they can compare the self-reported race and ethnicity of students in friendship dyads. Surveys like Add Health offer more realistic estimates of interracial friendship than ones that simply ask respondents whether they have any friends of a different race.

Patterns of interracial friendship differ considerably according to race. Using data from Add Health, Ted Mouw and Barbara Entwisle find that 14.9 percent of friendships identified by Whites are interracial, whereas the comparable estimates for Blacks, Hispanics, and Asians are 28.6, 66.5, and 57.7 percent, respectively. These dramatic racial differences are partly a reflection of the relative sizes of different racial groups within schools. Whites, for instance, have fewer opportunities and need for interracial contact than minorities because they typically attend schools in which they are the majority rather than the minority. At the same time, adolescents' actual likelihood of interracial friendship falls considerably below their expected likelihood on the basis of opportunities for contact, regardless of their race.

Many studies of interracial friendship among youth identify all potential friendship dyads in a school and examine the likelihood of actual friendship as a function of their similarity on several characteristics, including race, socioeconomic background, and academic orientation. Taking into account school-level propinquity, these studies demonstrate that the actual likelihood of a friendship among potential dyad pairs is significantly greater if they include students of the same race, even after taking into account similarity on other characteristics. They also suggest that the line dividing Blacks and non-Blacks is especially difficult to cross. Studies that additionally include measures of opportunity structure for friendship formation within a school, such as residential segregation and tracking, also find evidence of same-race bias.

Social science studies in general have relied on a measure of race that divides respondents into mutually exclusive categories on the basis of their racial

and Hispanic identification: White, Black, Hispanic (regardless of race), Asian, and Native American. More recently, studies have moved beyond conventional measures of race, acknowledging the fact that Hispanic is not really a separate racial category, that racial groups are comprised of several different ethnic groups, and that a growing number of individuals identify with more than one racial group. Studies exploring the intersection between race and ethnicity in adolescent friendship find that White Hispanics are more likely to nominate Whites and White Hispanics as friends than Blacks and Black Hispanics and, similarly, that Black Hispanics are more likely to befriend Blacks and Black Hispanics than Whites and White Hispanics.

There is also evidence that Hispanic and Asian adolescents show a preference for same-ethnic peers over different-ethnic (same-race) peers and a preference for different-ethnic (same-race) peers over different-race peers. For instance, a Chinese adolescent has a greater chance of befriending a Chinese peer than a Korean peer, but they have a greater chance of befriending a Korean peer than a White peer. Patterns of friendship for multiracial adolescents differ according to racial background and are quite complex.

A smaller number of studies have examined the dynamics of interracial friendships in adolescence. These studies suggest that, in comparison to same-race relationships, interracial relationships are lower quality, as evidenced by their number of activities, stability, and reciprocation. Using data from Add Health, Elizabeth Vaquera and Grace Kao find that 54 percent of interracial friendships are reciprocated, in comparison with 66 percent of same-race relationships. Differences between same-ethnic friendships and different-ethnic (same-race) friendships are less pronounced and less consistent. Studies have yet to examine the sources of differences in the dynamics of interracial and inter-ethnic friendships. For instance, interracial relationships may have lower rates of reciprocation than same-race relationships because they receive less support from families or friends.

A handful of studies have used Add Health data to examine interracial romantic relationships in adolescence. These studies suggest that, among students who are romantically involved, the likelihood of having an interracial relationship declines considerably during the course of adolescence. Studies also find evidence that interracial romantic

relationships are slightly less stable than same-race romantic relationships, and that they involve fewer public and private displays of affection (e.g., meeting a partner's parent or thinking they were part of a couple). However, interracial relationships fail to differ from same-race relationships in terms of intimate displays of affection (e.g., kissing).

Despite the considerable evidence that interracial contact increases racial tolerance, little research has been conducted on the consequences of interracial friendship for attitudes and behavior. This could reflect the fact that it is difficult to determine whether associations between interracial friendship and subsequent outcomes are due to the selection of individuals who form these relationships or their actual influence.

INTERRUPTIONS, CONVERSATIONAL

An interruption is a speech behavior that occurs when one person begins talking when another person is already talking and the original speaker stops talking. Interruptions can have implications for relationships depending on how they are interpreted. Interruptions may be interpreted as either

positive or negative depending on the personalities and backgrounds of the individuals involved, the nature of their relationship, and the content and context of the interaction. This entry describes how interruptions occur, who interrupts, how interruptions can be interpreted, and the implications of interruptions for relationships.

Dominance Perspective

Conversational interruptions have been framed in two ways in the literature. One view is that interruptions are violations of turn-taking rules. Many people accept that during conversations speakers should take turns and one person should speak at a time. Within this perspective, an interruption breaks these rules and violates another's right to continue speaking. Thus, individuals who interrupt are seen as dominating others.

Considerable evidence was garnered for this argument during the 1970s and 1980s from research on interactions involving individuals who differ in levels of perceived social power. This research showed that more powerful individuals tend to interrupt more often than less influential individuals. For example, doctors tend to interrupt more than patients, and employers tend to interrupt more than employees. In terms of close relationships, research has shown that parents tend to interrupt more than young children, but adolescents tend to interrupt more than their parents. Interpreted from the dominance perspective, this latter finding suggests that as children age, they attempt to gain more power or influence in the family by interrupting their parents.

The most controversial area of research has been the study of conversations between men and women. Early naturalistic studies showed that in cross-gender conversations, men tended to interrupt almost twice as much as did women. This finding was interpreted as confirming the assumption that men hold more social power than women. However, beginning in the 1990s, this conclusion was challenged by critical reviews of previous research, which revealed that whether men or women interrupt depends on the individuals involved and the context of the conversations. For example, in controlled studies in which men and women had equal expertise and social power, men and women initiated equal numbers of interruptions.

Conversational Style Perspective

Interruptions can also be interpreted within the larger social context of conversational behaviors. Interpersonal communication consists of the coordination and interpretation of subtle nonverbal cues, including voice quality, rhythm, volume, patterns of turn taking, and the use of overlapping speech, including interruptions. These nonverbal behaviors provide listeners with cues that signal how a speaker intends his or her words to be interpreted. Habitual use of particular nonverbal cues makes up a person's conversational style. One's particular conversational style depends in part on individual personality characteristics, but also on learning that comes from repeated social experiences. Members of specific cultural or social groups, or even families, learn to use similar patterns of nonverbal cues to signal certain intentions. Thus, individuals from different social backgrounds can have quite different, and often incompatible, conversational styles. If these individuals interact, their utterances can be misinterpreted due to different understandings about the meanings of nonverbal cues. For example, some speakers interject with comments such as "Right" or "I know" while others are speaking. These short utterances can be interpreted as attempts to take over conversations by those who strictly adhere to turn-taking rules or as encouraging listener responses by those who prefer more collaborative conversation. In other words, the former would view these interjections as interruptions, whereas the latter would view them as noninterruptive, simultaneous speech.

According to Deborah Tannen, who popularized the idea of conversational styles, interruptions occur when speakers use incompatible habits for turn taking and simultaneous speech. She claims that in many cases simultaneous speech can be initiated with the intention of being supportive, and whether the initiation of simultaneous speech ends up causing an interruption depends on whether the other individual stops talking. Thus, an interruption occurs because of the behaviors of both speakers, not because one speaker is trying to dominate the other speaker.

Two conversational styles that include different habits with regard to the use of simultaneous speech and interruptions have been studied. A

high-involvement style is characterized by a fast rate of speech, fast turn taking, short pausing, and frequent initiations of simultaneous speech. Speakers who use a high-considerateness style talk more slowly, use slower turn taking and longer pausing, and avoid simultaneous speech. High-involvement speakers use simultaneous speech to build rapport and signal involvement, whereas high-considerateness speakers avoid simultaneous speech to honor the principle of not imposing. The use of similar styles enhances involvement in the conversation; opposing styles may lead to interruptions. For example, when a high-considerateness speaker pauses within her turn, the high-involvement speaker will start talking because she believes that silence signals a lack of rapport, and because the high-considerateness speaker believes that overlapping speech is imposing, she will stop talking. Therefore, an interruption occurs because of the conversational habits and intentions of both speakers. This interpretation of interruptions has been supported by the finding that adolescents use a high-involvement style, whereas parents use a high-considerateness style; therefore, adolescents tend to interrupt their parents, and this difference in conversational styles often leads to negative feelings.

In conclusion, interruptions occur frequently in conversations for complex reasons involving the coordination of the communication habits of two or more speakers. Conversational interruptions can be interpreted as either affiliative or dominating depending on the nature of the relationships and the social background and intentions of the relationship partners. Whether interruptions are viewed as having positive or negative impact on a relationship depends on the compatibility and/or mutual understanding of the individuals having a conversation.

INTERVENTION PROGRAMS, DOMESTIC VIOLENCE

Domestic violence is a pervasive social problem that has devastating effects on all members of the family, as well as the larger society. Domestic violence includes physical, psychological, verbal, and sexual abuse perpetrated by one intimate partner against another partner. Rates of physical violence vary according to the sample from which they are calculated. The 1995 National Violence Against Women Survey, which measures violence as a criminal behavior, indicated that 22 percent of women and 7 percent of men reported being victimized by an intimate partner at some time in their lives. This entry discusses the history of intervention programs with domestic violence offenders, reviews the current state of offender treatment, and discusses current issues and challenges in the field.

Prior to the feminist movement in the 1970s, violence in the home was considered largely a private matter. In the 1970s, a group of feminist activists, led by individuals like Erin Pizzey and Susan Schecter, worked to develop a grassroots movement to change the acceptability of wife beating and to provide safety and shelter for female victims of violence. The shelter movement was successful in bringing the issue of male partner violence into the public dialogue and began offering a safe but temporary respite for victims of this violence. Eventually it became clear that simply providing a safe haven for victims was not enough. The work needed to focus not only on providing safety for victims, but also on getting men to stop being violent. Only recently have researchers recognized that women are also violent in relationships and that

intervention programs need to be developed to address female violence.

Most of the beginning work developing specialized treatment for domestic violence offenders grew out of the same feminist movement that developed shelters for victims. Advocates used what they learned working with victims to develop treatment for offenders. An emphasis that began in the early days of offender treatment and continues today is on requiring that offenders assume responsibility for their violence and that they are held accountable for the abuse they perpetrate, rather than allowing them to blame the abuse on their partner's behavior, their childhood experiences, or their drinking or drug use. Much of the early work, based on feminist principles, also emphasized changing men's sexist beliefs, which allowed them to believe that they are entitled to control their partner's behavior and to use whatever force is necessary to maintain their role as head of the household. The emphasis on accountability (and punishment) and the belief that men assault women because of patriarchal norms that support male dominance lead to an admonition against using any type of mental health treatment in response to male violence. The belief was that men hit because it works to control women, not because they have any mental illness that could be treated using a mental health perspective.

Current State of Domestic Violence Offender Treatment

Although the emphasis on accountability remains prominent in most offender intervention programs, most programs tend to use an eclectic set of interventions. Many programs still focus on teaching men about the negative effects of constricted male roles through sex-role resocialization and increasing men's awareness of control tactics so that they will be more aware of their abusive behaviors and will have increased empathy for victims. However, other programs have expanded their focus and teach offenders skills to replace destructive behaviors, work to help men change faulty patterns of thinking that lead to negative feelings and abusive behaviors, or help men deal with childhood experiences, attachment injuries, and shame through trauma-based approaches.

Controlled studies of the effectiveness of these programs began in the 1980s. Currently, more than 30 studies on program effectiveness exist. Many challenges face these analyses. Some studies rely on formal reports to the police. However, only a small percentage of reoffenses are reported to the police. When studies rely on victim reports (which are considered the gold standard), there are still difficulties. For example, follow-up is difficult. Many studies have a high level of attrition from pretest to follow-up. Several meta-analyses have been conducted that combine the effects found in each individual study and compare men who have received treatment with men who have not received treatment. These meta-analyses have consistently found that, although some men change after completing an offender program, men who are arrested for domestic violence but do not complete a program may also change. The amount of change attributed to completing treatment over and above the amount of change attributed to being arrested is small. Julia Babcock, in her meta-analysis, reported that treated batterers have a 40 percent chance of becoming nonviolent, and without treatment they have a 35 percent chance of becoming nonviolent. Thus, in her study, which compared the effect from all controlled studies of offender treatment with the effect found in the nontreated samples in each study, she found a 5 percent increase in success rate attributable to treatment.

State Standards for Domestic Violence Perpetrator Treatment

To ensure the quality of intervention programs provided to offenders, Roland Maiuro reported that in 2007 more than 90 percent of all states had developed standards for domestic violence offender intervention. These standards reflect the prevailing state of offender treatment. Almost all current state standards recommend or require that offenders be treated in groups. A variety of reasons are offered for requiring group treatment, including the idea that men will feel less isolated when confronting their problems, that they can participate in role-plays when learning new behaviors, and that they can give each other feedback. However, there is currently no empirical support for the value of group treatment over individual treatment.

In fact, some concern has begun to be raised that the group format can lead to negative male bonding. For example, a wife in one group reported that her husband came home and told her she had it easy and that he was much less violent than the other men in his group. Concern has also been expressed that group treatments may not address the specific factors leading an individual to become violent.

State standards also recommend or prescribe the focus of treatment. Although most states allow providers to address both male power and control and other social psychological concepts, 27 percent of the states in Maiuro's survey required that the only focus of treatment be on power and control; however, models that emphasize power and control as the only cause of domestic violence have not been shown to be more effective than other treatment models.

The length of the groups required by state standards also varies. Some states require as few as 12 weeks of treatment, whereas others require as many as 52 weeks. Most research finds little difference in outcome based on length of treatment in part because the dropout rate is higher in longer programs. Some studies find that men who complete the longer programs are more likely to end their violence than are men who complete shorter programs. However, overall, the 50 percent dropout rate for domestic violence offender treatment is a serious problem impacting the effectiveness of these programs and is higher than the dropout rate in general mental health treatment.

Current Issues and Challenges in the Field

Reducing Attrition

Although the field currently knows little about what is effective in treating abusive men, some interesting work has begun to examine ways to decrease dropout rates. For example, one study found that attendance monitoring and mandatory monthly court reviews decreased attrition from 52 to 36 percent. Another study found that a marathon group in which men attended 12 hours on Friday night and all day Saturday, in comparison with a standard 2-hour orientation group, reduced attrition from 45 to 25 percent in the first four sessions. Another study found that supportive telephone calls and

hand-written letters to men who missed a session reduced attrition. Finally, one study found that African-American men with high cultural identification had lower dropout rates in a group for African-American men only than they did in a heterogeneous group. Further work is needed in this area.

Couples Treatment

Although only 30 percent of state standards allow couple sessions to be used in addition to male-only groups, research is beginning to suggest that, with carefully screened couples, couples treatment, and especially multicouple group treatment has been shown to be as effective as male-only treatment groups. These groups generally exclude couples if a victim is fearful of her partner and if the abuser is not prepared to take responsibility for the abuse. Couples treatment may be especially useful if a couple chooses to stay together after the abuser has completed a gender-specific group and/or if the couple has not been court ordered to treatment, but both or either partner is using low-level violence in their relationship. Although couples treatment for violent couples remains controversial, a variety of rationales have been offered for couples treatment, including the fact that different types of abuse needs different types of treatment, and that relationship conflict is a strong predictor of domestic violence and couples who choose to stay together often need help resolving conflict. Finally, there is evidence that in many relationships, both partners use violence, and violence by the female partner is a strong predictor of violence by the male partner and of increasing levels of injury for the female partner. If the male is the only partner who learns nonviolent ways of resolving conflict, the violence in the relationship is not likely to end.

Making Distinctions Among Types of Abuse

Another important issue that faces professionals attempting to treat domestic violence is the fact that not all violence is the same. Although Maiuro's review of state standards found that 91 percent of these standards do not make distinctions between types of violence, research is clear that there are different types of violence. Different labels have been used to describe different types of violence,

yet most researchers at least distinguish the terroristic or characterological type of offender from the situational type of offender. Situational offenders become violent in response to a specific situation in the home. Often times both partners are aggressive. There is generally no personality disorder present. In contrast, the terroristic offender is much more likely to have a psychopathic personality disorder and to use coercive control in his everyday relationship with his partner. Most domestic violence researchers recommend that providers carefully screen offenders and offer treatment based on the characteristics of the offender, rather than the one-size-fits-all treatment offered by most certified programs. While most programs use the same approach with all men referred to the program, research is clear that all offenders are not the same. Further work needs to be done to determine which programs are most effective with which offenders.

Substance Abuse and Domestic Violence

Other distinctions that need to be addressed in treatment include distinct treatment needs presented by individual offenders, such as substance abuse. There is considerable overlap between battering and problems with alcohol or other drugs. Although most treatment programs offer only substance abuse or batterer treatment, there is growing support for integrated treatment. The standard belief in the domestic violence field is that treating substance abuse without specifically providing domestic violence offender treatment will not lead to cessation of violence. However, a group of substance abuse treatment researchers, including Tim O'Farrell and Bill Fals Stewart, have demonstrated that behavioral couples treatment for substance abuse is more effective in reducing domestic violence among participants than is individual substance abuse treatment.

Treatment for Female Offenders and Same-Sex Offenders

Finally, not only do gaps exist in treating different types of violence and co-occurring conditions (e.g., substance abuse), gaps also exist in targeting treatment to special populations. In particular, the field knows little about treating same-sex couples

or violent females. All of the published randomized trials have been conducted with violent heterosexual men. However, as indicated earlier, both males and females use violence in relationships. Violence also occurs in same-sex relationships. As a result of mandatory arrest laws, increasing numbers of heterosexual women are being arrested for domestic violence. There is a growing body of research seeking to understand these women. Most of this research points to the high levels of victimization and trauma that many violent women have experienced and suggest that treatment for these women needs to include an effort, not only to help them reduce their violence, but also to address earlier trauma. The largest gaps exist in understanding and intervening in violence between same-sex partners.

INTERVENTION PROGRAMS, SATISFACTION AND STABILITY

Partners committing to lifelong partnerships often hope for at least two favorable outcomes: to have a happy relationship and for the relationship to remain intact. However, longitudinal studies demonstrate dramatic declines in marital satisfaction across the first 10 years of marriage, and about half of American marriages end in divorce. Chronic dissatisfaction and relationship instability are associated with an increased risk for psychopathology in partners, compromised physical health, and less adaptive developmental outcomes in children. Satisfaction and stability are threatened by a variety of factors that can be thought of at three broad levels of analysis: relational, social environment, and physical environment factors. Relational factors are defined by the interactions between partners and include problems such as poor communication, power struggles, and low levels of intimacy. The social environment includes unsupportive communities and social networks, whereas the physical environment refers to factors such as economic hardship or stressful working conditions. Although existing data clearly suggest that many couples at risk for dissatisfaction and instability often experience problems at more than one level, few couples receive comprehensive intervention programs that address needs at multiple levels.

This entry reviews intervention programs for satisfaction and stability across these three levels of analysis: relational environment, social environment, and physical environment. The review begins with when and why couples seek treatment and the tendency for couples to focus on relational factors while overlooking problems in the social and physical environments. Couple therapies are

reviewed to illustrate interventions focused on relational factors, premarital programs as interventions from the social environment, and government programs as interventions intended to reduce stressors in the physical environment.

When and Why Do Couples Seek Interventions?

Data suggest that only 25 percent of marriages can be characterized as both satisfying and stable, but only about 10 percent of married couples ever seek premarital or couple therapy. Furthermore, the average married couple waits approximately 6 years after the onset of serious problems before entering couple therapy. Studies suggest that couples seeking treatment report several common problems including emotional dissatisfaction, communication problems, sexual problems, conflicts regarding money, and fears about separating or divorcing. It is also important to note that couples report seeking interventions not only to *decrease negative* aspects of the relationship, but also in hopes of *increasing positive* aspects of the relationship—that is, because of their love for their partner, wanting to save the good parts of the marriage, or a general desire to improve the relationship. Many of the presenting problems identified by couples seeking treatment are at the relational level of analysis. However, highly prevalent problems stemming from the social or physical environment, such as unsupportive communities or economic conditions, tend to be given lower priority or are entirely overlooked by couples and can even escape the attention of therapists. Interventions focused primarily on relational factors can be beneficial, but failure to address possible stressors from the social and physical environments can ultimately undermine intervention efforts.

Intervening at the Relational Level: Couple Therapy Interventions

The three therapies reviewed here are selected because their approaches embody some of the general principles of effective interventions for behavior, emotion, and cognition. These treatments have also been designated as “Empirically Supported Treatments” by the Society of Clinical

Psychology, one of the American Psychological Association's largest groups of psychologists specializing in interventions. Empirically supported treatments are based on randomized controlled trials demonstrating the benefits of a specific type of therapy, tested in more than one scientific study, and in which the group receiving treatment benefits significantly more than a control group that did not receive treatment.

Behavioral Couple Therapy

Behavioral Couple Therapy views dissatisfaction and instability as arising from a decrease in positive behaviors and an increase in the prevalence of negative behaviors. Behavioral Couple Therapy interventions can be broadly categorized into guided behavior change and skill-based interventions. Guided behavior change helps couples decrease negative behaviors (e.g., being late) in the interest of helping partners change more pervasive behavioral patterns (e.g., being disrespectful). Positive behaviors are increased through behavioral activation intervention components that encourage couples to engage in new sets of positive behaviors (e.g., leaving a kind note). Skill-based training focuses on coaching partners through specific methods for improving specific relational skills, such as how they communicate information and understand communication from their partner. Successful Behavioral Couple Therapy results in a more favorable ratio of positive to negative behaviors during interaction and increased levels of skill to cope with relational challenges.

Emotionally Focused Couple Therapy

The intimate bond between once loving partners can be torn apart by negative experiences that are driven by misinterpreted emotions and overly negative emotional reactions. Emotionally Focused Couple Therapy draws heavily on Adult Attachment Theory, providing a rich theoretical basis for understanding how current attachment styles between each partner govern the type of bond between partners. Anxious or avoidant attachment styles of partners often foster negative emotional reactions in a relationship and misinterpretations of partner's emotions. These factors can trigger a vicious cycle of negative feelings (e.g., fear and

anger) that create insecurity and a feeling of disconnect between partners.

The aim of Emotionally Focused Couple Therapy is to re-create an intimate bond between partners by changing the present insecure bond to a secure one, signified by security, safety, emotional accessibility, and responsiveness. Therapists do little to direct the client toward a specific goal; partners are provided a safe environment to express their hidden needs and wants, resulting in a deeper mutual understanding between partners, more positive experiences, and a secure, emotional connection. When successful, Emotionally Focused Couple Therapy results in a renewed secure attachment between partners, satisfying the need for close, secure relationships with others.

Insight-Oriented Couple Therapy

Dissatisfaction and instability, from an Insight-Oriented Therapy perspective, stem from individuals' lack of insight into underlying needs, automatic emotional reactions, and patterns of thinking about relationships from their early experiences. These early experiences can lead to relational thoughts and behaviors that are incongruent with the demands of current relational experiences. Insight-oriented therapy has three basic phases. First, therapists help each partner understand his or her own and his or her partner's relationship histories with family members and caregivers that have shaped current beliefs and behaviors regarding relationships. The therapist then helps couples link these insights to current relationship beliefs and behaviors. More adaptive relational outcomes follow when couples come to understand how their present emotions and behaviors are rooted in earlier core relationship themes that may be maladaptive in the context of the current relationship.

Is Couple Therapy Effective?

Couple interventions across most modalities, including Behavioral Couple Therapy, Emotionally Focused Couple Therapy, and Insight-Oriented Therapy, are generally effective in improving and maintaining relationship satisfaction and stability. Across clinical trials, an average 80 percent of couples report higher levels of satisfaction at termination than couples not receiving any therapy

at all. Interestingly, clinical trials reveal that beneficial effects are not limited to relationship satisfaction. Couples interventions are also effective in treating other types of comorbid disorders, including depression, anxiety, and post-traumatic stress.

Data supporting the durability of treatment over time provide a more mixed picture. What is robust at long-term follow-up assessments is that treatment is better than no treatment, and in many cases long-term treatment fares better than short-term treatment. However, relapse rates can vary across modalities and across the few studies with follow-ups assessed more than 1 year after the end of therapy. For example, in a clinical trial comparing Behavioral Couple Therapy and Insight-Oriented Couple Therapy, a 4-year follow-up found that about 50 percent of couples in Behavioral Couple Therapy reported being satisfied, compared with about 70 percent in Insight-Oriented Couple Therapy. Of course, higher satisfaction does not guarantee increased stability. Stability results at the 4-year follow-up found that 38 percent of Behavioral Couple Therapy patients had divorced, compared with only 3 percent in Insight-Oriented Therapy. There are also groups of individuals who show little or no gains during therapy or at follow-up assessments, and these couples are classified as “unresponsive.” This sizable minority of couples not maintaining gains in satisfaction, who eventually divorce or who are unresponsive, has led researchers to look beyond interventions at the relational level.

Intervening with already distressed couples, in the confines of a therapist’s office, for 50 minutes a week, is prototypical of couple therapy intervention approaches. The limited scope and dose of this intervention approach has led some researchers and practitioners to think in different ways about the timing and breadth of interventions. Regarding timing, longitudinal studies demonstrate that maladaptive relational behaviors, emotional instability arising from insecure attachment styles, and poor insight into unrealistic expectations are often present before a couple marries. A number of environmental factors such as unsupportive social networks or economic stress are also identifiable before marriage. Increasing recognition that threats to marital satisfaction and stability exist at multiple levels before marriage has led researchers to consider a broader range of

premarital intervention approaches. Premarital interventions incorporate Behavioral, Emotion-Focused, and Insight-Oriented Couple therapy principles through relational-level interventions, but unlike the therapeutic context, premarital interventions tend to be proactively delivered within a couple’s social environment.

Interventions from the Social Environment: Premarital Interventions

For centuries, in many Western countries, marriage was the gateway to economic stability, mating, and parenthood. Today, it is increasingly possible to be economically self-sufficient, over half of those in the United States will cohabit, and it is relatively common to rear children without marriage. These dramatic changes in the social environment have coincided with a view of marriage primarily as an instrument for personal happiness, as less binding, and as relatively independent of one’s community standing. Premarital interventions are often delivered by religious organizations and increasingly by government-sponsored programs. In an era in which social environments place less value on marriage and are less supportive of marriage, social institutions strongly encouraging participation in premarital interventions may convey cultural value regarding the importance of marriage and may also provide opportunities to build social support from other couples or mentors.

Premarital interventions educate and counsel couples in ways similar to the couples therapies reviewed earlier. Most premarital intervention programs share three common intervention components: behavioral interventions focused on building relationship skills, fostering insight into trait-like differences between partners (e.g., attachment styles), and bolstering positive aspects of the relationship. A recent study applying the criteria for Empirically Supported Treatments found evidence for four different premarital programs: Prevention and Relationship Enhancement Program (PREP), Relationship Enhancement, Couple Communication Program, and Strategic Hope-Focused Enrichment. Meta-analyses of effectiveness studies have generally found large effects on satisfaction immediately following participation. Couples that participated in premarital programs

were more satisfied than 79 percent of couples that did not participate. It is also important to note that there is encouraging evidence for the mechanisms underlying the effectiveness of premarital interventions on satisfaction. Participants in standardized (e.g., PREP) and nonstandardized (e.g., Catholic Church) premarital programs are less likely to resort to domestic violence and also demonstrate improvement in interpersonal skills (e.g., communication, empathy), which are associated with higher levels of satisfaction.

Although immediate results are an important component regarding effectiveness of premarital interventions, how well these results are sustained throughout the course of marriage is an equally important aspect of evaluating premarital intervention effectiveness. Follow-up studies conducted 6 months after initial interventions demonstrate that couples maintain the positive effects of their participation. This is seemingly true until the 1-year mark after marriage, at which point longitudinal findings for the effectiveness of treatment begin to differ across studies. Some researchers argue that the high levels of satisfaction experienced after participation in premarital programs is sustained for 3 years, whereas others argue that effects on satisfaction only last through the first year of marriage. Although more long-term clinical trials of premarital interventions are needed, current findings generally suggest that premarital interventions stemming from the social environment can be protective of satisfaction and stability.

Policy Interventions for the Physical Environment

A stressful physical environment is a powerful threat to satisfaction and stability and a potential impediment to successfully implementing interventions at the relational level or from the social environment. A couple besieged by financial burden, multiple work stressors, living in a crime-ridden neighborhood, or living in neighborhoods with high rates of drug and alcohol abuse may not be able to devote time and attention to seeking out or successfully implementing interventions of the sort described earlier. For example, during the first 5 years of marriage, men's unemployment doubles the risk of divorce. Other studies find that perceived stress at the workplace is associated

with increased marital conflict. Numerous studies link stressful physical environments to decreased satisfaction and stability, which suggests that, for couple therapies or premarital interventions to be effective, interventions aimed at relieving environmental stress is often necessary.

Public policy decisions to fund intervention programs for marriage at both the federal and state levels have focused on encouraging marriage, providing premarital interventions to prevent instability, and relieving economic pressure. Temporary Assistance for Needy Families (TANF) is the primary federal program for policy interventions for protecting marital satisfaction and stability. The program delivers \$16.6 billion to states each year. States match the federal funds and are free to structure public policy programs to encourage the formation and maintenance of marriage. Some states choose intervention programs that provide financial incentives for low-income couples to enroll in premarital intervention programs before marriage; others choose job training, child care, or cash assistance to families.

Effectiveness studies are underway in many states, but thus far there are no longitudinal follow-ups of randomized clinical trials to show whether these policy interventions are successful. The most encouraging data to date suggest that there are relatively high rates of participation and retention in some TANF-sponsored programs. Furthermore, well-trained professionals without an extensive psychological educational background can deliver the programs effectively. Although there is an intuitive appeal to interventions from the social environment or interventions that lessen stress from the physical environment, it is important to remember that in practice both couples and interventionists often overlook the influence of environmental factors and the need to intervene directly on environmental factors. It is likely that a combination of effective policies targeting couples' social and physical environments, combined with effective relational-level interventions, is ultimately needed to protect or enhance a couple's satisfaction and stability.

Future Directions for Satisfaction and Stability Interventions

Despite tremendous advances in developing intervention programs, there are still many areas for

improvement in research and practice. One important task will involve experimental tests of which components in intervention programs have the strongest causal effects on outcomes. In addition, little is known about which components are more helpful for increasing satisfaction and which are more helpful for protecting relationship stability. For example, it may be that premarital interventions aimed at communication skills are particularly protective of satisfaction, whereas interventions aimed at sustainable employment may be especially protective of stability.

Another pressing question is how interventions at the couple, social, and physical environment levels interact to promote healthy relationships. Arriving at more precise estimates of the “dose” of intervention needed at the three levels discussed in this entry is important because it would allow interventionists to find the right balance between efficiency and thoroughness of intervention. Given limited financial and human resources when intervening with couples, this increased precision would allow more couples to receive interventions.

Despite the need for further improvements, it is important to remember that most couples benefit from current intervention programs. Effective interventions come from interventionists incorporating best practices, from communities that are supportive of couples, and from policies that alleviate stressors in the physical environment. Increased collaborative efforts across these three levels will likely be integral to ensuring that couples receive a combination of interventions that facilitate their hopes for a happy and stable relationship.

INTIMACY

Intimate relationships enrich our lives with meaning and pleasure. Confiding in close relationship partners provides significant benefits to physical and mental health, distinguishes more rewarding from less rewarding relationships, and contributes to relationship satisfaction. Human beings have a *need for intimacy* that, when unfulfilled, leaves them feeling lonely and depressed. This entry defines intimate interactions and relationships, discusses three specific forms of intimacy (emotional support, expressions of positive regard, and sexuality), and addresses intimacy within friendships and romantic relationships. It concludes with discussions of intimacy changes over time, how people cope with the psychological risks of intimacy, and how individual differences in intimacy needs affect close relationships.

Three Defining Characteristics of Intimate Interactions

Karen Prager and Linda Roberts distinguished intimate interaction from other kinds of interactions by three necessary and sufficient conditions: self-revealing behavior, positive involvement with the other, and shared understandings.

Self-Revealing Behavior

Self-revealing behaviors are those that reveal personal, private aspects of the self to another. Self-revealing

behavior, or self-disclosure, is related to greater emotional involvement, fulfillment of needs, and relationship satisfaction. Self-disclosure facilitates the development of new intimate relationships and helps to maintain ongoing ones. Self-revealing behavior and accompanying emotional support are the *sine qua non* of intimate interactions for men and women.

Both verbal and nonverbal behavior can be self-revealing. Deeply self-revealing behavior usually involves the expression of “vulnerable emotions,” such as hurt or sadness that expose the “innermost self.” When interaction participants reveal more personal, vulnerable aspects of themselves through self-disclosure, and when they express feelings about what they have disclosed, they perceive their interactions to be more intimate.

Self-revealing behavior is that aspect of intimacy that has been most closely associated with higher levels of well-being; however, the mechanism by which it benefits the individual has not yet been determined. One study tested the hypothesis that changes in hormone levels, specifically salivary testosterone levels, would account for some of self-disclosure’s health benefits. The study found that higher self-disclosure moderated short-term testosterone changes in men who interacted with a female peer versus sat alone for 15 minutes.

Positive Involvement

Positive involvement refers to the individual’s devotion of full attention to the partner during an interaction. It also refers to positive regard for the other that is communicated through nonverbal and verbal cues. Some behaviors that signify positive involvement convey *immediacy*, defined as the directness and intensity of interaction. Decreased distance, increased gaze, and greater facial expressiveness create immediacy, as does verbal “tracking” of the partner’s communication and use of present-tense verbs. Interactions characterized by immediacy are associated with positive affect.

Partner responsiveness refers to behavior that conveys attention, interest, understanding, and empathy for the other’s perspective. In Harry Reis and Philip Shaver’s interpersonal process model of intimate interactions, intimacy is a process that begins with one person’s self-revealing behavior and continues with the other person’s display of understanding, validation, and caring toward the discloser.

Research supports the contention that responsive behavior contributes to daily experiences of intimacy in romantic couple relationships, over and above effects of self-disclosure. In both college-age dating couples and married couples, interactions are not as intimate when partners are perceived to be insensitive or unresponsive to the other’s self-disclosure. Responsiveness is also important in helping relationships. Early research by Carl Rogers identified therapist acceptance, warmth, and caring as critical conditions for therapeutic change. A recent study found that rape victims disclose less about their experiences when counselors are less responsive.

Mutual Understanding

The third condition for an interaction to be intimate is that it results in shared understandings between partners. Through intimate interaction, both partners understand (or come to understand) an aspect of the other’s inner self. This intimate knowledge endures beyond the interaction and becomes a distinguishing feature of relational intimacy.

Partners who believe they are understood accurately are more satisfied with their relationships, as when partners read their thoughts accurately during an interaction. One study compared interaction partners’ ability to guess what the other was thinking in pairs of strangers, casual acquaintances, friends, and dating partners, assessing the influence of intimacy and gender in each group. Partners with higher perceived levels of relational intimacy were better able to guess the other’s thoughts than less intimate dyads. Female partners were more perceptive than males regardless of the level of relational intimacy.

Forms of Intimate Expression

Several areas of research have shed light on specific types of intimate interactions. These include research on reassurance and emotional support, communication of positive regard, and sexuality.

Reassurance and Emotional Support

Some intimate interactions are characterized by *emotional support*, in which one partner shares a

difficulty and the other offers comfort, reassurance, confidence building, and more benign perspectives for thinking about the problem. Adults who perceive that others, especially their spouses, are available to provide emotional support when they need it enjoy positive outcomes, including better mental health and immune functioning and less marital distress.

Recent research indicates that it is just as important for partners to share one another's joys as it is for them to provide sympathy for their sorrows. Shelly Gable, Gian Gonzaga, and Amy Strachman videotaped young dating couples while they talked with each other about a positive event and a negative event, and then they asked them to report on how understood, validated, and cared for they felt during the interaction. The listening partner's responses to disclosures of positive events, more than his or her responses to negative event disclosures, predicted the disclosing partner's feelings of well-being and relationship satisfaction 2 months later.

Expressions of Positive Regard

Communicating positive, loving feelings toward a partner is an important aspect of intimate communication, both as a disclosure and as a response to disclosure. Perceiving one's partner as having a positive view of oneself, especially a partner who knows one very well, helps partners maintain high self-esteem.

Partners who communicate positive regard to one another may be in a better position to sustain intimacy in their relationship. Work by Sandra Murray and her colleagues suggests that people determine how much vulnerability they will risk with their partners, in part, on the basis of how positively they believe their partner regards them. Expressions of positive feelings contribute uniquely to couple relationship partners' daily experiences of intimacy.

Sexuality

Heterosexual couples that remain married report that their sexual relationships are better after marriage, whereas those that divorce report, in retrospect, that theirs were worse. Whether they engage in more kissing and affectionate touching or more frequent sexual contact or both, sexuality

both signals and maintains relationship satisfaction. Although satisfied partners engage in more frequent sexual relations than less satisfied partners, frequency varies as a function of partners' age, sex, sexual orientation, and length of time together.

Desire or lack thereof is a more significant indicator of a relationship's functioning than coital frequency. Pamela Regan found that sexual desire is more closely associated with feelings of love than sexual behavior in the minds of college students, although passion may better reflect a developing intimate relationship than one that is stable and ongoing. Couples that present to therapists with sexual desire problems have a poorer prognosis than those whose problems are centered on a lack of shared gratification. Although satisfaction with the sexual relationship correlates positively with romantic partners' overall relationship satisfaction, the presence of sexual contact does not guarantee that partners are emotionally intimate.

Intimate Relationships

The defining characteristics of intimate interactions—self-revealing behavior, positive involvement, and mutual understanding—provide the basic elements for defining an intimate relationship. Intimate relationship partners have shared multiple intimate interactions that, over time, distinguish an intimate relationship from a casual or nonintimate one by virtue of accumulated knowledge or understandings of the other.

Intimate Friendships

As people get to know one another, the intimacy in their interactions increases. Among teenagers and adults, the breadth and depth of self-disclosure and emotional support increases as relationships progress from casual acquaintances to close friendships. As relationship satisfaction, love, and feelings of security increase, so too does intimacy. This pattern of increasing intimacy with acquaintance is discernable in face-to-face contact between college friends and, as more recently demonstrated, in teenagers' online relationships. More intimate friendships have more staying power, as a recent 19-year longitudinal study of intimate friendships from college to middle adulthood demonstrated.

From their first contact with a new acquaintance, girls and women on average communicate more intimately than men do and continue to do so once they become friends. This gender-related pattern replicates in Western cultures outside the United States, but is less evident in non-Westernized countries. Maria Cancian suggests that Western men have less intimate friendships than women do because Western cultures have linked intimacy with femininity. Gender differences are not due to different conceptions of intimacy held by women and men, however. Rather, they reflect the fact that men, relative to women, describe themselves as less concerned with meeting emotional intimacy needs within their same-sex friendships.

Sex differences in friendship intimacy seem to reflect traditional norms for masculine and feminine behavior in the United States. In gay communities, some men may actively reject traditional norms for masculine behavior, and intimacy in their friendship pairs resembles that for female pairs. Similarly, androgynous boys (i.e., those who have incorporated feminine traits into their personalities) are more likely to have intimate male friendships than masculine sex-typed boys. In contrast to men, women are believed to be “relationship experts” and are encouraged—even pressured—to place more emphasis on becoming skillful at relating intimately. This expectation is reflected in women’s ability to communicate their emotions effectively to their spouses. Excessive concern about intimacy on the part of women may have a downside, however. In their zeal to maintain a high level of openness, warmth, and emotional support in their friendships, women may fail to deal constructively with anger and competitiveness, occasionally leading to inappropriate aggressive behavior against their closest friends.

Intimacy and the Romantic Relationship

Intimacy is a central desire and expectation that most romantic partners bring to their relationships. More intimate couples are happier couples; partners who self-disclose more to one another, who have more frequent sexual contact, who are emotionally responsive, and who perceive each other as each perceives him or herself are more satisfied and stable couples.

Mutual understanding assumes special significance in the context of an ongoing couple relationship because the personal knowledge that is obtained through intimate interactions endures and accumulates. Over time, understandings of the other extend beyond the experiences contained within any particular interaction. These understandings, or *intimacy schemas*, mediate the impact of individual interactions. Intimacy schemas guide future relationship behavior and elicit emotional reactions to specific partner behaviors. When frequent intimate interactions result in partners feeling understood, other potentially volatile differences, including religious and ethnic differences, are less likely to contribute to relationship problems.

Intimacy schemas, if they represent mostly positive experience, can result in a backdrop of loving, positive feelings about the partner that buffer the relationship from negative emotions that arise. This *positive sentiment override* can sustain the relationship even when shared intimate experiences are not immediately forthcoming. A similar pattern exists with perceptions of support availability, which may persist during times when the partners are not seeking support from each other. Positive expectations of support availability reliably distinguish between more and less satisfied couples. Conversely, when partners hold negative perceptions of the relationship, those perceptions predict divorce with more than 80 percent accuracy.

More relational intimacy is usually associated with more satisfaction; however, some couples have less intimacy than others, but are satisfied because their level of relational intimacy fulfills their lower needs for intimacy. Partners whose needs are not met may argue about intimacy-related issues, such as how much each should express to the other about his or her private feelings and thoughts, how often partners should have sexual relations, and so forth. Partners who argue about intimacy report higher levels of marital distress than those who have other kinds of incompatibilities.

Because romantic relationships typically involve intense emotions, both positive and negative, the skillfulness with which partners handle and communicate their emotions contributes to both relational intimacy and relationship satisfaction. Partners who not only manage their own emotions skillfully, but are able to respond skillfully to the other partner’s emotional expressions, create an

atmosphere of *intimacy safety* in their relationship, which enhances intimacy and thereby enhances marital satisfaction.

Relational Intimacy Over Time

In romantic relationships, on average, intimate interactions decline in frequency over time. Sexual intimacy declines most precipitously within the first 1 to 2 years. There are also documented declines in affectionate expression, in the number of pleasing things partners do for each other, and in the time partners spend in joint leisure activities. These changes do not necessarily create dissatisfaction for the partners, however.

In established, long-term relationships, partners' level of mutual understanding may mitigate the need for frequent intimate interactions. Even in the absence of explicit self-disclosure, close friends are better able to infer each other's thoughts and feelings during an interaction than are pairs of strangers. Research suggests that long-standing friends and romantic partners may not need to self-disclose in order to know what the other needs in the way of support, acknowledgment, or validation. Possibly, relational intimacy is an overriding knowledge and familiarity with the partner that may reduce the need for frequent self-disclosure.

Regulating Intimacy: Intimacy's Risks and Joys

In the best relationships, the possibility of a joyful and meaningful intimate encounter coexists with the risk of hurt. In an intimate relationship, partners maintain a delicate balance between openness and unguardedness, on the one hand, and self-protection and concealment, on the other hand.

Relationship partners are well aware that they can be hurt in the context of an intimate relationship. Partners who feel less secure may inhibit their levels of self-disclosure or distance themselves for the sake of self-protection. Disclosure regarding taboo topics (e.g., extrarelationship activity) is avoided in college student dating relationships because some topics are perceived as threatening to the relationship. Secrecy is sometimes used to prevent rejection or breaking up.

Sex differences in self-disclosure are mitigated in heterosexual romantic relationships where

women and men report similar patterns of self-disclosure. Despite these similarities in disclosure levels, women are lonelier in their romantic relationships than are men, initiate more separations, and report more problems. Women and men have similar standards for their romantic relationships, although women are more likely to report that their standards are not being met. Either women's socialization to be relationship experts causes them to be more aware of relationship problems or more willing to report them or women are more effective relationship partners than are men, resulting in men who are less likely to be lonely.

Individual Differences and Intimacy

Some people appear to be content with much less openness, emotional support, sexual contact, and/or affectionate expression than others. Dan McAdams's research on intimacy motivation has supported the notion that some people desire and seek out opportunities for intimate interaction more frequently than others. High-intimacy motivation may be an advantage because individuals whose intimacy needs are stronger put more effort into their intimate relationships and engage in intimate and problem-solving communication more frequently. Perhaps as a result, individuals with strong intimacy needs have more satisfying relationships. Further, they prefer partners who are warm and open and have similar interests. Partners whose needs are met more frequently have more intimate contact and less conflict.

Individual differences in working models of attachment (i.e., secure vs. insecure working models) are also associated with variations in intimacy needs and preferences. People with certain insecure attachment expectations (e.g., those who dismiss their need for a close and secure relationship) have little tolerance for the risks of intimacy and are more likely than others to maintain multiple and superficial sexual relationships. In contrast, secure individuals are more often sexually exclusive and least likely to engage in behavior destructive to their relationships. Individual differences in intimacy-related needs and fears appear to be systematically associated with attachment expectations.

INTIMACY, INDIVIDUAL DIFFERENCES RELATED TO

Close relationships are commonly seen as providing opportunities for individuals to engage in intimacy, including self-disclosure, interdependence, and trust, with a single partner. Moreover, relationships with high levels of intimacy experience greater relationship satisfaction and longer relationship longevity. Although the presence of intimacy plays an important role in predicting satisfaction in close relationships, as well as in maintaining these relationships over time, individuals differ not only in how interested they are in the pursuit of intimacy, but also in their ability to engage in such a pursuit. This entry reviews prevailing theoretical models that describe individual differences related to intimacy, as well as the measurement of these differences.

Erikson's Life-Span Approach to Intimacy

According to Erik Erikson's life-span model of psychosocial development, individuals go through a series of eight stages during their lives, each of which is marked by a conflict that must be resolved. Successful resolution of each stage leads to a positive outcome, whereas unsuccessful resolution leads to ongoing challenges with that particular task (e.g., trust vs. mistrust).

Considerable research on Erikson's life-span model has focused on the two key tasks worked on during adolescence: forming a stable identity (Stage 5 in Erikson's model) and, subsequently, forming intimate relationships (Stage 6). During early adolescence, individuals face the task of Ego Identity versus Role Confusion, in which they must develop a sense of individual identity or remain confused about defining themselves. Only those who have successfully developed a sense of identity are able to move on and effectively pursue the task as the next stage: Intimacy versus Isolation. In this stage, individuals evaluate potential romantic partners and whether they are interested in settling down. Because the theory of life stages proposes that an individual's capacity for intimacy depends at least partially on successful resolution of tasks from earlier stages, including identity, individuals who have

not yet reached closure in identity formation, meaning they have not successfully resolved their identities, may not be ready to merge their evolving identities with another. In line with this view, research indicates that those who form stable identities in adolescence are also most likely to form intimate attachments in early adulthood.

Erikson's view that individuals must form stable identities prior to attempting to merge those identities with another person in their pursuit of intimacy has received some criticism. In particular, some researchers believe that this model appropriately describes the connection between identity and intimacy for men, but believe it is less appropriate for describing how women work on these tasks. For example, Carol Gilligan theorizes that women are more likely to work on intimacy prior to forming a stable identity, and that this work on intimacy may even help women define themselves.

Successful resolution of both the Ego Identity versus Role Confusion and the Intimacy versus Isolation tasks can be measured using either a semistructured interview or a self-report questionnaire. The semistructured interview examines individuals' attitudes and behaviors toward intimate relationships. The self-report questionnaire consists of 12 items assessing each of the stages and assesses whether individuals have successfully resolved a given task.

Intimacy Goals

In an extension of Erikson's life-span approach to personality, Nancy Cantor and colleagues' work has focused on how individuals within a given group or culture may all take on a given task during a particular life period, but will do so in distinct ways. According to this approach, both situational and personal factors influence how individuals approach or "take on" these tasks. For example, following the dissolution of a close relationship (e.g., through divorce or death of a spouse), an individual may be more interested in self-reliance than in interdependence. In turn, whereas one person may see a close relationship as an opportunity to become interdependent with another person, another may see it as an opportunity to explore a new identity and/or achieve independence from one's family of origin.

Although the prevailing cultural meaning for relationships emphasizes the pursuit of intimacy, not all individuals are ready or able to exclusively or even predominantly focus on merging with another and sharing emotional intimacy. Moreover, although committed to pursuing relationships, individuals are likely to vary widely in their actual skill at creating and maintaining intimacy. In turn, individuals differ systematically in the extent to which they pursue intimacy goals within their relationships.

Individuals' general orientation toward the pursuit of intimacy goals in romantic relationships is measured using the Social Dating Goals Scale, a 13-item self-report scale assessing individuals' focus on self-disclosure, interdependence, and reliance in a dating relationship. Scores on this scale are positively correlated with ego achievement and negatively correlated with interpersonal ego diffusion, indicating that those with a strong focus on intimacy goals have successfully resolved their identity issues. Interestingly, and in line with previously described models of individual differences in intimacy, those who have not yet resolved their identity issues are more likely to pursue self-focused goals in their close relationships than intimacy-focused goals. Scores on the intimacy goals scale are also positively correlated with secure attachment and negatively correlated with anxious attachment. There is no association between strength of intimacy goals and avoidant attachment, suggesting that people with a strong focus on intimacy goals in their relationships are not particularly fearful of or uninterested in such relationships—they simply have other goals to pursue.

McAdams's Intimacy Motivation

According to Dan McAdams and colleagues, an individual's motivation affects how he or she interacts with others, as well as the types of behavior he or she is able to evoke from others. These motives are characterized by specific thought and affect patterns, and they influence interpersonal behavior. Specifically, this model proposes that motives lead to particular expectations and behavior, which in turn affect others' behavior, as well as one's perception of the others' behavior.

One such motive, intimacy motive, describes the extent to which an individual experiences the

need for close, warm interpersonal relationships. McAdams differentiates the intimacy motive from other interpersonal motives, such as the need for affiliation and the need for power. Those who are high in intimacy motivation spend more time thinking about and interacting with people and in interpersonal relationships, feel more friendly and connected to others during social interaction, and appraise social situations as more desirable and appealing than those with weak intimacy motivation. For example, compared with those who are low on intimacy motivation, individuals who are high on intimacy motivation are more likely to engage in conversation and write personal letters. Individuals who are high in intimacy motivation are also more likely to adopt a communal, listening role in interactions, as well as to report more episodes involving self-disclosure.

According to this model, intimacy motives are linked to personality dispositions and are measured by the Thematic Apperception Test (TAT). The TAT is a widely used projective test within personality psychology in which people see a standard series of ambiguous pictures and must tell a story about each picture, including the event shown in the picture, what has led up to it, what the characters in the picture are feeling and thinking, and the outcome of the event. Researchers then analyze the stories to uncover underlying needs, attitudes, and motives. For example, one picture shows two people sitting on a park bench near a river. Themes related to concern, communication, and positive affect would be scored as reflecting a high intimacy motive.

Individual Differences in Attachment

In the late 1980s, researchers Cindy Hazan and Phillip Shaver extended classic theory and research on attachment between children and their caregivers (developed by John Bowlby and Mary Ainsworth) to adult romantic relationships. In particular, these researchers noticed that interactions between adult romantic partners shared similarities to interactions between children and caregivers, including a desire to be close to each other, a feeling of comfort when their partners are present, and a tendency to use partners as a secure base when encountering various surprises, threats, and challenges that life presents. These similarities

led Hazan and Shaver to extend attachment theory to adult romantic relationships and to see the principles of attachment between children and caregivers as fundamentally the same as the principles of attachment between adult romantic partners.

Individuals' attachment styles in their adult romantic relationships are associated with particular patterns of interactions, beliefs, attitudes, and strategies of conflict resolution. Individuals who have developed secure attachment models in early childhood are the most likely to succeed at creating intimacy in close relationships because they have a secure base on which to build communion. However, individuals who have developed insecure models of attachment in early childhood may be reluctant or even unable to pursue intimacy in romantic relationships because they lack a secure base on which to build such interactions.

Researchers typically assess attachment styles in adulthood using self-report measures. The most commonly used approach is the Experiences in Close Relationships (ECR) scale, a 36-item self-report measure that assesses individuals' scores on two subscales, Avoidance (or Discomfort With Closeness and Depending on Others) and Anxiety (or Fear of Rejection and Abandonment).

Other Models Assessing Intimacy

Although the models described previously have received considerable attention in the literature on individual differences in intimacy, other researchers have developed different approaches to conceptualizing and measuring intimacy in close relationships. Karen Prager, for example, defines *intimacy* in terms of intimate behavior (such as self-disclosure), affective tone (such as positive feelings), and listening and understanding (such as feeling understood by one's partner). Her diary method of assessing intimacy, the Interaction Record Form for Intimacy, asks participants to rate daily interactions on 17 items, which are then grouped into three categories that define intimacy.

Another way of conceptualizing intimacy is by assessing the extent to which individuals define themselves in terms of their close relationships, which is called *relationship self-construal*. This approach is taken by Susan Cross and her colleagues, who describe people who are high on

relationship self-construal as thinking and acting in ways that develop and enhance their close relationships, and using such relationships for self-definition, self-enhancement, and self-expression. (In contrast, people who are high on independent self-construal view the self as independent and separated from others.) Relationship self-construal is assessed using a brief self-report questionnaire that assesses the extent to which people think about their close friends and family when they think about themselves and whether they feel that close others are a part of who they are.

Conclusions

Although this summary of individual differences in how intimacy is conceptualized and measured has presented these different models of intimacy as distinct from one another, it is likely that these measures are related in multiple ways. For example, the extent to which someone pursues intimacy goals in close relationships depends on how effectively he or she has resolved identity issues. Similarly, attachment security is related to both intimacy goals and intimacy motivation. Future research is needed to examine how these distinct individual differences in intimacy work together to predict feelings, thoughts, and behaviors in close relationships.

INVESTMENT MODEL

Relationship scientists have exerted considerable effort toward understanding why some relationships persist over time, whereas others wither and die. Many researchers focus on the determinants and consequences of positive affect—attraction, satisfaction, or love. The implicit or explicit assumption is that if partners love each other and feel happy with their relationship, they will be more likely to persist. In some respects, this point of view makes good sense: All things considered, it is easier to stick with a happy relationship than a miserable one. Although satisfaction is certainly important, it is only part of the picture in understanding persistence.

The Investment Model was developed to explain why satisfaction is not enough to sustain long-term involvement—why some relationships persist despite dissatisfaction, why some people abandon relatively happy relationships to pursue desirable alternative partners, and why relationships persist despite day-to-day fluctuations in satisfaction. According to the Investment Model, commitment is the key to understanding tendencies to remain in relationships. This entry describes the Investment Model, outlining the primary causes of commitment, discussing some of the more important consequences of commitment, and illustrating the utility of this model for understanding “unjustified persistence,” such as persistence in an abusive relationship.

Determinants of Dependence and Commitment

The Investment Model is based on the principles of interdependence theory, which argues that dependence is a central structural property of relationships—a property that is particularly relevant to understanding persistence. Dependence describes the extent to which a person literally “needs” a given relationship or relies uniquely on the relationship for attaining desired outcomes. How do people become dependent? Interdependence theory identifies two main processes through which dependence grows. First, people become more dependent to the extent that they experience high satisfaction. *Satisfaction level* describes the degree to which an individual experiences positive versus negative affect as a result of involvement. Satisfaction grows to the extent that a relationship gratifies the individual’s most important needs (e.g., companionship, intimacy, sexuality, and belongingness), as well as to the extent that obtained outcomes exceed comparison level or the individual’s generalized expectations regarding the quality of a relationship (i.e., expectations based on previous experience or social comparison). Dependence is also influenced by the quality of available alternatives. *Quality of alternatives* describes the perceived desirability of the best available alternative to a relationship. Quality of alternatives increases to the extent that a person’s most important needs could be fulfilled independent of the current relationship (e.g., by a specific alternative partner, the general field of eligible others, or on one’s own).

Thus, interdependence theory suggests that dependence is greater when an individual wants to persist in a given relationship (satisfaction is high) and when he or she has no choice but to persist (alternatives are poor). The Investment Model extends these claims in two respects. First, the model suggests that satisfaction and alternatives do not fully explain dependence. If dependence were based merely on the satisfactions derived from a current relationship in comparison to those anticipated elsewhere, few relationships would endure. Many relationships survive periods during which they are not satisfying, even when attractive alternatives are available. The Investment Model therefore asserts that a third factor explains persistence. *Investment size*

describes the magnitude and importance of the resources that become attached to a relationship—resources that would decline in value or be lost if the relationship were to end. People may invest directly or indirectly: Direct investments are those resources that are put directly into a relationship, such as time, self-disclosure, and emotional energy. Indirect investments occur when initially extraneous resources become inextricably connected to the relationship, such as children, mutual friends, or shared possessions. Both types of investments enhance dependence by increasing the costs of ending a relationship—to abandon a relationship is to sacrifice invested resources.

The Investment Model further extends interdependence theory by suggesting that commitment emerges as a consequence of increasing dependence. *Commitment level* describes the intent to persist in a relationship, including long-term orientation toward the involvement, as well as feelings of psychological attachment to it. How does commitment differ from dependence? Dependence is a structural property of relationships—dependence describes the addictive effect of wanting to persist (feeling satisfied), having no choice but to persist (possessing poor alternatives), and needing to persist (high investments). As people become more dependent, they tend to develop strong commitment. Commitment is the sense of allegiance that is established with regard to the source of one’s dependence. Because John is dependent on Mary, he develops an inclination to persist with her, comes to think of himself as part of “John and Mary,” and tends to consider the broader implications of his actions, such as implications for his partner or long-term goals for the relationship. As such, the psychological experience of commitment reflects more than the bases of dependence out of which it arises. Commitment is the psychological construct that directly influences everyday behavior, including relationship maintenance mechanisms and decisions to persist in versus leave a relationship.

Consequences of Commitment

The empirical literature provides consistent support for Investment Model predictions. Commitment is positively associated with satisfaction and

investment size and is negatively associated with quality of alternatives. Each of these variables makes a unique contribution to predicting commitment. Also, (a) compared to less committed people, highly committed people are substantially more likely to persist in their relationship, and (b) commitment level mediates the associations of satisfaction, alternatives, and investments with persistence.

Of course, strong commitment does not magically cause relationships to persist. Rather, commitment promotes adaptive relationship-relevant acts, which in turn cause relationships to persist. Researchers frequently label these adaptive acts *relationship maintenance mechanisms*, defined as the specific means by which partners manage to maintain long-term, well-functioning relationships. Why should commitment promote prorelationship behaviors? As noted earlier, committed individuals experience high satisfaction, perceive their alternatives to be poor, and have invested heavily. They are psychologically attached to their relationships, and they think about their relationship over the long run, rather than merely in the here and now. The implications should be clear. First, committed individuals literally need their relationships; the more one has to lose, the more effort one exerts to hold onto what one has. Second, committed individuals are oriented toward long-term outcomes and typically recognize that it is in their long-term interest to develop patterns of reciprocal prorelationship behavior. Third, because committed individuals are psychologically attached to their relationships, they may experience themselves and their partners as merged into a single entity, such that self-interest and partner interests become blurred. Finally, strong commitment may yield communal orientation, including inclinations to respond to the partner's needs in a relatively unconditional manner.

Numerous maintenance mechanisms have been identified, including both behavioral maintenance acts (changes in behavior) and cognitive maintenance acts (cognitive restructuring). The behavioral maintenance acts include: (a) *accommodation*, or the willingness, when a partner enacts a potentially destructive behavior, to inhibit the impulse to retaliate and instead react in a constructive manner; (b) *willingness to sacrifice*, or the tendency to forgo immediate self-interest so as to promote the well-being of the partner and relationship; and

(c) *forgiveness of betrayal*, or the victim's willingness to forgo desire for retribution and demands for atonement, instead reacting in a less judgmental, more constructive manner. The cognitive maintenance acts include: (a) *cognitive interdependence*, or the tendency to think in terms of "we, us, and our" rather than "I, me, and mine"; (b) *positive illusion*, or the tendency toward relationship-enhancing illusion—the inclination to perceive one's relationship as both better and not as bad as other relationships; and (c) *derogation of alternatives*, or the tendency to disparage tempting alternative partners, minimizing the attractiveness of their abilities or attributes. Each of these maintenance mechanisms has been shown to be promoted by strong commitment and in turn to promote couple well-being and longevity.

Unjustified Persistence: Remaining in an Abusive Relationship

As noted earlier, simple positivity of affect (e.g., attraction, satisfaction, and love) is not enough to predict stay/leave behavior. Sometimes people persist in completely unsatisfying relationships. Continued involvement in an abusive relationship serves as a good illustration of this phenomenon. Why do people who have been physically battered sometimes choose to stay with their partners? Why would someone remain in a relationship that carries a real risk of serious injury or death? Explanations that emphasize personal dispositions—such as low self-esteem or learned helplessness—tell only part of the story. Through its emphasis on dependence as the structural basis for commitment, the Investment Model helps us understand why abused individuals may sometimes feel that they have no choice but to remain with their partners—because their alternatives are poor and/or because they have invested a good deal in their relationships.

Indeed, the Investment Model has been employed to predict and understand the conditions under which people are likely to remain in abusive relationships. Such research reveals that the decision to persist typically is only minimally related to how dissatisfied the victim is with the relationship. Rather, persistence is first of all predicted by quality of alternatives, in particular by

the quality of the victim's economic alternatives—victims are more likely to persist when they have poor alternatives due to limited education or low personal income. As such, they are constrained from developing a life independent of the abuser. In addition, persistence is predicted by investment size—victims are more likely to persist when they are married to their partners, have been involved for a longer period of time, and have children with their partners. Thus, the Investment Model can fruitfully be used to understand “inexplicable” persistence: People often persist with unjustified, unsatisfying courses of action—unprofitable enterprises, insupportable wars, and unwinnable arms races—because they have nowhere else to go and/or have invested too much to quit.

Conclusions

It is noteworthy that the Investment Model has been shown to predict feelings of commitment, decisions to persist, and diverse relationship maintenance mechanisms not only in young adults' dating relationships, but also in marital relationships, and not only in heterosexual relationships, but also in gay and lesbian relationships. Moreover, the model has been tested in diverse cultures—in the United States, the Netherlands, and Taiwan. Finally, the model has been used not only to understand commitment in romantic contexts, but also to understand commitment to friendships, commitment to diverse formal and informal groups, commitment to consumer products, and commitment to jobs and organizations. Thus, the investment model is a powerful means of understanding how and why people become committed to a given course of action, choose to persist at it, and become motivated to engage in benevolent maintenance behaviors that serve to support continued involvement.

IOWA FAMILY TRANSITIONS PROJECT

This program of research was initiated in rural Iowa in 1989 and has continued since that time for almost 20 years. The study began as an investigation of a cohort of more than 500 early adolescents in two-parent (the Iowa Youth and Families Project) and single-parent (the Iowa Single Parent Project) families. During the adolescent years, the study focused on the development of these focal adolescents (G2) and their relationships with their parents (G1), their siblings, and their close friends. Because the current phase of the research involves the transition of cohort members from their families of origin to a second generation of families, it is now called the Family Transitions Project (FTP).

As the G2s have moved from adolescence to adulthood, the project has added new relationships to the study involving adult friends, romantic

partners, and their G3 children. Retention of G2s in the study has been excellent: 95 percent of the original cohort members have participated in at least one annual assessment during the past 4 years. Each generation in the study has been assessed over a several year period of time using a measurement strategy that is both extensive (i.e., covers multiple domains of personal and social characteristics) and intensive (i.e., employs a multi-informant approach that includes self-reports, other family member reports, teacher reports, ratings by trained observers, school records, and public records). This review discusses findings from this research on the quality of these different types of relationships over time.

Parent–Child Relationships

Research on the parent–child relationship has focused particularly on reciprocal processes in this intergenerational union. An important initial publication in this domain showed that disruptive behavior by the adolescent during a problem-solving task was positively related to harsh and inconsistent parenting over time in a reciprocal process; that is, the more disruptive the adolescent, the more harsh the parent and vice versa. Disruptive adolescent behavior also reduced nurturing and involved parenting over time while such parenting also seemed to reduce disruptive behavior. Cooperative adolescent behavior had no influence on positive parenting; however, nurturing and involved parenting appeared to promote cooperative adolescent behavior. These findings were extended by research showing that parental and adolescent negative affect in general, not just related to problem solving, were reciprocally interrelated across the years from early to late adolescence. When parents and adolescents demonstrated high levels of negative affect toward each other during early adolescence, their expression of negative affect toward each other continued to increase across adolescence, but slowed slightly during late adolescence. The basic message from this program of work on parent–child relationships is that patterns of negative reciprocity are robust and developmentally damaging when they occur by early adolescence.

Sibling Relationships and Friendships

In an important demonstration of how perceptions of quality (i.e., happiness and satisfaction) develop in sibling relationships, the project drew on the behavioral model of romantic relationships to propose that greater observed hostility and lower observed warmth in sibling interactions would reduce perceived quality over time during the adolescent years. Findings were consistent with these predictions. Moreover, perceived relationship quality had no impact on the style of sibling interactions. This analysis supported the view that it is interactional quality in close relationships that either fosters or reduces a positive evaluation of the relationship. A similar analysis focusing on adolescent friendships showed that G2 hostility toward a friend diminished the quality of their relationship, whereas supportive behaviors enhanced it. These results replicated the findings related to siblings. In addition, this study showed that the behaviors that G2 demonstrated toward friends were strongly influenced by the same types of behaviors by G1 parents toward G2.

Romantic Relationships

Romantic relationships of both the G1 and G2 generations have also been studied. Findings for the G1 generation include the following: (a) conflicts about work and family life diminish marital quality, (b) economic pressures and couple psychopathology increase marital problems but supportiveness and effective problem solving between couples help buffer these stress effects, (c) supportiveness in social networks enhances relationship quality but conflicts can diminish it, (d) negative cognitive biases and neuroticism exacerbate negative behavioral interactions that increase the likelihood of marital instability, and (e) satisfaction with sexual relationships enhances marital quality and reduces marital instability.

Research on the adult romantic relationships of the G2 generation show that G1 parenting characterized by nurturance, involvement, and effective childrearing practices predicts G2 interactions with a romantic partner that are high in warmth and low in hostility. This interactional style promotes greater relationship quality. This program

of research also has shown that positive G2 personality attributes like optimism and positive emotions promote success in romantic relationships, whereas negative personality characteristics like neuroticism intensify instability and conflict. In addition, nurturing interactions in the family of origin have been shown to promote G2's secure romantic relationship style and relationship success during the adult years.

Future Directions

In the coming years, the Iowa Family Transitions Project will continue to conduct research on relationships in these three-generation families, including relationships between the G1 grandparents and G3 grandchildren. The project is unique in several respects. It provides a rare opportunity to study relationship initiation, development and termination across many years and multiple generations, and does so with a rural population that is largely ignored in the social science literature.

ISOLATION, HEALTH EFFECTS

Social epidemiologists have traditionally defined *social isolation* as low levels of social integration, indexed by fewer and less diverse social connections with others. Conversely, higher levels of social integration are evidenced by increased numbers of various social ties, including ties with family, friends, religions, clubs, and other group memberships that create social relations with others. Importantly, evidence supports a profound effect of social isolation on physical health, including increased risk for disease and mortality. The health risks of poor social integration underscore the substantial biological implications of human relationships. Notably, even individuals with seemingly ample numbers of social ties (e.g., are married, have an extensive family network, have work relationships) report feelings of isolation and loneliness, and such perceptions may carry health risks as well. As such, both structural determinants and perceptions of isolation are receiving current empirical attention in order to understand how social connections relate to physical well-being. After presenting evidence for social isolation's effects on mortality and morbidity, this entry describes plausible mechanisms linking social isolation to physical health, including contemporary thinking about these important associations between human relationships and health.

Isolation and Mortality

The notion that social isolation has powerful effects on well-being and mortality was proposed in social theory over a century ago. In his sociological study of social regulation in the late 1800s, Émile Durkheim concluded that low levels of social attachment led to a higher likelihood of suicide, highlighting the pivotal role of social bonding in individual and societal survival. More than a half-century later, epidemiological studies began to confirm the impact of social isolation on mortality. Common among these and more current studies has been the extensive measurement of family ties, friendships, marital status, and group memberships in order to characterize individuals' social integration. Provocative evidence

has accumulated that having fewer social ties is as good a predictor of earlier death as are substantial biomedical risks like cigarette smoking and sedentary lifestyle. In their seminal study of almost 7,000 residents of Alameda County, California, Lisa Berkman and S. Leonard Syme found that individuals who reported the fewest social ties were significantly more likely to die over a 9-year period compared with those having the highest levels of social connections, even after controlling for well-established biomedical risk factors. A later reanalysis of the Alameda County study data by Teresa Seeman and her colleagues suggested that the importance of various social ties changes for survival as people age. Although being unmarried related more strongly to earlier death than ties with family and friends for residents below age 60, among those older than 60, having fewer than five contacts per month with close friends and/or family was a better predictor of mortality than marital status. Notably, social isolation among those older than 60 related to a 17 percent higher risk of death, compared with older adults with 5 or more family or friend contacts per month.

Since the 1970s, associations between isolation and mortality have been widely replicated with residents from Tecumseh, Michigan; Durham County, North Carolina; Evans County, Georgia; Sweden; and Finland, among various samples. In some studies, the effects of isolation on survival have been stronger for men than women, and racial differences have also been found, but more research is needed to determine the nuances of the isolation and health link. In all, supported by strong evidence from these large-scale, general population-based studies, the association between isolation and mortality has gained a foothold in the biomedical and behavioral science literatures, substantiating long-held beliefs about the role of social relationships to human survival.

Disease Development, Progression, and Survival

Sparked by the early research on survival, the effect of social isolation on disease onset and course gained empirical attention in the 1980s. Research to date has focused primarily on cardiovascular disease (CVD), including risk for heart

disease development (incidence) as well as survival after heart disease onset. Some studies indicate that after controlling for important biomedical risk factors, social isolation indeed increases risk for cardiac disease incidence. More consistent evidence exists for the effect of isolation on cardiac disease-related mortality and all-cause mortality among patients with existing heart disease. In a comprehensive study of ischemic heart disease, stroke, and cancer incidence and survival, Thomas Vogt and collaborators assessed social connections of CVD- and cancer-free health maintenance organization members and found that reduced network size and scope (when social ties are limited to one domain, such as the family, with few ties across various other domains, such as social clubs, church, or the workplace) increased the risk of all-cause mortality across a 15-year period. Reduced network scope also increased the risk of developing ischemic heart disease, but was unrelated to cancer or stroke incidence. In a study of 763 Swedish men without CVD at baseline, Kristina Orth-Gomer and colleagues found that lower social integration was related to almost four times the risk of developing heart disease across a 6-year period compared with higher social integration. Beverly Brummett and colleagues examined *supportive* social contacts among more than 400 patients with existing coronary artery disease. Social support network size was based on responses to several questions that asked the patient to identify persons with whom they liked to talk and do things and who provided emotional and tangible resources during stressful times. Over a 5-year period, patients with three or fewer supportive social contacts had twice the risk for mortality due to both cardiac-related mortality and all-cause mortality, compared with those with greater than three socially supportive contacts. This effect of isolation was independent of age and, notably, disease severity.

Some studies also point to a possible association between social isolation and cancer mortality. For example, among Alameda County study residents, George Kaplan and Peggy Reynolds found that women who had no or few social contacts were twice as likely to die across a 17-year period from all cancer types compared with women with many social contacts. However, other studies have failed to find a relationship between isolation and cancer

mortality, and only a few among studies of cancer *development* suggest social isolation as a risk factor. Thus, the role of social isolation in cancer incidence and survival remains uncertain.

Aside from its relationship to chronic disease, social isolation also appears to influence the course of acute illness. In a well-controlled study by Sheldon Cohen and colleagues of psychological and social factors related to the development of the common cold, health study volunteers reported on their social connections and were later exposed to varying doses of a cold virus. After viral exposure, individuals characterized by lower levels of social integration were 4.2 times more likely to develop an upper respiratory infection compared with those more socially integrated. Taken together, evidence has accumulated linking a deficit in social connections to the increased risk of both disease and mortality. What is less understood are the pathways leading to social isolation's deleterious health effects.

How Does Isolation Impact Physical Health?

The challenge for contemporary researchers is to identify the mechanisms that contribute to the increased health risk experienced by socially isolated individuals. Various avenues for explaining isolation's effects on health have been proposed and evidence suggests important interactions among psychological, social, and biological factors that confer risk to persons without significant social ties. Socially isolated individuals evidence heightened biological markers of risk, including higher levels of stress hormones, higher resting blood pressure, and weaker immune responses compared with those with more social ties. Such evidence provides one potential physiological explanation for subsequent health risks of isolation, but the origin of these biological risk factors among the socially isolated remains unknown. A better understanding of behavioral and psychosocial factors that contribute to physiological dysfunction will help shed light on the complex relationship between social isolation and health.

One behavioral pathway linking social relationships to health might be the influence that significant others have on one's enactment of healthy behaviors. For instance, a spouse can remind a pain patient to take required medication, friends encourage continued exercise when it becomes a

social activity, and children may serve as caretakers for elderly parents. Alternatively, others can discourage unhealthy behaviors like smoking or excessive alcohol use. With few social ties, there exists little or no external influence on decisions about health behaviors. Greater attention to the ways that social isolation relates to decisions and enactment of health behaviors is needed.

Social support, considered to be the emotional, physical, and informational resources provided by others, especially during stressful times, has been suggested as a key factor in the link between social integration and health. According to the direct effects model, social support is proposed to exert effects on health by bolstering people's sense of belonging, purpose, and control. Thus, social ties are integral to emotional and psychological well-being, which also relate strongly to physical health. The buffering model suggests that social support can buffer the harmful effects of stress on the body; as such, the socially isolated may be at risk for exacerbated and potentially harmful physiological stress effects. Indeed, evidence exists for both models. Importantly, studies also indicate that lower levels of social support can explain why fewer social ties relate to poor health. Understanding how various supportive aspects of social relationships influence physiological function and health outcomes is helping to clarify important associations among social isolation, integration, and physical health.

Finally, other psychological factors associated with social isolation likely influence physical health as well. The socially isolated have higher rates of depression and anxiety, both of which can exacerbate and be exacerbated by poor health. More recent evidence suggests that the psychological experience of loneliness, apart from objective indicators of social integration (i.e., numbers of social ties), has unique effects on the body and may too be a pathway contributing to the health effects of social isolation. The psychological concomitants of social isolation have yet to be fully revealed, and doing so will provide additional elements to the complex picture concerning the health effects of isolation.

Conclusion

In general, a significant lack of social contacts appears to have important effects on our physical

health. The socially isolated have higher rates of mortality as well as physiological and biological profiles indicative of health risk. There also exists some evidence that social isolation is related to increased risk for disease, especially coronary heart disease, and acute illnesses, such as the common cold. There is considerable current interest in understanding the mechanisms linking isolation to health. There also remains a question concerning whether there exists a linear or threshold effect in the social tie and health relationship: Do those with moderate to high levels of social contacts benefit from the addition of more social ties, suggesting an ever-increasing, linear contribution of integration to health, or does the health benefit of increasing one's social network only befall the socially isolated? There is evidence for both a linear and threshold model, and further examination in this area is necessary. In all, continued attention to the interplay among biological, psychological, and social factors that tie social isolation to increased morbidity and mortality will promote further understanding about the crucial role of social relationships to health.

J

JEALOUSY

Jealousy is an unpleasant emotion that arises when one perceives that an important relationship with another, or some aspect of that relationship, is threatened by a third party (a rival). It can have powerful personal and social impact. On the one hand, jealousy may lead to desirable outcomes: redirecting a loved one's attention to the self and reestablishing bonds. On the other hand, it also can have serious negative consequences. For example, jealousy is often implicated as a cause of spousal abuse and is the third or fourth most common motive in nonaccidental homicides across cultures. Romantic relationships provide particularly fertile ground for the elicitation of jealousy. However, jealous feelings also occur across a variety of interpersonal relationships. For example, jealousy can be experienced by children when their parents shower attention and affection on a sibling, or by a person who feels upset over being excluded by friends who are socializing together. Thus, jealousy requires the involvement of three individuals (the self, the partner, and the rival), which is sometimes referred to as a *love triangle*. This entry covers theories of jealousy, including conceptual debates about its origin and definition, presents empirical work on the ontogeny of jealousy as well as work on individual differences in jealousy, and discusses empirical challenges faced in the field.

Definitions and Theory

Although everyone would agree that jealousy involves unpleasant feelings, there is no unanimity on the exact nature of the distress. The feelings we call jealousy may be a blend of affective reactions that arise from more basic emotions such as anger, fear, and sadness. One possibility is that all of these emotions may be experienced simultaneously by a person during a jealous episode. A second possibility is that an individual does not feel several emotions at once, but rather experiences a series of different emotions over the course of a single jealousy episode. Which emotion is felt at any given time would depend on the exact aspect of the situation on which the person is focused. For example, contemplating future loneliness when the relationship is over might elicit sadness, whereas focusing on the partner's dishonesty might elicit anger. A final possibility is that jealousy is a unique emotional state that produces its own distinct feelings and behaviors that differ from other emotions such as fear and anger. In any case, it is generally assumed that the function of jealousy is to motivate behaviors that will break up the threatening liaison between the partner and rival and maintain the relationship between the self and the partner.

Close personal relationships provide individuals with an abundance of physical and psychological benefits. Therefore, it is probable that people have a variety of psychological predispositions toward maintaining relationships. In human phylogenetic

history, it is likely that people who established and protected relationships usually left more offspring. Thus, whatever psychological dispositions helped maintain relationships would have been selected for and passed down to us through our genes. Jealousy is likely to be one such evolved psychological trait. It may even have originally evolved as a response to competition among siblings who compete for a parent's resources, attention, and care. However, once jealousy evolved to protect one particular type of relationship, it likely became useful in protecting other important relationships such as friendships and romantic relationships from interlopers.

In everyday conversations, the term *jealousy* is frequently used to refer not only to feelings that arise in a love triangle, but also to feelings that are based on longing for or desiring what another person has. For example, someone might exclaim, "I'm so jealous of your good grades!" Although the same word might be used in these different contexts, many researchers would argue that the underlying emotional state is probably different. Wanting what another has is more aptly described as envy, whereas jealousy occurs over the potential loss of an existing relationship to another person. Rejection, or fear thereof, also can be an important part of jealousy. However, the rejection that triggers jealousy is generally seen as different from some other types of rejection in that one's interpersonal loss involves another's gain.

Jealousy is also sometimes categorized into two subtypes—"suspicious jealousy" versus "fait accompli jealousy." Suspicious jealousy occurs when one fears that there is a potential, but uncertain, threat to the relationship. Fait accompli jealousy is a response to a betrayal that is certain or has already occurred.

Development of Jealousy

Signs of jealousy have been found in young children. Some research has shown that a parent's attention merely being directed toward another child is enough to elicit jealousy in infants as young as 6 months. These infants exhibited more negative emotion when their mothers interacted with a lifelike baby doll, relative to when their mothers played with a nonsocial toy (i.e., a book

that made sounds). This suggests that at least some primitive forms of jealousy can be elicited without complex thoughts. However, with additional cognitive development, the triggers for jealousy become more sophisticated. For example, by preschool age, the specifics of a social triangle affect whether jealousy arises. One study found that 4-year-old children showed more jealousy when their mothers interacted with a similar-age peer than when she interacted with an infant. Jealousy in younger infants was not affected by the rival's age. Thus, it appears that, over the course of development, an individual's social and cognitive appraisals of the exact nature and meaning of the interactions between the rival and the loved one become increasingly important in determining whether jealousy is experienced.

Research approaching jealousy from a social-cognitive perspective has focused primarily on two general factors that cause a loved one's involvement with another to be particularly threatening: (1) when it reduces relationship rewards that are derived from the primary relationship, and (2) when it challenges some aspect of a person's self-concept, self-regard, or other self-representations. Thus, people ponder the meaning and ramifications of their loved one's relationship to the rival: "Will this rival relationship reduce the important things I get from my relationship with my partner such as attention, affection, and support?" and "What does this mean about me? Am I unlovable, unattractive, unworthy?" The answers to these questions generally affect the intensity and nature of the jealousy that is experienced.

Individual Differences

Attachment Styles

Research suggests that differences in attachment style may play an important role in jealous reactions. According to attachment theory, people's experiences, starting in infancy, lead them to form internal working mental models of relationships that include beliefs about others and the self. Some research categorizes attachment styles into three types: (1) secure people feel comfortable being interdependent and intimate with an attachment figure, (2) anxious-ambivalent people want closeness but fear abandonment and worry that their

attachment figure may not truly love them, and (3) avoidant people are uncomfortable with too much intimacy and have difficulty in completely trusting the attachment figure. Research suggests that the anxious-ambivalent attachment style is associated with a propensity toward perceiving a greater number of relationship threats, which may lead to more frequent and/or more intense bouts of suspicious jealousy. Individuals with a secure attachment style are less prone to experience jealousy over an ambiguous threat. Some studies suggest that attachment style also may be associated with how people choose to express their jealousy. Securely attached individuals report that they are more likely to express, in constructive ways, their jealous anger toward their partner while attempting to maintain the relationship. Avoidant individuals report expressing more jealous anger toward the rival and are likely to create distance in the relationship, whereas people with anxious attachment attempt to suppress overt acts of jealous anger.

Gender

Some studies find women to be more jealous than men, whereas other studies find the reverse. Overall, however, there seems to be no major consistent differences in the intensity of jealousy in the two genders. Early work suggested that jealousy in men was a stronger motive for murder than in women. However, careful analyses of murder motives, taking into account men's overall greater tendency to commit extreme violent acts, show that a woman who commits murder is as likely to be motivated by jealousy as a man who commits murder. Some research even suggests that women murderers may be relatively more motivated by jealousy than male murderers (albeit the difference is slight).

A controversial topic that has been the focus of much research is whether men and women are jealous over different forms of infidelity. One theory, which is sometimes referred to as the Jealousy as a Specific Innate Module (JSIM) view, hypothesizes that gender differences should exist in jealousy over a romantic partner's infidelity: Men should feel relatively more upset over sexual betrayal and women over emotional betrayal. This view proposes that historically men and women have faced different threats to their rates of producing viable offspring (inclusive fitness). Because fertilization

occurs internally within women, a man could never know with 100 percent certainty that an offspring was his own. Therefore, the problem faced by ancestral man was to ensure that he spent his resources (food, time) only on children that were genetically his. Supporting nongenetically related children would not only decrease the number of biological children that he had, but would also help pass another man's genes on in place of his own. Hence, the JSIM theory proposes that men who were particularly vigilant to sexual infidelity could prevent this from happening. Thus, modern men should be particularly jealous of sexual infidelity. A woman, in contrast, always knows that an offspring is her own, and therefore a mate's sexual infidelity per se would not pose as large of a threat as it would to a man. Instead, an ancestral woman had to guard against her mate giving his resources to other women and their children, which would decrease the likelihood of the woman's own children surviving and reproducing. Thus, present-day women should be particularly jealous over emotional infidelity. Inherent in this is the assumption that a man's emotional involvement is a proxy for his spending resources on another.

Some support for gender differences consistent with this view came from early studies that reported that when people were forced to predict whether a partner's sexual or emotional infidelity would be more upsetting, relatively more women than men picked emotional infidelity. However, several lines of new research with other types of measures and with participants who have actually experienced a loved one's betrayal have not found consistent gender differences in reactions to sexual and emotional infidelity. One study with adults of a wide age range found that men and women, regardless of sexual orientation, focused more on the emotional aspects of their partner's actual betrayal relative to the sexual aspects.

This raises the interesting question of why evolution would have failed to produce gender differences. One possibility is that there may have been no need for sexually dimorphic jealousy mechanisms—a more general jealousy process may have addressed the inclusive fitness risks faced by either gender. Perhaps the most successful way for both sexes to prevent a partner's infidelity would be to be watchful of the common early warning signs of either form of infidelity. People usually display

flirting behaviors such as increased eye contact and smiling well before they have sex or fall in love. This occurs in modern times and presumably in the ancestral past. Because the same behaviors can signal the beginnings of emotional interest, sexual interest, or both, attunement to these common early warning signals would enable both men and women to prevent their partners from engaging in either form of infidelity. This hypothesis is consistent with the emerging evidence that men and women show similar reactions to sexual and emotional infidelity.

Pathological or Morbid Jealousy

Sometimes jealousy takes such extreme characteristics that clinicians will diagnosis it as *pathological jealousy* (also called *morbid jealousy*). This disorder involves intense negative feelings, frequently produces strong urges to spy and check on a partner, and can motivate violent behaviors. Patients suffering from pathological jealousy often have delusions that their romantic partner is cheating on them. Before giving a diagnosis of pathological jealousy, clinicians must believe that the patient has weak and implausible evidence of betrayal or is responding to a betrayal with an overly intense or exaggerated reaction. Of interest, there are gender differences in the prevalence of pathological jealousy, with approximately 64 percent of the cases occurring in men and 36 percent of the cases occurring in women. Recent research suggests that at least some cases of pathological jealousy are a form of obsessive-compulsive disorder, and the disorder is sometimes treated with the antidepressant medication, fluoxetine.

New Methodologies for Studying Jealousy

Several paradigms have been created in the developmental arena to actively elicit jealousy over a parent's attention to a sibling or other child, including the one described earlier. In adults, paradigms that induce jealousy in live interactions are far more scarce (less than a handful of studies). Recently, several researchers have begun grappling with this issue by designing studies that involve interpersonal interactions that produce jealousy in controlled and ethical ways. David DeSteno and

colleagues have designed an orchestrated social encounter in which one person (a confederate of the experiment) rejects the actual participant in favor of a third person. As predicted by social-cognitive theories of jealousy, this work found that threatened self-esteem plays an important role in the elicitation of jealousy and provided further evidence for the link between jealousy and interpersonal aggression. Eddie Harmon-Jones and associates also have employed a rejection scenario in which participants play with two computer-generated players. This study is one of the first to look at brain activity during jealous experiences and found that greater jealousy is associated with increased activity in the left frontal cortex. Research on other emotions suggests that the brain's left hemisphere may play a particularly strong role in emotions that lead to approach behaviors, such as occur during anger or pleasant emotions. This can be contrasted with emotions associated with withdrawal behaviors such as fear or sadness. These data are consistent with the hypothesis that jealousy, at least initially, is an emotion that inclines one to engage in approach behaviors, which may include active attempts at breaking up the threatening liaison or maintaining the relationship.

Examination of jealousy in established romantic relationships can be particularly challenging ethically. The researcher must be concerned about the potential damage to the romantic relationship that might occur as a result of any jealousy manipulation. For this reason, the vast majority of research on romantic jealousy has relied either on hypothetical scenarios in which participants try to imagine themselves in situations and then attempt to predict how they might feel or react or on retrospective recall of jealous experiences. Such approaches clearly offer important insights about jealousy. However, they also have limitations. People often are not good at accurately predicting how they will feel about something that is not currently happening, especially when they have had no actual past experiences with the emotional situation. For example, if one has never had the experience of a partner cheating, then it is difficult to know how one would react when actually confronted with such a situation. Recall of past jealousy experiences may be a better measure of jealous feelings. Yet, it too has limitations, such as potential recall bias or memory omissions.

A new paradigm, created in Christine Harris's lab, helps overcome some of the ethical obstacles of actively eliciting jealousy in couples. A participant is shown a flirtatious computer dialogue that is purportedly between the participant's partner and a rival. In actuality, there is no rival, and the partner is told exactly what to enter into the computer. This has the advantage that jealousy is actually elicited, but any potential harm to the primary relationship can be completely eliminated at the end of the experiment by revealing that there was no real third person and that the partner did not actually engage in flirtatious behaviors. (Follow-up phone interviews conducted after the experiment also confirmed the lack of relationship harm.) This experimental work has documented that physiological arousal increases during jealousy and has also shown that jealousy can be expressed through derogation of the rival.

Conclusion

In summary, there is no doubt that jealousy can have negative ramifications as discussed previously. However, jealousy also can have positive effects for the individual and for the relationship. For one, it alerts one to potential relationship threats, which can promote behaviors that help to maintain the relationship (such as discussing the threat or encouraging the partner to take steps to avoid potential temptation). For example, a 7-year longitudinal study found that individuals who were high in jealousy were more likely to have successful relationships than individuals who were low in jealousy. Other work suggests that jealousy may have differential relationship impact depending on one's attachment style. Securely attached individuals reported that a past jealousy experience brought them closer to their partners—an effect not experienced by anxious-ambivalent or avoidant individuals.

JOB STRESS, RELATIONSHIP EFFECTS

Research on the association of job stress with the health and functioning of personal relationships, particularly relationships outside of work, has a long history. Most of this research has focused on the impact of job stress on family relationships, exemplified by research on *work–family conflict* and (more currently) *work–family balance*. A persistent assumption in research is that the impact of job stress is assumed to be more significant for women than for men. There exists, however, considerable evidence that job stress also affects men's relationships. Job stress, moreover, may affect relationships beyond those in the worker's household, although this possibility is much less commonly examined in the literature. In addition, job stress may not necessarily have deleterious

effects on family or other relationships. Individual workers and families develop successful ways of coping to mitigate the negative impacts of job stress on their relationships.

Contemporary research on the relationship effects of job stress is a multidisciplinary endeavor, encompassing social psychology, sociology, organizational behavior, and policy research. Research has evolved in response to social trends, especially the increasing labor force participation of mothers in the last 40 years and the increase in dual-earner families. The first section of this entry reviews major terms and theoretical approaches used in this research area. The second section examines the specific types of job stress that are believed to affect relationships. The third section reviews gaps in the literature on relationship effects.

Theoretical Approaches

There is abundant evidence that chronic job stress (including interpersonal conflict at work) is related to poorer physical and mental well-being. Since 1980, researchers have paid increasing attention to how the contagion of stress from the workplace to personal relationships may reduce well-being. Stress contagion from the job to other settings is generally classified into two types: *spillover* and *crossover*. *Work spillover* is defined as job stress that crosses the boundary from work into another area of life. Spillover can be either behavioral (paying less attention to a spouse or child) or affective (feeling more impatient with them). Crossover occurs when stressors experienced on the job have an impact on the behavior or mood of a significant other person, such as a spouse or child.

Researchers from many disciplines have contributed to the study of work spillover and crossover. For example, social and gender role theories in sociology have long influenced research on the relationship effects of job stress. Psychological and organizational research on spillover has applied the sociological definition of social role, which is the set of normative expectations for behavior in an important domain of life. Gender roles are defined as expectations for appropriate masculine and feminine behavior. From these definitions of social and gender roles emerged the ideas that conflict can develop between job duties and family

relationships, and that women are more likely to experience significant relationship effects from job stress because of social expectations that women rear children and defer their own careers to accommodate their husbands.

Studies conducted in the 1960s and 1970s, when fewer mothers participated in the paid labor force, started with the premise that work–family conflict was primarily a problem for working mothers. Changes in women’s employment patterns, however, have led to shifts in both the definition of work–family conflict and in the focus of research. The majority of married women in the United States and other developed nations now are cobreadwinners for their households, and their contributions have helped raise family living standards. Research has also established that men are contributing more time to household work and to child care. A more contemporary view of work–family conflict is that it is experienced when household breadwinners do not have enough time to fulfill their joint work and family commitments. Work–family conflict is viewed as the result of having too few hours in the day. This evolving view about the cause of work–family conflict also strongly suggests that men as well as women experience its effects.

The shift in explanation about what causes work–family conflict has also led to the introduction of more eclectic theoretical perspectives into the study of job stress spillover and crossover. Specifically, studies of spillover and crossover have been greatly influenced by theories about stress exposure. Chronic job stress is believed to cause fatigue, exhaustion, anger, or withdrawal from household responsibilities and relationships, and it affects both men and women.

Stress exposure theories emphasize not only exposure to job demands, but also situational and personal factors that influence how workers perceive and cope with those demands. For example, Robert Karasek’s influential demand-control model includes predictions about how job demands and worker control over the pace and number of those demands influence other areas of life. High demand–high control jobs encourage workers to become active problem solvers, low demand–low control jobs encourage workers to be passive copers, and high demand–low control jobs (high-stress jobs) produce exhaustion, fatigue, and social withdrawal. A modification of the Karasek model

to include social support also suggests that positive social relationships can protect workers from the negative health effects of excessive job demands.

Job Stress and Family Relationships

The application of stress exposure theories to research on relationship effects of job stress has led to several advances over empirical findings predicted by traditional social and gender roles theories. First, long work hours and the combination of a couple's work hours are associated with experiencing more job demands and more spillover and crossover of job stress into family relationships. Spillover from work to family is particularly acute in single-parent families. Second, and contrary to the predictions of traditional role theory, men's and women's relationships are both affected by job stress. The impacts, however, differ. Women are more likely than men to take preventive actions against bringing job stress home, such as by working fewer hours and avoiding more demanding jobs. Men are more likely than women to expect family members to adjust to their job stress. Third, interpersonal conflict at work, job insecurity, lack of control over work demands, and insufficient rewards relative to efforts can affect a worker's family. Daily job stressors of all types are associated with marital arguments and withdrawal. Job stress may affect the quality of relationships with children negatively by decreasing time spent with children and increasing arguments. Fourth, there are individual and between-family differences in how job stress affects family relationships. Families with a history of conflict are particularly vulnerable to tensions associated with job stress. Workers who have a history of psychological distress or neuroticism are more likely to report spillover of job stress into their family relationships.

Researchers have also examined positive, problem-focused coping strategies that mitigate the impact of job stress on family relationships. Supportive spouses respond to each other's job stress and mitigate the impact on their children. In related research on the work-family interface, the term *work-family balance* has shifted the focus away from a wholly negative view of how work influences family life. Empirical studies have found

that dual-earner couples typically develop successful (or at least good enough) collaborative strategies to perform major household tasks, rear and monitor children, maintain rewarding household relationships, and stay employed. Parents also actively negotiate arrangements with their employers to make it possible to fulfill work and family commitments, both over the short and long term. Although some of these strategies may involve juggling too many demands and lead to the perception that life is stressful, the aim of the strategies is to keep family relationships healthy in the long run.

Underexplored Areas in Job Stress Relationship Effects

The study of the relationship effects of job stress has been shaped by changing experiences among workers in developed nations (the United States, Europe, and Asia). Less attention has been paid to equally important changes in family relationships that may complicate the picture, such as the increase in the number of single-parent families, stepfamilies, and parental cohabitation in lieu of remarriage.

Several studies in the last decade have focused on job stress effects on relationships in single-parent families. As mentioned, single parents are more likely to report frequent spillover between job stress and home life, particularly in low-income families where parents lack adequate resources for child care.

Few studies have explicitly considered work spillover and crossover effects in families led by remarried parents or cohabiting partners. Cohabitation has become common in the United States and Europe, and many children spend several years of their childhood with a cohabiting parent. This is a critical gap in research because step and cohabiting families tend to report more family conflict and less cohesion. As described previously, research on job stress spillover and crossover has shown that the impacts on relationships vary depending on the degree of conflict and supportive interactions in households.

The impact of parental job stress on children also deserves fuller exploration, particularly in single-parent families. There is considerable research indicating that mothers and fathers withdraw from

interacting with children or experience tension with them after a bad day at work. National data on time use, however, suggest that long work hours (and maternal employment) have not reduced the number of hours, on average, that married parents spend with their children. Both mothers and fathers in two-parent families spend more time with their children than they did 30 years ago and have increasingly spent that time on activities that contribute to their children's cognitive and social development. (Employed single mothers spend about the same amount of time with their children as they did 30 years ago, but are also increasing time spent on child developmental activities.) One possible explanation of these trends is that working parents perceive a greater need to invest in their children to ensure educational and future occupational success. Parents spend less time on housework, leisure pursuits, and (if married) with each other.

Finally, job stress may have an impact on overall levels of social integration in a society. The impact of job stress on the transition to marriage and parenthood is rarely studied. It is well-known that men and women in economically developed nations are marrying later, and the reasons are not entirely clear. In Europe, several theorists have raised the possibility that job stress and long work hours among early career men and women delay marriage and discourage childbearing within marriage, causing startling declines in overall fertility. Even fewer theorists have considered the impact of job stress on the formation of friendships. A recently published study suggests that job demands and stress among recent cohorts in the United States are responsible for the decreasing size of social networks, with perhaps lasting consequences on social integration and well-being.

JUSTICE NORMS APPLIED TO RELATIONSHIPS

In relationships, members exchange resources (i.e., each member makes contributions to the relationship and receives benefits from the relationship). Researchers have long been interested in the rules and norms that govern these exchanges. Although several *justice norms* have been postulated, scientists have tended to focus on three of these rules: the equity rule (rewards are distributed in proportion to the contributions made by each individual), the need-based rule (rewards are distributed in response to the needs of each individual regardless of his or her contributions), and the equality rule (everyone receives similar rewards regardless of needs or contributions). Many different resources can be exchanged in relationships. Resources can be both tangible (e.g., money, material goods) and intangible (e.g., affection, love, time, effort) and vary depending on the relational setting. This entry discusses the three justice norms that people may use when distributing resources in their relationships.

Equity, Need, and Equality

The rule that has received most attention in research is the *equity rule*. John Stacy Adams originally formulated Equity Theory in the 1960s to explain employees' job satisfaction and motivation, but he postulated that the equity rule would be relevant in all human relationships in which exchanges of resources take place, including close relationships such as relationships between romantic partners or close friends. According to Equity Theory, a distribution is equitable when the ratio between contributions and rewards of each individual to an exchange is equal. Imagine a situation in which two friends take on a job to paint someone's house for a certain amount of money. When the job is done, the two friends have to divide the money between them. All else being equal, if one friend has spent twice as many hours on the job, then, according to Equity Theory, the money should be divided accordingly (i.e., that friend should receive two thirds of the money and the other friend one third). The ratio becomes unequal whenever either member is receiving too much or too little, relative to what they are contributing. Equity Theory proposes that individuals who perceive themselves as either overbenefited (receiving more than a fair share) or underbenefited (receiving less than a fair share) will become distressed, but that underbenefit is more distressing than overbenefit. Equity Theory further predicts that the distress leads to efforts to either restore actual equity (by changing one's own contributions or by convincing the other individual to change theirs) or psychological equity (by changing one's perceptions and expectations of each individual's contributions and rewards). If this fails, individuals may end the relationship or disengage from it.

The idea that equity applies to all human relationships has been challenged by researchers who postulate that the justice norm used will depend on the type of relationship. According to these researchers, the equity rule is the typical justice norm in exchange relationships (business relationships and relationships between strangers), but not in communal relationships (relationships among romantic partners, friends, and family members). An important feature of communal relationships is that people are concerned with the other person's welfare and well-being. In such relationships,

people are thought to use a *need-based rule*: They are responsive to the other person's needs without expecting or wanting a benefit in return. Also, receiving a benefit does not create a debt that has to be reciprocated at a later time. The responsiveness to needs is expected to be mutual: Each member will try to accommodate the other person's needs to the best of his or her ability. Going back to the example of the friends painting the house: Suppose these are close friends and the friend who spent fewer hours on the job really needs the money, but was unable to put in the hours because he got sick. In that situation, the other friend might very well go 50:50 on the money. He might even give the whole amount to his friend if the friend's needs are pressing (e.g., the friend is otherwise unable to pay the rent) and he does not desperately need the money at present.

Still other researchers have suggested that, particularly in close relationships, people use an *equality rule*, that is, they split benefits (and sometimes costs) evenly among members regardless of each member's contributions. In the prior example, friends using an equality rule would split the money evenly regardless of the fact that one friend spent more hours on the job than the other and regardless of differences in needs. Although the equality rule has been distinguished as a separate rule, it has been argued that dividing benefits (or costs) evenly can be consistent with both an equity rule and a need-based rule and is therefore difficult to test in research. A situation in which resources are divided equally is equitable when both members contribute the same. In a situation where both members have equal needs, an even split is consistent with following a need-based rule. In the remainder of this entry, we therefore focus on research examining the equity rule and the need-based rule.

Research

Equity

Whether one feels equitably treated in a relationship is a subjective experience. Therefore, researchers generally measure perceived equity with self-report methods. In many studies, a global measure of equity is used. Respondents are typically asked to think about everything that is exchanged in their relationship with a specific other person

(e.g., a romantic partner, friend, or coworker) and provide an overall assessment of the equity or inequity of the relationship. Other studies use detailed or domain-specific measures of equity. For example, romantic partners might be asked to rate their own contributions, their partner's contributions, their own outcomes, and their partner's outcomes in a number of areas (e.g., love, status, money, goods, services, and sex). A formula is then used to compute the (in)equity in the relationship.

Research indicates that in a wide variety of interpersonal relationships, including romantic relationships (dating, engaged, married, couples facing a serious illness, older people), friendships, and relationships at work (with coworkers, clients, supervisors), individuals who feel equitably treated score higher on indices of well-being such as (marital) satisfaction and lower on measures such as negative feelings about the exchange (e.g., anger, sadness, guilt), loneliness, depression, burnout, and absenteeism, compared with individuals who feel inequitably treated, particularly underbenefited. A limitation of the research in this area is that many studies are cross-sectional, which means that perceptions of equity and the proposed outcome variables are measured at the same time. This precludes statements about causality, that is, it is impossible to tell whether inequity leads to distress, as is postulated by Equity Theory, or that distress leads to inequity. In longitudinal studies, support for both causal pathways has been found. Several authors now suggest that the relationship between perceived equity and other variables such as satisfaction and commitment may be circular and that perceived equity can be both a cause and a consequence.

Need

Support in favor of the use of a need-based rule in close relationships stems mostly from laboratory studies. These studies have shown that participants are more responsive to another person's needs when they are in an existing communal relationship with this other person as opposed to an exchange relationship (e.g., close friends compared with casual acquaintances) or are led to desire a communal relationship as opposed to an exchange relationship with this other person. Research conducted with married couples has shown that people

consider the need-based rule to be more ideal in marital relationships and that spouses try to follow that rule to a greater extent in their relationships than the equity rule or the equality rule. There is also some evidence that, at least for women, the perception that communal rules are followed in the relationship is associated with increased perceptions of fairness.

Equity and/or Need in Close Relationships?

With respect to relationships among strangers, acquaintances, and other less intimate relationships, there is considerable agreement among scientists that the equity rule is an important justice norm in these relationships. With respect to close relationships, scientists advocating the equity rule and the need-based rule have been on opposite sides for many years. As discussed previously, there is empirical support for both rules in close relationships. How can these research findings be reconciled? Some authors have argued that both rules are not as different from one another as they appear at first sight. Researchers advocating a need-based rule maintain that in close relationships members should be mutually responsive to each other's needs. If both parties adhere to this rule, then in the long run such an exchange would be equitable. It has been argued that an immediate reciprocity ("tit for tat") strategy is indeed maladaptive for ongoing close relationships, but that people do strive for reciprocity or equity in the long run. Other researchers postulate that, although many people would consider the need-based rule ideal and worth striving for in close intimate relationships, people don't always live up to this rule. It has been suggested that people may change to an equity rule when their needs are not met or when they are under stress. Thus, according to these researchers, both rules apply to close relationships; however, they clearly maintain that the need-based rule is the ideal rule and that people strive toward using this rule.

Scientists have also examined the possibility that some people are more likely to use a certain norm than other people and that there might be individual differences in people's sensitivity to violation of these norms. Research has shown that people differ in how exchange-oriented

(a tendency to seek immediate reciprocity) or communally oriented (a tendency to respond to other people's needs) they are in their relationships. Although some research shows that people high in exchange orientation or low in communal orientation are more sensitive (i.e., experience more negative outcomes) to inequity, these findings are not entirely consistent over studies. Other individual difference variables that have been examined are attachment style and self-esteem. There is some evidence that suggests that securely attached individuals (who generally believe that others are trustworthy) are more likely to perceive equity in their romantic relationship, whereas individuals with an anxious attachment style (a tendency to worry about abandonment and not being loved enough) are more likely to feel underbenefited. It has also been suggested that individuals with a secure attachment style might be more likely to follow a need-based rule in their relationship compared with people with an anxious or avoidant style. However, this assumption has not been empirically tested yet. With respect to self-esteem, some research suggests that individuals with low self-esteem are more negatively affected by feeling underbenefited in a romantic relationship than are individuals with high self-esteem.

One other factor that has been studied in equity research is gender. Research generally shows that men are more likely to report feeling overbenefited in their romantic relationships, whereas women are more likely to report feeling underbenefited. There is also evidence that women are more negatively affected by perceptions of inequity, overbenefit, and underbenefit than are men.

K

KINKEEPING

Kinkeeping, in most of the related research, has been defined as keeping in touch with family members and/or keeping family members in touch with one another. Occasionally, kinkeeping has been more broadly defined to include providing tangible assistance to family members (e.g., helping with tasks such as household chores), but this definition seems too broad. Some researchers include emotional support as part of kinkeeping work, while others see the provision of emotional support as a specialized role. In this entry, the definition of kinkeeping is restricted to activities related to communication and contact, activities that promote a sense of continuity and solidarity in families.

This entry discusses the need for kinkeeping, the activities and impact of kinkeeping, and the presence in many families of the position of family kinkeeper. Consideration is given, as well, to kinkeeping in the context of transnational immigration and in the Internet age.

Why Is Kinkeeping Necessary?

In contemporary society, maintaining solidarity and continuity in families may become problematic as families experience disruption stemming from, for example, death, geographical and social mobility, immigration, and life-course transitions such as marriage and divorce. These and other factors may pose a challenge to maintaining kin

relationships. If family members do not make an effort to keep in touch, kin ties may become attenuated. Kinkeeping in families seeks to ensure this does not happen.

Structure of Kinship in Adult Life

In North America and Europe, the basic family unit is the nuclear family, that is, parent(s) and children. Living arrangements reflect this emphasis in that most households consist of nuclear families (with some variation due to marital status, childlessness, sexual orientation, and ethnicity). Over time, as children grow up, marry, and have children of their own, several nuclear families result; these remain connected through social and emotional ties. This broader network, consisting of older parents and their adult children and grandchildren, has been characterized as a modified extended family. Although large family reunions involving the wider extended family may occur from time to time, the modified extended family, involving adult siblings and their parents and children, comprise the family ties that seem most important to individuals in our society. Much of the work of kinkeeping involves maintaining ties between members of the modified extended family.

The Work of Kinkeeping

Kinkeeping work may include activities such as hosting or arranging family gatherings; transmitting

family news among family members; keeping in touch by phone, mail, or electronic means; creating and maintaining a family genealogy; and recognizing special occasions such as birthdays and anniversaries. Another kinkeeping activity is maintaining family harmony, for example, by acting as a mediator or peacemaker to resolve family disputes.

Some researchers have included preserving traditions as kinkeeping. These traditions may be religious, ethnocultural, or special ways of celebrating holidays that seem unique to a family's members. Preserving these traditions often provides a sense of family identity and gives meaning to family relationships. Preserving traditions may be particularly important to older family members who are immigrants, but assimilation of younger family members into the ways of the host country may result in the loss of traditions. Some research has pointed to the important role older immigrants play in preserving traditions, thereby enhancing feelings of family solidarity and continuity. Researchers have termed this symbolic kinkeeping, referring to activities that go beyond activities such as hosting or arranging family gatherings to include activities that reinforce a sense of meaning and importance of family. Examples of such activities include passing on ethnic culture, religious values, family stories, and special family recipes.

Transnational Kinkeeping

Immigration and emigration pose a multifaceted challenge to family ties. One of the challenges is maintaining family bonds across vast distances and in the face of cultural change. Some research has shown that older immigrants act as links between kin in different countries through sharing news and photographs and other such activities. As is discussed below, the Internet and cell phones have no doubt made transnational communication much easier than it was in the past. In addition, affordable air travel has enabled older immigrants to make visits back to the country of origin, adding to the opportunity to maintain their own personal ties and to nurture those between family members in the old and new countries, for example, by keeping everyone up to date on family news.

Family Kinkeeper: A Specialized Role

Whereas kinkeeping is performed informally by several family members in many or most families, a Canadian study found that in many families there is someone who is perceived to perform the specialized role of kinkeeper. In that study, just over half the participants said there was a person in their family who works harder than others at keeping family members in touch with one another. The researchers conceptualized this person as occupying a position in a familial division of labor and called this position the kinkeeper.

Kinkeeping is mainly a female activity (although it is important to note that men do kinkeeping work as well and occupy the position of kinkeeper in a minority of families). It is not surprising that kinkeeping is gendered in this way since much research has found that relationships between women are key linkages in kinship relations in North America. The mother–daughter tie has been found to be the strongest of all kin ties among adult kin and daughters to be the most common providers of help to aging parents.

The position of family kinkeeper is most commonly passed from mother to daughter. One of the main reasons for kinkeeping appears to be challenges to maintaining sibling ties over the adult life course, first as siblings have children and second as they have grandchildren. The death of parents seems to bring this challenge into focus as middle-aged women come to perceive that their family and their siblings' families will drift apart unless conscious kinkeeping efforts are made. There is some overlap as age-related changes lead mothers to begin to decrease their kinkeeping activities and adult daughters to begin to increase their efforts; in time, however, a new family kinkeeper moves fully into the position.

Although there is little recent research on kinkeeping, future research might test the hypothesis that as gender roles in general have become less traditional, men's involvement in kinkeeping may have increased. More men may be doing kinkeeping work and occupying the position of family kinkeeper.

The Impact of Kinkeeping

Having a family kinkeeper is associated with greater extended family interaction and a greater

emphasis on family ritual. Kinkeeping may also have an impact on individual well-being. Among today's older women, performing kinkeeping activities is positively associated with reported happiness. This may be a cohort effect in that these women were socialized to traditional gender role expectations and experience satisfaction when they fulfill these expectations. Today's younger and middle-aged adults are less traditional about gender roles and show no association between kinkeeping activities and reported happiness.

Kinkeeping and the Internet

There is little research on how the Internet has enhanced kinkeeping. It is very likely, however, that the Internet is used for kinkeeping activities in many families and that it will be used even more in the future as computer-savvy cohorts age. It is easy to see how the Internet could be used for virtual family reunions, maintaining family trees, maintaining a family photo album, having family chat rooms, locating distant relatives, and so on. Documenting these possibilities, however, remains a task for future research.

Although the methods by which kinkeeping occurs may change in the future, as families themselves continue to change, the prevalence of kinkeeping activities attests to the importance individuals attribute—and no doubt will continue to attribute—to maintaining family relationships and to a sense of family identity and continuity.

KIN RELATIONSHIPS

Kin relationships are traditionally defined as ties based on blood and marriage. They include lineal generational bonds (children, parents, grandparents, and great grandparents), collateral bonds (siblings, cousins, nieces and nephews, and aunts and uncles), and ties with in-laws. An often made distinction is between primary kin (members of the families of origin and procreation) and secondary kin (other family members). The former are what people generally refer to as immediate family, and the latter are generally labeled extended family. Marriage, as a principle of kinship, differs from blood in that it can be terminated. Given the potential for marital breakup, blood is recognized as the more important principle of kinship. This entry questions the appropriateness of traditional definitions of kinship for new family forms, describes distinctive features of kin relationships, and explores varying perspectives on the functions of kin relationships.

Questions About Definition

Changes over the last 30 years in patterns of family formation and dissolution have given rise to questions about the definition of kin relationships. Guises of kinship have emerged to which the criteria of blood and marriage do not apply. Assisted reproduction is a first example. Births resulting from infertility treatments such as gestational surrogacy and in vitro fertilization with ovum donation challenge the biogenetic basis for kinship. A similar question pertains to adoption, which has a history going back to antiquity. Partnerships formed outside of marriage are a second example. Strictly speaking, the family ties of nonmarried cohabitantes do not fall into the category of kin, notwithstanding the greater acceptance over time of consensual unions both formally and informally. Broken and reconstituted families are a third example. The growth in divorce, remarriage, and the formation of stepfamilies has created complex kin networks in which relationships between people who have blood ties are not sustained, and kinlike relationships exist between people who have no blood ties. The chosen families of gays and lesbians are a fourth example.

Their extended family networks, often including former lovers, former spouses, friends, children from heterosexual marriages, and children acquired through adoption or the use of birth technologies, are personally constructed rather than governed by rules of blood and marriage.

The diversity in networks of kin relationships is relatively new, and scientific and lay vocabularies have difficulty keeping pace with social reality. The field does not have the terminology for new and complex kin relationships. The term ex-granddaughter-in-law, introduced by Gunhild Hagestad, serves as an example: Not only do scholars need to get used to the idea that grandchildren can be middle-aged adults with families of their own, but the field lacks the words for relationships shaped by divorce and remarriage.

In scientific texts, the terms *quasi* or *fictive* kin are often used to denote relationships where the traditional rules of kin membership do not apply. These terms carry the connotation that there are real family relationships (defined by blood and marriage) and other family relationships. There is a need to rework the definition of kin relationships to take better account of social reality. Insight can be gained from the practice of law, where regulations regarding adoption, guardianship, gay marriage, registered partnership, inheritance, visiting rights, and maintenance obligations are being developed. Increasingly, conceptualizations of kin relationships need to consider construction and flux rather than take an assumed established structure as their point of departure.

Characteristics of Kin Relationships

An essential difference between kin relationships (other than the marital tie) and nonkin relationships is that the former are given whereas the latter are made. The family of origin forms a constellation of relationships into which a child is born and that exists independently of that individual. This constellation of relationships is, however, very dynamic. It changes as new generations are born and old generations die. Positions within intergenerational chains shift as children become parents and parents become grandparents.

Endurance is another distinctive quality of kin ties: They continue to exist even if left dormant.

Nevertheless, as research on the consequences of divorce for intergenerational family ties shows, they are not inalienable.

Though one's family of origin is "in no sense chosen" (1993, p. 167), to use the words of Janet Finch and Jennifer Mason, there is an element of choice regarding which kin ties are honored. Research findings show that these choices are guided by, among other factors, kinship norms. In most Western societies, the normative obligation to provide support is weaker for genetically more distant family members. Norms are also weaker for ascendant (up lineal lines) than descendent (down lineal lines) kin. The strongest kinship norm is the obligation toward children, followed by that toward parents. Cross-cultural research finds variations in the prioritization of kin relationships. An emphasis on lineal bonds is more typical of Caucasian and Asian families, whereas an emphasis on collateral bonds is more typical of Black families.

Kinship norms do not form a set of preordained rules. As Graham Allan states, kin solidarity in Western societies is permissive rather than obligatory. The norms do not require mutual aid, and under specific circumstances (e.g., poor relationship quality, large geographic distance), it is socially acceptable to deviate from them. A strong theme in research on practices of support and care is that kin responsibilities are negotiated interactively. Sometimes negotiations are overt and explicit, but more often they are implicit. Important elements in the negotiations are shared histories, relationship quality, conflicting commitments, and the personalities of those involved.

The negotiation of kin responsibilities is more likely in individualistic (Euro American) cultures, which stress independence, self-sufficiency, and the pursuit of personal goals, than in collectivistic (Islamic or Confucian) cultures, which stress kin-group membership and the submission of individual goals to the needs and wishes of the family. Ethnic minorities and lower-income groups in Western societies also tend to have collectivistic kin orientations. In collectivistic cultures, the family is seen as defending its members against social and economic hardship. The avoidance of disgrace is a strong motivator to comply with kin-group demands.

Kinship relationships do not exist in isolation. They form a network of bonds of varying intensity

across time and across members. The interdependencies between kin network members are crucial to understanding kinship behavior. The concept of linked lives is often invoked to describe the ways in which decisions taken by a kin network member or events taking place in the life of a kin network member have repercussions for others. Grandparenting research, for example, has documented the consequences of middle-generation divorce for contacts with grandchildren. Contacts might improve, worsen, or remain unchanged, depending on the quality of ties with the parents of the grandchild. Sibling research has shown that the decision to provide help and companionship to parents is structured by expectations about what siblings will do. Those who have a sibling who is emotionally closer or lives nearer to the parent are less inclined to step in and help. Kinkeeping is another concept that captures how kinship operates as a network. Specific family members, often women, fulfill the role of keeping others informed about what is happening in the family, organizing get-togethers, and encouraging direct interactions. Kinkeeping serves to facilitate access to others.

Perspectives on Kin Relationships

Research on kin relationships is more readily associated with anthropology than with sociology and psychology. Literature searches using the word *kin* produce many more references to anthropological work than to studies conducted in sociology and social psychology. Typical for anthropology is that kin relationships are studied as a system that is crucial to the organization of society. In an attempt to understand the orderly functioning of small-scale societies in the absence of state or governmental institutions, anthropologists tend to view kinship as providing a stable political structure and a basis for social continuity. Classic anthropological studies focused on the way in which political groupings, which were recruited through kinship, protected their economic interests and passed their property on. Kin-group membership, marriage rules, and matrilineal versus patrilineal succession are central to these studies.

Research on kin relationships in sociology and psychology is scattered throughout the literature, appearing under headings such as intergenerational

relationships, sibling relationships, and grandparenthood. The adult parent–child bond has been studied more extensively than any other kin relationship. Research on extended kin such as aunts and uncles, nieces and nephews, and cousins is sparse. Information on these sets of relationships most often comes from studies of childless older adults. A consistent finding is that extended kin figure more prominently in the social networks of childless older persons than in those of aging parents. Although primary kin (parents, children, siblings) generally remain significant throughout life, qualitative studies show that, for some, extended kin fulfill unique supplementary functions—as family historians, mediators, mentors, and buffers in conflict. Given the dominant research focus on the nuclear family, little is known about the conditions under which special bonds between extended family members are developed.

Though the research on kin relationships conducted by sociologists and psychologists is generally not framed as research into the organization of Western societies, it does provide insight into their structural and institutional characteristics. First, this field of research contributes to an understanding of sources of social inequality. Work on intergenerational transmission, for example, reveals the ways in which advantages and disadvantages are passed on from generation to generation. Transmitted resources are both material (gifts, inheritances, financial support) and nonmaterial (cultural and social capital, norms and values, educational and professional opportunities). Studies using kin network characteristics as determinants of life chances form another example. Findings consistently show that kin support has a positive impact on health independent of potentially confounded factors such as socioeconomic status, health-risk behaviors, use of health services, and personality.

Second, research on kin relationships is informative about mechanisms underlying social cohesion. Part of this research is based on the premise that kin relationships serve as bridges between social groups. For example, families are one of the few contexts where people of different ages meet and interact. Analyses of marriage patterns reveal whether people marry in or outside their social circle. Another strand of research focuses on kin relationships as a critical basis of social

control. Strong interdependencies imply that the behavior of fellow family members can be called into question. Given increasingly egalitarian relationships, the direction of social control is not only from the old to the young but also the other way around.

Third, research on kin relationships provides insight into processes of modernity. This is achieved by examining the changes in kin relationships that accompany changes in economic conditions, labor market arrangements, government provisions, laws, and cultural climate. A leading question is whether given economic and social circumstances facilitate or require particular kinship patterns. Family sociologists writing in the 1950s argued, for example, that a nuclear family system with its self-contained units was best suited to meet the mobility requirements of industrialized societies. More recently, migration scholars have attributed the rise in transnational families, where members live across national borders, to the growing wage gap between poor and rich countries and the increased demand for care services in developed countries.

KIN SELECTION

Kin selection refers to the evolutionary process leading to adaptations that promote altruism among close genetic relatives. Also known as Inclusive Fitness Theory, Kin Selection Theory was first described by William Hamilton in 1964 and is perhaps the most significant addition to Darwin's theory of evolution by natural selection in the 20th century. At the time of Hamilton's publication, altruism had been a biological mystery; there was no cogent account for why evolution would select for altruistic behaviors that reduced one's own chances of surviving and reproducing and enhanced the survival and reproduction of another. After all, natural selection was thought to produce solely selfish behaviors—a "nature red in tooth and claw." Hamilton's elegant theory provided the missing logic for how altruism could have evolved. This entry discusses the logic of kin selection and provides examples of the kinds of questions Kin Selection Theory can address.

The Logic of Kin Selection

The key to understanding kin selection is to take a gene's-eye view. A gene, unlike an individual, can propagate in two different ways. The first is by promoting the survival and reproduction of the body in which it resides. The second is by promoting the survival and reproduction of other bodies that have a high probability of possessing an identical copy. Who is likely to share a copy of the same genes? By virtue of sharing common ancestors, close biological relatives have a greater than average chance of sharing genes. The more closely related kin are to one another, the greater the likelihood they will share genes. For instance, nuclear family members (mother, father, children,

and siblings) on average have a probability of .5 of sharing a particular gene in common. The probability of sharing a particular gene in common with a grandparent, niece, nephew, aunt, uncle, or half sibling drops to .25; a first cousin drops to .125, and so on. This probability describes the degree of relatedness between two individuals and is a crucial component of Kin Selection Theory. An example is provided for how to compute degree of relatedness at the end of this entry.

Hamilton proposed a set of mathematical equations that captures the rules evolution might have approximated to shape a system producing kin-directed altruism. In its most basic form, kin selection can be represented by the equation $r_i C_i < r_j B_j$. This states that selection will tend to favor altruistic motivations when the costs associated with individual i performing an altruistic act (C_i) weighted by individual i 's degree of relatedness to himself (r_i) are less than the benefits bestowed on recipient j (B_j) discounted by the i 's degree of relatedness to j (r_j). Since r_i equals 1 (people have a probability of 1 of having the same genes as themselves), the equation is typically written $C < rB$, where it is understood that the person performing the altruistic deed is oneself and another person is the beneficiary.

Questions Addressed by Hamilton's Equation

Hamilton's equation is a powerful tool for investigating when it pays to behave altruistically (or selfishly) toward another and when one should want others to behave altruistically (or selfishly) toward oneself or related others. It also provides a means of examining conflicts of interest. For instance, since Bart is more closely related to himself, he may want to be selfish and not share his Butterfinger with his sister Lisa (maybe just a crumb), but his mother Marge likely sees the world differently and would want Bart to share right down the middle since she is equally related to Bart and Lisa.

When To Be Altruistic?

Hamilton's equation can be used to compute when it pays to be altruistic to another individual. For instance, from Bart's perspective, when should

he help Lisa? Starting with Hamilton's equation: $r_i C_i < r_j B_j$, it is possible to substitute in the degrees of relatedness. Bart is the one incurring the costs of helping (C_i), and since he is 100% related to himself, $r_i = 1$. In this example, Lisa is the one who benefits (B_j). Last, r_j is Bart's degree of relatedness to Lisa, which is $\frac{1}{2}$ (see below for how to compute this probability). Hamilton's equation becomes $C < \frac{1}{2} B$ or $2 C < B$. In words, this means that it would pay for Bart to help Lisa when the benefits to her are greater than twice the costs to him. Lisa needs to really benefit from an altruistic act for it to be worth Bart's while to help her. If she were a half sister with a degree of relatedness of $\frac{1}{4}$, Lisa would have to really really benefit, greater than four times the costs Bart incurs for being helpful ($4 C < B$).

Of course, Hamilton's equations are simplified and do not take into account the many other variables selection weighs when shaping altruistic motivations. For instance, age, context, and the benefits of reciprocated altruism are not considered yet are known to play an important role when individuals decide when and whom to help. Nevertheless, they provide a good first approximation of the patterns of altruism one might expect. Additionally, Hamilton's equations may be most likely to apply to acts that carried fitness consequences generation after generation in ancestral environments. In particular, Hamilton's equation is expected to operate when resources are scarce and decisions about altruistic effort have large fitness consequences (e.g., risking one's life to save someone, sharing food when one is hungry or during famine, etc.).

When Will a Person Believe That Another Should Behave Altruistically?

In addition to computing when Bart would likely help Lisa, Hamilton's equation enables computations about when Bart should want Lisa to help him. Starting with Hamilton's equation, $r_i C_i < r_j B_j$, it is important to consider who is incurring the cost and who is benefiting. In this example, Lisa is incurring the cost to be altruistic to Bart, and Bart is reaping the benefits. Because Bart is interested in his perspective in this decision, it is necessary to indicate his degree of relatedness to the individual incurring the costs (Lisa) and his degree of relatedness to the individual receiving

the benefits (himself). Hamilton's equation thus becomes $\frac{1}{2} C < 1 B$. This is because Lisa is incurring the costs, and Bart's degree of relatedness to her is $\frac{1}{2}$. Bart is getting the benefits, and his degree of relatedness to himself is 1. Restated conceptually, while Bart cares that Lisa is incurring some costs to help him out, he is only half as sensitive to her costs as he is to his own gains. This is because Lisa only has a .5 probability of sharing Bart's genes. So from Bart's perspective, Lisa should help whenever the benefits to Bart are at least half the costs to her.

Conflicts of Interest

Hamilton's equations can also be used to identify points of conflict. Each person sits at the center of a unique web of familial relationships (e.g., one's sister is someone else's daughter, granddaughter, niece, mother). This means that tradeoffs optimal to oneself may not be viewed as optimal by others with different degrees of relatedness to the actors involved. As the above examples show, it is possible to calculate the answer to the question "When should Lisa help Bart?" from both Lisa's and Bart's perspective. For Lisa, the answer is whenever the benefits to Bart are greater than twice the costs to her, or $B > 2C$. For Bart, the answer is whenever the benefits to himself are greater than only half the costs to Lisa, or $B > \frac{1}{2}C$. Thus Lisa and Bart will not see eye-to-eye whenever $\frac{1}{2}C < B < 2C$. This range of costs defines the scope of conflict. Although much of the research on genetic conflicts of interest has been done in nonhuman species, researchers have identified conflicts of interest during human pregnancy where offspring attempt to extract more resources (e.g., blood glucose) than is optimal for the mother to give.

In general, what this exercise shows is that from a gene's-eye perspective two people are unlikely to share the same view about who should be delivering benefits of what magnitude to whom. This has implications for understanding socialization concerning altruism. Who would teach Bart to share with his sister when $C < 2B$? Not his mom. She would urge him to share whenever $C < B$ because from her perspective she is equally related to Bart ($r = \frac{1}{2}$) and Lisa ($r = \frac{1}{2}$), cancelling both degrees of

relatedness from the equation. If it were left to Lisa, she would teach Bart to share whenever $2C < B$. So to a certain extent, children might have decision rules that are resistant to certain types of socialization, particularly processes that do not match the cost-benefit outcomes that would have maximized their own inclusive fitness. This possibility has not been fully explored, and future research is needed to determine the extent to which Hamilton's equation explains modern-day human behavior.

It is worth keeping in mind that individuals do not consciously calculate Hamilton's rule to decide when to share or be selfish. Rather, these rules are likely to be integrated into a variety of motivational and cognitive processes in a manner that causes some acts of altruism to seem minor and others more laborious. Additionally, kin selection is only one route to altruism based solely on probabilities of relatedness. Certainly, kin share with and help each other due to principles of reciprocal altruism and mutual valuation. These are likely very strong factors involved in generating altruistic behaviors among close genetic relatives. A complete understanding of the relationships among family members requires consideration of all sources of altruistic motivations.

Cognitive Architecture of Kin Selection

Hamilton's theory of inclusive fitness and the associated equations have helped propel the field's understanding of human social relationships. Nevertheless, almost 50 years after its publication, the field has only just begun to explore the psychological mechanisms mediating kin-directed altruism. For instance, according to Hamilton's equation, a key variable is degree of relatedness, r . But how does the mind approximate r ? Certainly people can make the calculations explicitly, but this probably is not how daily decisions are made.

Since people cannot see another person's genes directly, the best evolution could do is to design a mechanism that uses cues that were reliably correlated with genetic relatedness in the ancestral past to compute an internal index of relatedness. One cue that has been investigated as an indicator of siblingship is childhood coresidence duration. Ancestrally, childhood coresidence would have been a good indicator that another individual was

a sibling because children being cared for by the same mother (and father) would have remained in close physical proximity. If childhood coresidence does indeed serve as a cue to siblingship, then it should influence the computed internal index of relatedness, which in turn should regulate levels of altruism. Indeed, the longer two individuals coresided during childhood, the greater the level of altruism between the pair. Certainly, cues other than coresidence duration might govern assessments of kinship such as seeing one's mother caring for a newborn, facial resemblance, and olfactory recognition. Because any cue to kinship should affect the calculation of one's degree of relatedness to another, a good litmus test for a potential kinship cue would be to see whether it does indeed predict levels of altruism in the manner predicted by Hamilton's theory.

How to Compute Degree of Relatedness (r): What Is the Probability You Share a Gene With Your Full Sister?

The answer is .5, and here is how this is computed. People can share a gene with their sister either because their mother gave each of them the same gene or because their father did. When computing r , each possible route of transmission needs to be considered separately. Starting with the mother, the probability she is the source of the shared gene equals the probability a gene in the child came from the mother \times the probability she gave the sister the same gene (both events need to occur, and in logic this requires multiplying the probabilities). Because people are a diploid species, receiving half of their genes from each parent, this translates into 0.5×0.5 , which equals .25. So the probability of sharing the same genes with a sister via a mother is .25. Following the same logic, the probability of sharing a gene with a sister via a father is also .25. This means that the probability of sharing the same gene with a sibling through either your mother or father is $.25 + .25$, or .5.

KISSING

Kissing is a highly species-typical instance of human behavior. Why do people kiss? Does kissing have important consequences? Do men and women use kissing to achieve different objectives? What about kissing technique? Why are males more likely to attempt to initiate open mouth kissing with tongue contact?

The origin of kissing behavior is a good place to start. Long before the invention of blenders and baby food, mothers probably chewed up food and then transferred small portions of the food from their mouth to their baby's mouth to introduce solid food into the baby's diet. Some people theorize that kissing is an evolved derivative of this primitive feeding gesture between mother and child.

There are at least three different types of kisses. Kissing can be used as a ritualized symbolic greeting gesture, as when people meet and kiss each other on the cheek or hand. Kissing on the face but rarely the lips also occurs among family members as a gesture of affection and caring between close relatives. Romantic kissing, on the other hand, is more likely to involve kissing on the lips and often has mating or sexual overtones.

Romantic kissing occurs in over 90 percent of human cultures. Even among those cultures where kissing is absent, courtship often involves face touching, face licking, face rubbing, and nose-to-nose contact, which like kissing brings the participants into close intimate facial contact. Some of humans' closest living relatives, chimpanzees and bonobos, appear to engage in kissing behaviors as well.

Kissing may be part of an evolved courtship ritual. Based on a recent study of 1,041 college students all but five had experienced romantic kissing, and over 20 percent estimated kissing more than 20 partners. When two people kiss, there is a rich and complicated exchange of information involving chemical (smell and taste), tactile, and postural cues. Kissing can have profound consequences for romantic relationships. A kiss will not necessarily make a relationship, but the evidence shows that it can break or kill a relationship. Most students who were surveyed report having found themselves attracted to someone in one or more instances, only to discover after they kissed him or her for the first time that they were no longer interested. It would appear, therefore, that kissing may activate evolved, hardwired unconscious mechanisms that function to assess the genetic compatibility, reproductive viability, and health of a prospective partner.

Evolution is not about survival, it is about reproduction. When it comes to competition for passing genes on to subsequent generations, insemination is the name of the game for males. For females, however, insemination is the mere beginning of the reproductive process that includes pregnancy, childbirth, breast feeding, and extended periods of childcare that can span many years. The costs and consequences of reproduction are dramatically different for females than for males. Because females bear the burden of the reproductive costs, females have been selected to put a lot of emphasis on making careful, judicious mate choices. Since females pick up the tab when it comes to reproduction, females have a vested interest in the other 50 percent of the genes being carried by each of their children. Clearly, females that not only mated preferentially with high-quality males but also picked mating partners who were likely to enter into a long-term committed relationship that involved providing for and protecting her and her dependent children would have had an adaptive advantage.

As a consequence, men and women often kiss for different reasons. Although both sexes rate kissing as a highly romantic act, women consistently rate kissing as more important at all stages of the relationship than do men. Not only do females place more emphasis on kissing, but they are more likely than males to insist on kissing before a sexual

encounter and more likely to emphasize the importance of kissing during and after sex as well. Most females would never dream of having sex with someone they never kissed. By comparison, many of the males in this survey said they would be happy to have sex without kissing, and males were far more likely than females to agree to have sex with someone who was not a good kisser.

Males tend to kiss as a means to an end—to gain sexual favors or to reconcile. Far more men than women think kissing can end a fight, and there is evidence that conflict resolution is facilitated by increasing amounts of kissing. In contrast, females kiss to establish and then monitor the status of their relationship. Among those in committed relationships, women continue to use kissing to assess and periodically update the level of commitment on the part of their partner. There is also evidence that the amount of reported kissing between partners is directly related to relationship satisfaction.

There are also differences in kissing technique. Males are more likely than females to initiate open mouth kissing and kissing with tongue contact. It is possible that the exchange of saliva during kissing may have biological consequences. Male saliva contains small amounts of the sex hormone testosterone, which if administered over sufficiently long period of time could affect a female's libido.

Suffice it to say that there is growing evidence that romantic kissing evolved as an adaptive courtship strategy that functions as a mate-assessment technique, a means of initiating sexual arousal and receptivity, and a way of maintaining and monitoring the status of a bonded relationship.

L

LANGUAGE USAGE IN RELATIONSHIPS

The words that people use in conversation convey information about who they are, their motives, their audience, and their situations. Findings from laboratory and naturalistic studies over the past decade suggest that the words people use can yield clues about the quality of their relationships. This entry discusses the role of language usage in romantic relationships, focusing specifically on issues of analysis, the types of words that are important in relationships, data collection, and clinical implications.

Language serves a variety of functions in relationships. It can be an index of relationship status, an instrument of relationship maintenance or change, or the embodiment of essential relationship characteristics such as autonomy and interdependence. Some have gone as far as to say that relationships are simply language games that change as language changes. In this view, a couple's language *is* the relationship. However, theorists in this area more often view language patterns and relationship beliefs as distinct phenomena that are intimately associated—seeing relationships as both a function of the words that couples use and a framework for future word use.

Analysis of Language Usage

There are three main quantitative approaches to linguistic analysis that have emerged over the past

half-century. The first is judge-based thematic content analysis, which uses human judges to identify the presence of various thematic references (e.g., love, anxiety, and motivation) on the basis of empirically developed coding systems. The second is latent semantic analysis (LSA), a bottom-up approach to language analysis that examines patterns of how words covary across large samples of text, akin to a factor analysis of individual words. LSA can be used, for example, to examine patterns of word use among satisfied couples compared with those who are dissatisfied. The third is word count analysis, which examines the relative frequency of words in a given text or speech sample. Word count programs vary in their designed purposes and complexity of analyses. For example, the General Inquirer, which arose out of the psychoanalytic and need-based traditions in psychology, uses complex decision rules to clarify the meaning of ambiguous words that are used in multiple contexts. Researchers studying language use in politics (e.g., speeches, political advertising, and media coverage) often use Diction, a word count program that characterizes texts by the extent to which they reflect optimism, activity, certainty, realism, and commonality.

One of the most often employed word count programs is Linguistic Inquiry and Word Count (LIWC), which was developed by social psychologists to investigate the words that people use when they write about emotional experiences. LIWC works by searching for words in a given text file that have been previously categorized into more than 70 linguistic dimensions, including standard

language categories (e.g., articles, prepositions, and pronouns), psychological processes (e.g., positive and negative emotion words), and traditional content dimensions (e.g., sex, death, home, and occupation). Research using computer programs such as the General Inquirer, Diction, and LIWC has provided substantial evidence of the social and psychological importance of word use. Of particular relevance for intimate relationships are personal pronouns and emotion words. These two broad categories of words and their significance for relationships are described in turn next.

Personal Pronouns

Much of the interest in the role of language in relationships has focused on pronouns, in particular first-person plural or *we* words (*we*, *us*, and *our*) because they appear to be markers of shared identity and affiliative motivation. It has been argued that the extent to which couple members think of themselves as part of a unit or larger group reflects cognitive interdependence and commitment, often termed *we*-ness. For instance, people increase their use of first-person plural pronouns after a large-scale collective trauma or a home football team victory. Among those in romantic relationships, highly committed partners use *we* pronouns more frequently when talking about their relationships (e.g., *We really have fun together*), compared with less committed ones (e.g., *She's really a lot of fun*). Thus, the use of *we* may capture important ways that couples think about their relationships. However, in the published studies that have examined language use during interactions between romantic partners (as opposed to when people are describing their relationships to outsiders), *we* use is surprisingly unrelated to either relationship quality or stability. Why might this be the case? One possible explanation is that *we* use during couples' interactions does not directly tap how they think of themselves as one unit, that couples' feelings of interdependence simply are not reflected in their everyday use of *we*. Alternatively, contextual effects may be at work. Although *we* use during problem-solving interactions and naturalistic daily conversations seem unrelated to relationship quality, *we* use during other types of interactions, such as those discussions specifically

geared toward positive aspects of relationships or discussions about the future, may tap aspects of interdependence.

Second-person pronouns (*you* and *your*) have been interpreted as indicative of other-focused attention. For example, high self-monitors—people highly concerned with how they are perceived by others—use *you* at higher rates than low self-monitors. Similarly, individuals high in trait anger use *you* at higher rates than those low in trait anger. With regard to romantic relationships, *you* use during problem-solving discussions has been found to be negatively correlated with relationship satisfaction and positively correlated with negative relationship behaviors. Couples' use of *you* may be more important in the context of problem-solving discussions compared with everyday conversations. For example, *you* use in discussions about daily events (e.g., *Are you going to the basketball game tonight?*) may be quite different from *you* use during conflict (e.g., *You can be really difficult sometimes!*).

Clinical researchers have argued that *you* statements are indicative of blaming or psychological distancing, whereas *I* statements reflect healthy communication patterns, such as self-disclosure and verbal immediacy. There are a couple of possible reasons that higher *I* use may indicate better relationship quality. Some have speculated that *I* use reflects higher levels of self-disclosure, promoting intimacy and closeness. *I* use also may reflect positive aspects of autonomy within a relationship. Although experiencing interdependence or relatedness is one key to relationship closeness, managing a sense of independence or autonomy within a relationship also is important. From an interactionist perspective, autonomy and interdependence are two separate constructs, with autonomy and interdependence at a balance in which each allows or enables the other.

In contrast to *I*, use of *me* appears to be linked to relationship dysfunction. For example, previous studies have shown *me* use to be positively related to negative interaction behaviors and negatively related to relationship satisfaction. Although the frequency of *I* use reflects self-disclosure and perspective taking, frequency of *me* use may reflect passive strivings or victimization narratives that are characteristic of poor-quality interactions and less-satisfying relationships.

Emotion Words

The other broad category of words linked to relationship quality is emotion words. In everyday life, when we want to know how a person is feeling, we usually just ask him or her. The specific words that the person uses to respond—words such as *happy*, *sad*, *angry*, and *nervous*—often indicate his or her emotional state. Emotion words measured by word count programs such as LIWC appear to generally reflect people's underlying emotions. Preliminary evidence suggests that they may play a key role in romantic relationships.

Although one would expect greater use of positive emotion words and lower use of negative emotion words to be related to relationship quality, there are a number of contextual issues to consider when taking a word count approach. The first issue relates to the person at whom emotion words are directed (e.g., *I am so angry with Sally* vs. *I am so angry with you*); emotion words can have different meanings depending on their targets. The second issue relates to when an emotion word is preceded by a negation (e.g., *I am not mad at you* vs. *I am mad at you*). Although studies show that variations in emotion word use are positively associated with variations in trait-level emotional expressivity, even when not taking negations into account, separating emotion words into separate categories based on co-occurrences with negations is useful in disentangling associations between emotion word use and relationship quality. The third issue relates to sarcasm (e.g., *Oh, great*). Word count approaches typically are unable to distinguish between emotion words that are used to express genuine emotion from those laced with sarcasm. By first identifying when emotion words are used in the context of couples' interactions and then coding them for relational context, co-occurrences with negations and sarcasm, a clearer picture of the relevance of emotion words for relationships is possible.

Emotion words that couples use in everyday conversations with each other are associated with relationship satisfaction and stability in a variety of ways, with important distinctions depending on whether these words are used genuinely, preceded by negations or used sarcastically. Genuinely expressed positive emotion words are positively related to people's own and their partners' satisfaction. Perhaps

surprisingly, preliminary evidence suggests that genuinely expressed negative emotion words are unrelated to satisfaction or stability. However, positive emotion words preceded by negations are negatively associated with relationship satisfaction. Further, both positive and negative emotion words used sarcastically are negatively related to satisfaction and stability. Thus, the current evidence suggests that associations between negative emotion words and relationship health may be obscured unless contextual issues of language such as sarcastic tone and co-occurrence with negations are taken into account.

Collection of Language Data

There are a number of sources of language data in the context of relationships. Most previous research has assessed word use during laboratory problem-solving discussions, but there are a wide variety of contexts in which word use during couples' interactions can be assessed. These include other types of laboratory interactions such as those geared toward eliciting social support, naturalistic conversations recorded at home, phone calls, and e-mails. One relatively new technology—instant message (IM)—has recently been used to measure couples' everyday language use. Unlike e-mail, IM allows its users to chat with each other in real time so that a conversation can unfold much in the same way that spoken conversation does. With regard to studying language use in relationships, IM provides an opportunity to examine the associations between word use and relationship quality in the absence of nonverbal cues. During IM conversations, the attributions that couple members make about each other are based solely on the words that they use and offer an exciting new approach to studying the words that couples use in their everyday lives—across conflicts as well as more positive moments.

Obviously, the language that couples use in their IMs represents only a fraction of the words that most couples—even frequent IM users—likely exchange with each other. It is unknown to what extent couples' IM conversations mirror their face-to-face interactions. Although some have suggested that online communication may be more disclosing and emotionally expressive than spoken communication, no

studies have directly compared the association between online communication and face-to-face communication in naturalistic settings. It may be that certain words that couples use are more salient in IM communication than in spoken communication, and vice versa. Other new technologies, such as the Electronically Activated Recorder (EAR)—a microrecorder that samples people's acoustic social environments—offer relationship researchers exciting new possibilities to study couples' word use as it naturally unfolds each day. Initial evidence suggests that the words people use in their relationships have different meanings depending on the context (e.g., during conflictual vs. supportive interactions). It seems essential that word use be examined across a variety of settings and situations before we can fully understand how and under what conditions word use is linked to relationship functioning.

Clinical Implications of Language Use in Relationships

There may be important clinical implications for the types of words that people use in their relationships. For example, in Behavioral Couple Therapy, couples often are encouraged to use more *I* statements when discussing problems in their relationship. Investigations of the role of word use in relationships present the possibility that encouraging couples' use of other types of words during therapy—such as positive emotion words—may be beneficial as well. Although therapists may not be able to readily change how happy people are in their relationships, they may be able to effect subtle changes in the words that couples use. This is in line with current cognitive and behavioral approaches to therapy, which are geared toward enhancing relationship functioning through the modification of couples' behaviors. Promising findings from experimental laboratory studies of unacquainted individuals show that manipulating word use can indeed lead to changes in perceptions of closeness. Additional experimental research and studies that assess changes in relationship quality and word use over time are still needed to elucidate the causal direction of these associations and, in turn, their clinical relevance. Such research would help clarify whether a couple's word use merely reflects their underlying thoughts and feelings about their

relationship or actively shapes the future course of that relationship.

LEADERSHIP

Leadership is “a process of social influence in which an individual, a leader, is able to enlist the support of other individuals, the followers, in the accomplishment of a task or mission.” One important concept in this definition is that leadership is a *social* process. Without groups, there would be no leaders and no need for leaders. The primary function of leadership is to coordinate the efforts of others to accomplish something that cannot be done by one individual alone. A second noteworthy concept is that leadership is based on influence (i.e., persuasion), not power. No leader can force group members to give their highest level of effort regardless of the amount of power in the position. Finally, leadership is about accomplishing a task or achieving a successful mission. An effective leader, then, is one who is able to motivate followers to give

high effort, help them achieve needed competency, and coordinate their efforts to attain the group's goals. How leaders effectively accomplish these three functions has been the subject of study since the turn of the 20th century.

It should be noted that the discussion of leadership given here applies to small groups or teams, in which leaders are in close contact with followers.

Research and Theory

Leadership is a multifaceted phenomenon involving interactions among multiple individuals in complex and dynamic environments. There have been many false starts and dead ends in the development of a scientific understanding of this phenomenon. An examination of how research and theory have developed over time provides a basis for synthesis and integration.

Traits

Early studies of leadership viewed effective leadership as dependent on characteristics of the individuals who occupied the leadership role. A wide variety of traits have been studied by contrasting leaders and nonleaders or effective leaders and ineffective leaders in corporations, military organizations, sports teams, and other settings. Traits studied for their relationship to leadership include intelligence, cognitive complexity, need for power, need for affiliation, physical appearance, energy, verbal fluency, originality, dominance, social skills, and many more. However, the findings of this approach were disappointing. A few leader characteristics (most particularly intelligence) bore a modest relationship to leadership status or effectiveness, but no single trait or combination of traits was sufficiently predictive to provide a basis for leadership selection, training, or explanation.

Behaviors

The failure of research on personality and other traits led to research on specific behaviors that might characterize effective leadership. One set of studies interviewed industrial workers about the behavior of their supervisors. Two types of supervisors were found frequently. One type, termed

production-oriented supervisors, spent most of their time structuring the work, assigning tasks, and monitoring for performance. A second type, termed *employee-oriented supervisors*, were more concerned with making sure that morale was high and that workers felt represented and protected.

In another research program, college students were placed in groups and given tasks (such as discussing a social problem or writing a witty essay), and the behavior of group members was observed and categorized. It was found that some students spoke more than others, and the talkative ones fell into two categories. Some, who were labeled *task specialists*, displayed behaviors that emphasized accomplishing the assigned task, such as offering ideas or asking task-relevant questions. Others, labeled *socioemotional specialists*, focused on making sure that every group member had a chance to speak or that tension was relieved by jokes and friendly comments.

An extensive examination of the behavior of military officers resulted in the development of questionnaires for reporting on leader behavior by subordinates, peers, or observers. The two major categories in these questionnaires were called *Initiation of Structure*, which included behaviors like assigning tasks, judging work output, and encouraging high performance. The other category, *Consideration*, included behaviors related to mutual trust and respect between leaders and followers.

Although all of these studies seemed to indicate that some leaders emphasize the task side of leadership and others the social or emotional side, no category of behavior was clearly related to leadership effectiveness. So, as was the case with the search for leadership traits, behavioral research found no simple answers to the complex questions of leadership.

Contingency Theories

In the 1960s and 1970s, progress toward understanding leadership was made by researchers who tried to relate characteristics of leaders with aspects of the leadership situation, such as follower support, task clarity, and formal authority. By and large, these studies indicated that the success of a leadership behavioral style or decision-making process depended on (i.e., was contingent on) the

nature of the situation. Directive, authoritative, and task-focused leaders were most effective when supportive followers and clearly understood tasks allowed the leader to direct the work group with confidence. However, situations that were more ambiguous, due to interpersonal tensions or vaguely define tasks, required leaders to be more open to influence and garner advice from followers.

Studies of follower motivation and satisfaction revealed that the effectiveness of a leader's coaching and counseling behavior depended on the personality of the follower and the nature of the task. Giving subordinates a lot of specific direction was most motivating when followers did not clearly understand their task and wanted the structure provided by the leader. However, when tasks became simpler or when followers were independent, the best leaders were those who were considerate and supportive, rather than demanding and directive.

Information-Processing Approaches

Leadership depends on perception and judgment. Leaders try to assess follower interests and capabilities, and followers evaluate leaders and potential leaders to decide how to react to their influence. Social psychologists have long known that perceptions and judgments are not simple and straightforward. Research on leadership shows the same pattern. What an observer (e.g., a follower or boss) sees in a leader's behavior is strongly dependent on what the observer expects to see. Once observers decide that a leader is effective or appropriate, they tend to also see behaviors that they think are characteristic of a good leader, even when those behaviors may be absent.

Similarly, leaders' judgments about followers are often oversimplified or self-serving to the leader. In other words, when a problem arises with a subordinate or group, a leader's desire to take credit for good outcomes and avoid responsibility for failure can cloud judgment.

Transformational Leadership

A long-standing subject of interest has been *charismatic* leaders like Alexander the Great, Mahatma Gandhi, or Martin Luther King, Jr. Such leaders are defined by their unusually great influence over

subordinates. Projecting an image of almost superhuman ability, combined with a transcendent vision, charismatic leaders evince very high levels of confidence in themselves and their followers. Charismatic leadership is sometimes referred to as *transformational* leadership because it transforms the leadership relationship from a quid pro quo contractual relationship into one in which leader and followers become totally dedicated to the collective mission.

Modern research on transformational leadership in groups and organizations reveals that followers respond enthusiastically to leaders who (a) show high task-related competence, (b) articulate a compelling vision, (c) treat each subordinate as a unique individual, and (d) challenge subordinates to explore new ideas and develop new competencies.

The Dark Side of Leadership

Recently, research has focused on some of the less attractive features that leaders may demonstrate. When leaders accumulate great power, they may (a) become disdainful and remote from followers, (b) develop a strong compulsion for taking action even when they aren't sure what action to take, and (c) begin to believe that the norms and rules followed by "ordinary" people don't apply to them.

Synthesis and Integration

Careful examination of the most empirically supported findings among these disparate perspectives provides a basis for a synthesis and integration. That integration indicates that successful leaders must establish a basis for influencing followers, building relationships that enable and motivate followers, and coordinating a group's resources for mission accomplishment.

Establishing Legitimacy as a Basis for Influence

Influential communicators must be seen as competent and trustworthy to be credible. Potential followers decide that a leader is competent by observing behaviors that match the followers' expectations for how a competent leader should behave. These expectations may not be explicit, but they affect judgments. Leaders who fit the "leadership

prototype” are deemed to have the necessary qualities to gain influence.

In the early stages of leader–follower interactions, judgments of a leader’s trustworthiness or honesty are again based on our expectations—for example, how an honest person behaves (e.g., makes eye contact, speaks in a sincere tone of voice). After followers have had a chance to interact with a leader over time, judgments are based on actual evidence of competency (e.g., moving the group toward its goals) and honesty (e.g., following through on promises and not making contradictory statements to different followers).

Building Relationships That Empower, Enable, and Motivate Followers

Once a leader has gained influence by establishing credibility, she or he must guide followers in the accomplishment of their tasks and motivate them to make the greatest contribution possible. Motivation and guidance depend heavily on good coaching. As a leader interacts and observes each follower, the leader begins to understand the follower’s skills, knowledge, and motivation. If those capabilities are not sufficient for successful completion of the follower’s responsibilities, the leader may intervene by explaining or teaching the follower. Effective coaching requires more than identifying a follower’s strengths and weaknesses. A leader must also be sensitive to a follower’s personality and values. People respond differently to instruction depending on how much they perceive that they need it. One follower might be comfortable with some level of task or role ambiguity because that makes the task a more interesting and satisfying arena for learning, growth, and achievement. Another follower might be upset by that ambiguity and greatly desire more structure and clarity in the job. Highly effective team leaders relate to each follower as an individual, understanding and responding to each in a way that helps the follower to stay interested and motivated by his or her responsibilities. That level of understanding is sometimes difficult for a leader to achieve because the leader’s own sense of self-esteem may interfere with accurate and unbiased judgments.

Another important aspect of the leader–follower relationship is that it is an interpersonal exchange.

Leaders give followers protection, help them to achieve their personal goals, and respect them as individuals. In exchange, followers give leaders loyalty, effort, and deference. As in other relationships, when the exchange is perceived as fair, both parties are motivated to make the highest contribution possible to their common goals. Fairness is often based on the way that a leader makes decisions. Leaders who listen to followers before making a decision (giving voice) and explain the reasoning behind the decision after it is made (justification) communicate respect for followers, and that respect enhances the quality the exchange relationship.

Deploying the Group’s Resources to Achieve Mission Accomplishment

The effective coordination of collective efforts requires a match between the nature of the task environment and the procedures used for group communication and decision making. When the goals and methods for accomplishing a mission are clear and well understood, as they would be for a highly experienced group, greatest efficiency of effort is achieved when leaders take authority and provide clear direction. However, when the exact nature of the goal or the best way to achieve it is unclear, as it might be in novel or highly complex situations, the most effective leadership is highly democratic and participative, which allows the knowledge and expertise of every group member to be applied to achieving the goal.

Even when all the procedures described earlier are followed, groups can encounter daunting situations because of physical danger, overwhelming task complexity, or extreme importance of succeeding. Under these circumstances, groups that have confidence in their own capability and believe strongly in the group’s ability to accomplish the mission can overcome even the most threatening situations. Leaders who are highly confident are calmer, less defensive, and more resilient—qualities that enhance their ability to understand the environment and the needs of their followers. Highly confident leaders instill confidence of the group in itself. Collective confidence is associated with high goals, perseverance, and the ability to cope with adversity.

LEISURE ACTIVITY

Leisure is generally seen as one of the most valued areas of our everyday lives. Many people are impatient to retire from work to pursue those activities that they enjoy the most—for example, traveling, visiting family members, going to museums, and so forth—and thus live a “life of leisure.” The importance that we attach to “leisure,” then, only makes sense when we contrast it with “work,” and this comparison is a relatively recent phenomenon. This entry discusses the emergence of leisure as a distinct component of everyday life and its importance as a context for interactions among family members.

Historical Background

In western Europe, as Geoffrey Godbey and Stanley Parker observed, time spent at work consistently increased from the Middle Ages until the middle of the 19th century, whereas in America, the work week averaged at least 70 hours for factory workers by 1850; in other words, work increased and leisure declined from the end of the Middle Ages until the height of the Industrial Revolution in the mid- to late 19th century. This reduction in leisure was not only mirrored in longer work hours, but, more generally, by perhaps

the single most conspicuous characteristic of industrialization: the spatial segregation of daily life, wherein work came to be done in a specialized place (at work) at a certain time and under particular conditions, and leisure (and family life, generally) tended to occur somewhere else (at home). Although the average work week in western Europe has diminished to less than 40 hours during the past century, it would be fair to say that industrialization created leisure the way we know it, as a distinct and largely residual sphere of life, as the time left over after work.

Family as a Context for Leisure

So how do modern Americans—and modern American families—“spend” all of this “extra” time? Questions regarding family leisure are complicated. For example, people define leisure activities differently, and one person’s leisure is another person’s work (hobbies and volunteer activities are good examples of this principle). Moreover, social scientists know considerably more about how families work than how they play, although we have long believed that “the family that plays together, stays together.” It is fairly easy, however, to make the case that leisure behavior is an especially useful lens through which to view family behavior. Leisure behavior is discretionary behavior and lends itself well to questions about what families do in the way of leisure activities, and with whom family members undertake these activities, when they do not have to do anything at all?

Family members face several issues if they decide to participate in a leisure activity together. Leisure involving more than one person, in general, can be difficult to coordinate due to a handful of reasons. For one, parents and children may not enjoy the same leisure activities, and children may not be inclined to pursue the same activities. It is also the case that marked differences in family members’ physical abilities and maturational levels can be a deterrent to joint leisure, both in terms of parents and children, as well as between siblings who are separated by several years. Along the same line, leisure activities hold different possibilities for interaction, some necessitating coordination among several people (e.g., playing cards) and others being essentially solitary activities that

provide restricted opportunities for interaction (e.g., reading). Further, leisure activities that may be undertaken by more than one person are still subject to the interactional preferences of those involved. For example, research shows that those who “specialize” in activities (i.e., become devoted to certain leisure activities and become quite skilled at them) tend to avoid participation with nonspecialists, and this is one way that companionate family leisure may be deterred (e.g., all family members enjoy playing tennis, but the husband played collegiate tennis, is a specialist, and is uninterested in pursuing that particular activity with others who cannot play tennis at his level). Research also shows that wider social network factors may bear on the extent to which family members participate in the same activities; for example, a wife may like going to garage sales and, further, may enjoy going to sales with her husband, but be disinclined to do so when her husband’s friends and/or relatives are also involved. It should also be recognized that differences between family members in the simple structural characteristics of everyday life—such as work and school schedules—can deter joint leisure regardless of activity and interactional preferences.

Marital Leisure

As a subset of family leisure, marital leisure is especially intriguing for those interested in the dynamics of married life for several reasons. Marital leisure underscores the importance of interpersonal compatibility, in that couples who generally like (and dislike) the same activities tend to pursue more leisure together and spend less time apart from one another. This fact is important because the extent to which wives and husbands pursue leisure activities together has long been one of the best predictors of their marital happiness. The strength of this association may not be as strong as is commonly assumed, however, and depends more on whether spouses are undertaking leisure activities that they both like versus those that only one of them enjoys. In fact, there is some evidence suggesting that leisure companionship is most closely linked with marital satisfaction only if it involves activities that both spouses like, whereas couples’ joint involvement in leisure that only the

husband enjoys is a source of dissatisfaction among wives. (The reverse, predicting husbands’ satisfaction from joint involvement in leisure the wife enjoys, was not found in this study.)

Finally, a developmental perspective on marriage observes that there are some fairly predictable changes in marital leisure over time. Leisure for most couples is largely couple-centered early in marriage, a pattern that changes with the arrival of the first child and the resulting restriction in their opportunity to pursue leisure as a couple alone, although parenthood may serve to reintegrate couples with their friends and extended families. Little is known about patterns of marital leisure further down the family life course in terms of what effects, if any, are seen in marital leisure as the last child leaves home (the “empty nest” phase) and as couples enter retirement, a stage wherein many retired couples paradoxically report that they feel too “rushed” to engage in much leisure, although, objectively, they actually have little to do.

LESSER INTEREST, PRINCIPLE OF

The *Principle of Lesser Interest*, also called the *principle of least interest*, is a theoretical principle suggesting that, in romantic partnerships, when one partner is more emotionally involved than the other, the less emotionally involved partner can

exploit the more involved partner in various ways. This entry explores the origins of this principle, empirical findings, and related research.

Commonly discussed in the social-psychology literature on dating relationships, the Principle of Lesser Interest is usually attributed to Willard Waller, who observed in the 1930s that romantic partners often proceeded at different paces in their emotional involvement with one another. In Waller's view, large differences in emotional involvement put the less interested partner in a position to exploit the more interested party because the less-interested party could dictate the conditions of association.

Although Waller is widely credited with developing the Principle of Lesser Interest, he acknowledged other important sources for the principle, including a popular French epigram and sociologist Edward Ross. Ross had written (some 17 years earlier) in his sociology textbook that, in a variety of social relationships, the person who cared less could exploit the person who cared more. Ross went beyond romantic relationships in his thinking to consider parent-child relationships as well, but Waller's coining of the term focused primarily on premarital dating relationships.

Although there is not a large body of research on the Principle of Lesser Interest, several studies show support for the principle and related ideas. Perceptions of unequal emotional involvement are common among contemporary dating couples, and men are more likely than women to be perceived as the partners with less interest in their relationships. Less-interested partners are seen as having more control over the continuation of their relationships, and couples with unequal emotional involvement tend to have lower satisfaction than couples with equal involvement. Some studies have found that unequally involved relationships are more likely to break up than those with equal emotional involvement. Closely related studies show positive outcomes from equal emotional involvement between dating pairs; equal levels of dependence and commitment have been associated with positive emotions and relationship satisfaction.

Waller would likely not be surprised at any of these findings. He found evidence of the Principle of Lesser Interest in his 1930s observations of college students in prestigious fraternities and sororities. He also observed gender differences in these

relationships, noticing that women seemed more astute in relationship processes, and that their perceptions of relative involvement were particularly predictive of breakup. Although it does not appear that he tracked relationships across time, he would most likely have expected a higher breakup rate among unequally interested couples and seen their breakups as preferable to long-term emotionally unequal partnerships.

Contemporary research on the Principle of Lesser Interest is sparse and limited by its predominant use of quantitative methods and a focus on White, heterosexual college youth. Yet a broader view of the related literature reveals great interest in this general area of inquiry, if not in the Principle of Lesser Interest specifically. In recent years, for example, many researchers have explored power relations between couples (both heterosexual and same sex), searching for the practices that go along with contemporary egalitarian ideals. Interview studies of American couples reveal that relationship dynamics consistent with the Principle of Lesser Interest are common. Yet unequal interest and power can erode the strength of relationships over time, leading prominent relationship researchers such as Pepper Schwartz to promote the benefits of "love between equals." Peer marriage, she argues, is conducive to longevity and staying in sync with one's partner. Schwartz's position is in line with Willard Waller's own conclusions. In 1938, he described lesser interest relationships as being unhealthy in the long term due to the potential for extreme exploitation. He suggested that it might be better if these relationships dissolved before getting to the point of marriage.

Finally, it is useful to remember that the Principle of Lesser Interest may have wider application than just romantic relationships, as Edward Ross suggested in 1921 in his sociology textbook. Parent-child relationships are another potentially important type of relationship in which to explore the lesser interest dynamic. Although not drawing on the same theoretical origins, research on the "intergenerational stake hypothesis" has revealed a tendency for parents to report more emotional investment in their children than their children report about them across the life course. This research could be taken a step further to explore the extent to which children exploit this unequal emotional involvement coming from their parents.

There could be consequences for relationship satisfaction, exchange, and even continuity. Research of this type could be seen as a modified example of Willard Waller's principle of lesser interest, and an application of this concept many decades after it was first conceived.

LIES IN CLOSE AND CASUAL RELATIONSHIPS

Lying—defined as intentionally deceiving another individual in a relationship—is ubiquitous in social relationships. Lies may take the form of either withholding information (lies of omission) or overtly communicating information that one knows to be false (lies of commission).

Both retrospective diary studies and experiments that take more contemporaneous measures of deception confirm that lying is a consistent part of social life. In fact, a number of studies show deception in face-to-face conversations with rates as high as three lies per 10-minute period. Lies are

also prevalent in virtual communication, both in e-mailed messages and instant messages (IMs). The nature of the deceptions and the motivation behind them occurring in relationships vary significantly. Some lies are other oriented, such as lies meant to make recipients feel better about themselves. Other lies are self-oriented, designed to self-aggrandize, promote oneself, or hide information in an effort to gain an advantage over a recipient.

Deception is found in two main types of relationships: close romantic relationships and more casual friendship/acquaintance relationships. Not only do lies occur with considerable frequency, but the lies may have significant consequences for relationships. This entry describes current findings concerning lying to close and casual others, as well as the methodological challenges in conducting research on lying in relationships.

Lying in Romantic Relationships

According to self-reports, lying is present in some degree in most romantic relationships. In one survey, almost all individuals (92 percent) admitted to having been deceptive toward a romantic partner. Although the number of self-described minor lies decreases in interactions involving a close relationship partner, the lies that do occur tend to represent more serious breaches of trust. In fact, almost two thirds of lies involving serious betrayals of trust involve people's closest relationship partner.

People reserve their most severe lies for those with whom they are romantically involved. Not surprisingly, diary study participants cite a wide variety of reasons for lying. Primary motivations for lying include attempting to get something someone feels entitled to, avoiding conflict, and efforts to present oneself in a favorable light.

Although lie tellers in romantic relationships often report that their deceptive behavior is driven by altruistic goals, such as to spare a partner's feelings, recipients of lies generally do not share the perspective that kindness and concern are the motivating factors of their partner. However, when the same individuals who report unhappiness at being the recipient of lies are placed in the position of being a "lie teller" as opposed to a "lie receiver," they view their deceptive statements as

altruistically motivated, justified, and induced by the lie receiver. Such research highlights that it is the social context surrounding a deceptive statement that gives the deceptive interaction its particular significance.

When explicitly seeking a dating partner or potential mate, deception is sometimes utilized as a strategy for attracting a potential companion. Social assets are exaggerated, and faults are hidden. Furthermore, men and women differ in their deceptive mate-seeking strategies. Consistent with widely held gender stereotypes, men are most likely to lie about their wealth and level of commitment, whereas women attempt to deceive men in regards to their physical appearance by using aids such as cosmetics. Additionally, although a significant degree of deception exists in the mate-selection process, most people are aware of and even expect deception as part of the courting process.

Such findings are consistent with evolutionary approaches to deception. For example, many non-human species use deceptive strategies, in terms of appearing bigger, stronger, or more sexually alluring, to attract a mate. Male green frogs lower the tone of their croak to sound larger and to ward off other potential competing males; female fireflies of certain species lure unsuspecting males by signaling a readiness to mate, only to eat their suitors upon arrival. Similarly, from an evolutionary perspective, humans may utilize their more sophisticated cognitive abilities to deceive in order to reflect wealth, fertility, or youth.

One of the reasons that lying may be so common within romantic relationships may be that lie tellers feel generally confident in their ability to deceive their partner. Not only do those people who lie to their partners feel that they are generally successful in not being detected in their lies, but they also believe that they are more successful in deceiving their partners than their partners are in lying to them.

The use of lies in relationships is not without costs, however. For example, a willingness to accept the presence of lies seen as altruistic, or “white lies,” is associated with less relationship satisfaction. Specifically, appearing to tell the truth in a relationship predicts greater relationship satisfaction and positive illusions about the relationship. It may be that deception early on is predictive of the future

erosion of integral components of the relationship, such as trust, intimacy, and commitment. Furthermore, individuals in failed romances may blame some other component of their interactions for their lack of positivity toward the relationship, when in fact the relationship failure may have been fostered by the false pretenses under which the relationship began.

Research explicitly examining the consequences of the use of deception in romantic couples finds that, although lies may have negative outcomes for the lie teller, there is actually a modest positive impact on the lie receiver—as long as he or she does not discover the deception. That said, although individuals tend to assume that their partners are more honest than themselves, if there is suspicion of lying, the consequences are negative for both parties. In the case of deception suspicion, even a small suspicion that one’s partner is lying has significant consequences on relationship satisfaction.

Although research consistently shows that deception is common in relationships, little work has examined individual differences in expressing and reacting to relational deception. One possibility that is receiving increasing attention is the connection between deception and attachment theory. Studies that directly examine the connection between adult attachment and deception find that people higher in attachment anxiety or avoidance are more likely to report deception in their romantic relationships, expect to be lied to more often, and show less authenticity in communicating with their partner. Furthermore, attachment security is connected to greater openness and more constructive patterns of communication. Given that one aspect of deception involves withholding particular types of communication, different working models of attachment are likely to predict the degree to which people engage in deception and the type of deception in which they engage.

Lying in Casual Relationships

Deception also plays a significant role in more casual relationships and, at least in terms of the frequency of deception, is likely even more ubiquitous than in romantic relationships. But deception does not always have negative consequences

for the functioning of relationships. For instance, deception skills are positively related to social competence. As one example of this phenomenon, adolescents who are best at deceiving others are also higher in social competence. Effective lying appears to serve as a social skill in which popularity is a consequence of the ability to both provide information to others that is socially desirable, as well as withholding information that might potentially hurt a recipient.

However, when someone is exposed as lying in casual relationships, the consequences are generally harmful. Liars who are found out are disliked by those to whom they lied even if the lies have no direct or significant impact on the recipient of the lies. Perhaps more important, those who learn that they have been lied to by a particular individual increase the level of their own lies to the liar. Consequently, the overall number of lies in an interaction increases significantly.

Furthermore, when lying to someone with whom one has only a casual relationship, or one with whom future interaction is unlikely, norms regarding deception seem to change. People appear to realize that the chance of their deception being discovered is lower and the lack of any bond with the receiver leaves people feeling less uncomfortable telling lies to strangers. Consistent with this view, lies that are told to strangers also tend to be less altruistic (in the sense of bolstering the recipient).

Certain situational factors also increase the use of deception. For instance, when one is confronted with the success of a partner, thereby threatening one's self-esteem, deception increases in an effort to improve one's social standing. Deception may thus be used as a means of improving mood and self-esteem when a threat is presented in the form of social comparison information.

There are also gender differences in deception in casual relationships. Overall, men and women generally lie the same amount, and the frequency of lies is similar whether the targets of the lies are male or female. However, although the frequency of deception may be approximately the same, the content of the lies told by men and women differ. Men's lies tend to be more self-oriented, motivated by a desire to enhance their self-image. In contrast, women's lies are more often intended to make the recipient of the lie feel more positively about him- or herself.

Methodological Issues

Researchers face several methodological hurdles in studying deception. For example, one common technique involves having experimental participants keep a retrospective diary of any and all lies told. The problem with this methodology is that one cannot be sure that every lie is remembered and recorded accurately. Another problem is that self-reports may be colored by self-presentation motives.

A second popular method in deception research asks participants to review a video or transcript of statements made recently to a partner and to indicate their accuracy. Although there is evidence that people will reveal lies when the subject matter is benign and there is no chance of punitive consequences, this method still relies on self-report and is therefore not a fully adequate solution. Deception researchers continue in their efforts to create a methodology that can accurately measure deception while avoiding reliance on self-reports.

The most recent efforts to find accurate measures of deception involve neuroimaging techniques, such as functional Magnetic Resonance Imagery (fMRI) and positron emission tomography (PET) scans. Results are promising, although as yet hardly definitive. For instance, there is evidence for increased brain activity in particular areas of the prefrontal cortex (involved in the coordination of thoughts and behaviors) and the amygdala (involved in processing and memory of emotional stimuli) while making deceptive responses. However, the results of such studies remain in their early stages.

LIFE REVIEW, ROLE OF RELATIONSHIPS

Humans are as much biographical as biological beings. Just as individuals may be understood in terms of cells and species, so too may they be characterized, in an equally fundamental sense, as storytellers considering and understanding themselves and their lives through the narrative terms of plots, events, and scripts of life; the characters, heroes, and villains; and the themes and settings in which events and interactions take place. Life review is the centerpiece of the life story.

Life review may be defined as the relatively systematic reflection on one's personal history, an elaborate form of reminiscence and retrospection. Robert Butler, a geropsychiatrist, coined this term and considered life review a normative developmental task of (although not restricted to) the later years, brought about by an awareness of life's end and/or critical life markers. The life review also holds a prominent place in the final stage of Erik Erikson's often cited life-span developmental theory. The life review serves both intra- and interpersonal functions and is believed to be most effective in social settings (i.e., in interaction with and in the presence of others); these personal and relational functions are described in this entry, particularly highlighting the social and group processes of the life review.

Personal Functions of Life Review

The personal functions realized by the life review range from the mundane and neutral (e.g., including reflective personal distractions during idle moments) to the profound and positive (e.g., clarifying problems and choosing courses of actions based on successful previous decisions; boosting self-confidence and morale based on the reflection on previous accomplishments). Some negative consequences of reviewing one's life have been noted, often attributed to rumination or perseverance on failures and associated with lowered self-esteem. The sharing of stories with others is believed to mitigate these potential negative consequences. The act of sharing is fundamentally a positive process and further enhances morale and self-esteem in this context through the role others might play in the process of reviewing a life, such as redirecting attention toward a more affirmative course and/or offering different and more encouraging interpretations of events and circumstances.

Relational Functions of Life Review

The relational functions of life review similarly range from the mundane to the profound. For example, life review may serve a purpose as basic as initiating conversations; individuals, in the company of others, may recall incidents, times, and circumstances as a means to "break the ice" or begin some dialogue. Life review may also serve to nurture or deepen relationships. Such effects have been noted in the Guided Autobiography, the group-based, thematic and semistructured approach to the life review developed by James Birren, a prominent gerontologist. In the structured setting of the Guided Autobiography, small groups (e.g., typically six persons) of women and men of various ages collectively review their lives according to a set of themes. This group process provides a cohesive setting for reflection and discussion—a process Birren calls the *developmental exchange*, in which trust in the group and intimate sharing are incrementally and mutually enhanced. Comparisons and contrasts may be observed, and individuals may see themselves and their lives reflected in the stories of others, removing perceived stigma and fostering

connections often across societal divides of age, gender, race, and other social categories.

Research also has found that individuals offer explicit prosocial and generative motives for telling their life story. Many individuals report that they want to share their stories with relatives and others, thereby providing a legacy and preserving the history of a family so that younger generations may come to know their elders and ancestors and hence their own family histories—their own stories. This teaching/informing function has been well established in life review research and appears to be a motive most significantly found among older adults.

Relatedly, the personalization and validation of a historical record is reported among the reasons for the telling and sharing of the life stories, most notably revealed in research with Holocaust survivors. Several international projects have been developed to capture these life stories as “living” and permanent records of the now elderly survivors of one of the world’s greatest atrocities. Survivors report their willingness to retell (or sometimes tell for the first time) their experiences so that such horror might never happen again—a way of giving to and protecting subsequent generations. Research has also found that it is important for individuals, such as these survivors, to have their stories witnessed. Reviewing these experiences in the presence of others claims, for the teller, the authority and the truth of the events; witnesses to these stories learn this truth and connect with the storyteller and his or her circumstances in a way that words on a page cannot.

These life lesson gifts, framed in the language of life review, have also found explicit expression in Ethical Wills, a way of sharing values, lessons, hopes, and dreams of an individual’s life with roots in the Hebrew Bible. Authors in this recently rediscovered field comment on the surprising imbalance in the efforts expended by individuals to bequeath and distribute the physical possessions acquired throughout life (by way of wills and other legal documents) relative to the dispossession of priceless nonmaterial assets: life’s meanings, personal goals, spiritual values, blessings, and forgiveness. The modern version of this formerly oral cultural practice is typically a written document, frequently in the form of a letter, and is often shared with others both prior to and following the

death of the author. An Ethical Will is a spiritual and narrative counterpart to the more familiar legal documents and recognizes that which is relationally and socially important in life.

Notwithstanding the prominent role of the “self” in these accounts, several researchers have proposed that the life review and other such stories are essentially coauthored by and with the significant others in an individual’s life. For example, in studies with women and men in later life, it was found that the events of others (e.g., birth of a grandchild, retirement of spouse) claim a significant place in an individual’s life review. Furthermore, the story is often adapted and shaped by the reports of another (e.g., when and how couples met), and a mutually consistent story emerges. Culture, too, plays a role in identifying the sorts of markers and events that an individual is likely to include in a life review and the ways in which such events are interpreted.

LIFE-SPAN DEVELOPMENT AND RELATIONSHIPS

All relationships develop over time, from the first interaction to the last one. This can take only a short time, as in dating relationships, or it can take a lifetime, as in sibling relationships. The development of one relationship can be viewed, in turn, within the broader perspective of the development of an individual who is involved in many different

relationships. Each relationship changes over time due to developmental changes of the two individuals involved in the relationship (they “grow together”) and as some relationships are dissolved and new ones are established. For example, the mother–child relationship likely changes if the mother takes a full-time job and thereby has less flexible time; also, the mother’s relationships with friends may change, and new ones with coworkers will be established. The metaphor of a *social convoy* over the life course nicely describes the flux and flow of these relationship changes: Individuals move through their lives surrounded by social partners to whom they maintain ever-changing relationships, as in a convoy of vehicles. This entry provides an overview of relationships from such a developmental psychology perspective.

Long-Term Stability of Relationships and Their Quality

The *long-term stability* of relationships and their quality follows three principles. First, relationships are the result of the continual interaction between two individuals. Thus, the quality of their relationship is influenced by their personalities (characteristic traits such as extraversion, neuroticism, etc.) and the history of their interaction. Therefore, the long-term stability of their relationship depends on the long-term stability of the two personalities involved. Also, their relationship is often affected by relationships with other people in their social network (external relationships). Therefore, any change of the personality of any of the people involved in these interactions limits the continuation of the relationship and can affect its quality (e.g., changes in satisfaction with the relationship, commitment, and attachment to the partner). The complex interactions between the involved personalities and relationships impose additional constraints on stability. Therefore, the stability of relationships is likely to be less than the stability of personality.

Second, human societies are characterized by continuous social and cultural change, such as economic or political change. As detailed analyses during the American Great Depression and the German Reunification have shown, such changes may have a strong impact on relationships. For

example, marriage, divorce, and birth rates dropped considerably in former Eastern Germany during the reunification. Third, individual development is organized in most cultures around *life-course transitions*, that is, age-graded, socially expected changes such as leaving the parental home, graduating from college, and beginning first full-time job, which, in turn, affect the relationships of the individuals in transition.

Although quantitative reviews of the stability and change in the number and quality of relationships have not yet been published, the few longitudinal studies that have compared relationship stability with the stability of individual personality traits consistently show that relationship quality is less stable than personality, particularly during life-course transitions, and that relationship stability is more challenged by societal change than personality stability.

Personality–Relationship Transactions

If relationships are less stable than personality, the chances are higher for personality to influence relationships rather than vice versa. Indeed, longitudinal studies have found more evidence for personality effects on relationships than vice versa. For example, sociability increases the probability of making new friends, shyness and social anxiety decrease this probability, neuroticism increases the probability of divorce, agreeableness decreases conflict in relationships, and conscientiousness increases involvement in family relationships. Among the few effects of relationships on personality that have been consistently found are effects of attachment security in infants on their later social competence, effects of friendships with antisocial peers on adolescents’ antisocial tendencies, and effects of the first stable romantic relationship on neuroticism and shyness (decreases). Thus, there is evidence for both directions of influences, but personality to relationship influences seem to be more frequent than relationship to personality influences.

However, these effects are often smaller than the correlations between personality change and simultaneous relationship change; in other words, relationships and personality often codevelop in a corresponding way. The main reason for this correspondence seems to be that people select and

evoke relationship experiences that deepen or accentuate their personality traits. For example, liberal students make friends more often with, and are more likely to marry, other liberal college students, which increases their liberal attitudes; aggressive children engage in vicious cycles of aggression with peers and family members, which increases their aggressiveness; antisocial adolescents join deviant cliques consisting of similarly minded peers, which increases their antisocial tendencies; and intellectually or physically competent students are more challenged by their mentors or trainers than less competent ones, which increases their competence.

Life-Course Perspective

Many of the relationship changes occurring over developmental time are due to age-graded, socially expected changes, often called *normative life-course transitions*. For example, moving out of the parental home changes the relationships with one's parents and siblings, but also with peers, who become more important. The term *norm* here refers to a social expectation rather than to a statistical norm (it is expected that young adults do not continue to live in their parents' home, although some do). In addition, non-normative life events may affect the relationships of an individual (e.g., a mother's separation from the father may also affect the mother-child relationship). A life-course perspective on relationships considers both normative and non-normative changes as they occur between birth and death, classifies these changes in ways that are meaningful for the given culture, and tries to understand how and why people master the challenges entailed by these changes more or less successfully.

The ways in which people master these challenges can also affect relationships. To consider again the example of a mother entering her first job, she likely would ask more household duties from her husband, has to find daycare for her children, pursues new friends at the workplace, and has less time for former friends. These relationship changes result from the mother's active efforts at coping with the transition to a full-time job by trying to adjust her social environment to her needs and life goals.

Thus, two different kinds of relationship changes over the life course can be distinguished. Life-course transitions and life events push people toward normative relationship change, whereas their regulatory efforts pull their relationships to fit their needs and goals, resulting in regulatory relationship change. For example, entering a university pushes freshmen to establish new relationships with their roommates and other students, and their regulatory efforts pull these new relationships to fit their needs for social interaction. Because the needs and goals vary across people according to their personality, and regulation is more or less successful according to personal competencies, regulatory relationship change is personality-dependent. Some freshmen spend more time getting to know other students in cafes, clubs, and at social events, whereas others spend more time lonely in their room and in the library. These two kinds of changes appear to be the main reasons that personality effects on relationships are more easily observed during life transitions, such as the transition to university, work, or retirement, and during adaptation to life events, such as divorce or unemployment, rather than during periods of high environmental stability.

Normative Life-Course Transitions

Normative life-course transitions are experienced by most people at certain ages and are guided by culturally shared expectations about when and how a transition should occur. For example, even within Western cultures, it is expected that a man will leave his family of origin at a certain age that differs across cultures (e.g., around age 20 in Denmark, but in the late 20s in Italy). All life-course transitions involve changes in relationships that present several challenges. They threaten to limit the continuity of certain relationships (e.g., with classmates after graduation), transform the quality of important relationships (e.g., with parents after leaving home), draw on the individual's social resources (e.g., by a status loss after retirement), and often dispose the individual to an ambiguous, less predictable future of relationships.

In Western cultures, the most important life-course transitions relate to changes in family, education, and work. The most important family

transitions are the birth of a sibling, leaving the parental home, first marriage, first parenthood, and the last child moving away from home (the so-called *empty nest*). In contrast, transitions that are less age-graded or less common are life events such as divorce and widowhood. The most important transitions related to education and work are school entry, school-to-school transitions, entry into the labor market, and retirement. Again, unemployment is rather considered a life event. This section deals with normative and regulatory relationship changes during these transitions at a more general level; other entries in this encyclopedia discuss these specific transitions.

All transitions involve significant changes in the social environment. An important insight from studies of transitions is that changes in relationships during a transition are not only caused by the transition, but are rather *proactive*. People and their close social network partners anticipate many of these changes and react in advance to this anticipation, not only when the transition has occurred. For example, parents may prepare their first child for the birth of the second child to minimize envy; classmates who know that they will soon attend different schools will often deemphasize their relationship, whereas those who expect to continue in the same school will deepen their relationship; and couples often try to coordinate their retirement years before.

Also, although some relationship changes during the transition are directly due to the transition, others are regulatory changes. For example, new siblinghood implies a new sibling relationship, but new siblinghood often also affects relationships with parents and other siblings because of a new rival family member, and sometimes also with peers due to increased social competence developed as families manage these changes. Similarly, the loss of school friends after the transition to a university is a direct consequence of the transition, but it is more or less quickly compensated for by new peer relationships at college, including roommates; and retirement is experienced more often positively than negatively partly because of the new freedom to keep liked former colleagues in one's social network and to rid oneself of obligatory relationships with disliked colleagues.

Non-Normative Life Events

For a long time, psychologists have studied adaptations to positive relationship-related life events, such as falling in love, and to negative relationship-related life events, such as parental death, separation, divorce, and widowhood. Overall, the effects of such events seemed rather short lived. Data from a large representative German longitudinal study where year-to-year changes in life satisfaction were obtained from 5 years before the event until 5 years after the event revised this picture. Although married people reported overall slightly higher life satisfaction than nonmarried people, this effect was largely due to the fact that even 5 years before marriage, people who eventually married were happier than nonmarried people. Thus, happier people more often tend to marry than less happy people (partly because happier people are more attractive to others than less happy people). Marriage had only a slight additional effect that showed up mainly during the year of marriage and the year before and after; 5 years after marriage, married people were exactly as happy as 5 years before marriage.

In contrast, divorced people were already considerably less happy than married people 5 years before divorce; happiness was lowest 1 year before divorce and then increased but stabilized 4 years after divorce at a level that was clearly lower than the initial level 5 years before divorce. Thus, whereas the effect of marriage was only transitory, the effect of divorce was long lasting. Also, this study showed large differences in how people reacted to marriage and divorce; some became quite unhappy already in the year after marriage, and some became much happier directly after divorce. Similar, although less marked, changes in life satisfaction were found for unemployment.

These recent studies of life events suggest that cross-sectional studies comparing people who recently experienced a particular event with a control group that did not experience this event, and longitudinal studies beginning in the year of the event or shortly before, may lead to misleading conclusions because they ignore preselection into these groups or changes occurring years before the event. That is, cross-sectional studies may seem to show the effects of an event when these results more appropriately are due to differences between

people. Also, they raise questions about the rosy common belief that marriage makes people happier in the long run. More important than the event seems to be who is experiencing the event (*selection effect*) and how individuals master the event (*regulatory effect*).

Because of the preselection effects, critical life events often cannot be considered random events that are unrelated to the individual experiencing the event. Even becoming a lottery winner is not independent of one's personality because not everybody risks losing money in lotteries. Becoming incarcerated, married, or HIV positive are different life events that nevertheless are similar in the fact that all may to some degree be predictable from personality.

Life-Course Management

Theories of *life-course management* and *developmental regulation* address the ways in which individuals master the challenges entailed in normative life-course transitions and non-normative life events, including how people deal with these challenges (regulatory change). Socioemotional selectivity theory suggests that people adapt their social motives over the life course according to their perception of how much time they have left in life. Such motives also involve existing or future relationships. When people perceive time as expansive, they pursue future-oriented goals and motives, such as seeking new relationships with friends and colleagues or striving to establish a stable partnership. In contrast, when they perceive time as limited, such as in older age or when they confront a life-threatening illness, they tend to pay less attention to less meaningful and distant relationships and focus instead on close relationships that help fulfill belongingness and generativity needs, such as relationships with their partner, their children, and closer friends and relatives. These predictions have been well confirmed in research on age-related changes in social networks; whereas aging people by and large preserve the "core" of their social network, the overall size of the network shrinks due to the loss of less close, peripheral relationships.

Most theories of life-course management distinguish between two groups of strategies that people

use when they adapt to life-course transitions and non-normative life events: changing or stabilizing the external world versus changing or protecting the own internal states. For example, the *life-course theory of control* distinguishes *primary* and *secondary control strategies*. These control strategies operate in tandem when people try to master life-course transitions or critical life events that threaten valued relationships. For example, after moving into a new town, people may look for new local friends to compensate for the loss of friends at the earlier place. Also, they may intensify communication with close friends and relatives, particularly those who live in or close to the new town. Both are instances of primary control. In addition, people may invest less time in nonsocial leisure activities such as watching TV alone, try to cope with feelings of loneliness, and lower their standards for time spent with friends (e.g., by convincing themselves that, although present circumstances are difficult, the future will be better). These are secondary control strategies.

Studies of aging suggest that as people move into later adulthood, they shift from an *activation mode* focusing on building new relationships to a *protection mode* aimed at preserving existing relationships and from an other focus to a self-focus. For example, many studies with married couples in middle and later adulthood found that older couples were better at expressing mutual affection and avoiding conflictual issues.

Conclusion

A life-span perspective on relationships views relationship changes over individual development as a function of normative life-course transitions, non-normative life events, and individuals' attempts to master the relationship changes due to these transitions and events by both primary and secondary control strategies. In doing so, such a life-span perspective stresses the active role of individuals in controlling their own relationship development. Combined with a personality differences perspective, it appears that relationship changes in response to life-course transitions and life events may considerably vary according to individual control beliefs and competencies.

(“I like volunteering”), an inanimate object (“I like my car”), an experience (“I like thinking about the future”), or another individual (“I like my friend”). These varied forms of liking involve positivity toward the liked object, but what differentiates interpersonal liking from other types of liking? In other words, what does it mean to like another person? This entry explores definitions of *interpersonal liking*, its development, and individual differences in this process.

Definitions of Interpersonal Liking

One conceptualization of liking comes from social learning theory. In this perspective, liking another individual does not differ from liking an activity, object, or experience. Social learning theory states that all behaviors result from the pursuit of a “reward” or some positive outcome. Thus, just as one might pursue an action because it feels good, one likes another person because being with that person provides benefits of some sort. Individuals differ in their perceptions of the benefits offered by another person (i.e., what is rewarding to some may not be rewarding to others) and can feel rewarded by numerous properties related to the other, such as the person’s characteristics (sense of humor, physical attractiveness, status, or warmth), feeling liked in return, companionship, or access to tangible rewards or opportunities (money, transportation, networking). These rewards make the relationship appealing, and the individual comes to associate the other with positive feelings.

A second conceptualization of liking distinguishes liking from loving. Zick Rubin theorized that, although liking and loving are both attitudes toward another person involving positive emotions and positivity about that partner, liking does not involve physical attraction and desire, whereas love does. Rubin developed questionnaires to measure liking (e.g., “My partner is the sort of person that I would like to be”) and loving (e.g., “If I could never be with my partner, I would be miserable”), and researchers administer these items to determine an individual’s feelings toward another person. It is clear from such items that Rubin considers liking to be a less complex attitude than loving, one that does not involve the same degree of investment in the relationship.

LIKING

Individuals express liking for a variety of phenomena. They can like an action enacted or planned

Other theorists categorize liking as one form of love. For example, Robert Sternberg describes three components of love: passion—arousal and physical attraction; commitment—devotion to and faith in the relationship; and intimacy—feelings of warmth, understanding, and connection to another person. These components, alone and in combination (e.g., the presence of passion vs. the presence of passion *and* intimacy), produce seven types of love. One of these types of love, referred to as liking, occurs when individuals experience intimacy without passion or commitment. In this instance, people positively regard each other and feel close without necessarily experiencing attraction or feeling committed. Another type of love in Sternberg's model is companionate love. As with liking, companionate love involves the intimacy component, whereby an individual feels close to another person without experiencing passion, but companionate love also includes commitment. Companionate love, then, is a stronger form of liking involving a desire to continue the relationship long term.

As a whole, theories of interpersonal liking suggest that it is a state of pleasant feelings and connectedness directed toward another person perhaps because that individual offers something desirable. Thus, interpersonal liking bears some similarity to other forms of liking given that both involve rewarding experiences, but interpersonal liking goes beyond general liking—that is, a positive attitude toward something—in that it involves intimacy and closeness with another person.

Development of Liking

How do individuals come to like others around them? What factors draw people together? After an initial encounter, there must be qualities that attract one individual to another that help transform a one-time meeting into a potential relationship. In essence, the initial interaction must be positive and must foster the expectation of future rewarding interactions. Existing research has identified four principles of attraction that contribute to liking: similarity, proximity, physical attractiveness, and reciprocity of liking.

Similarity

On the whole, people tend to like those who are similar to them: people who have similar backgrounds, similar interests, similar values and attitudes, and similar dispositions. Why are such similarities attractive? Research suggests that sharing common interests and beliefs with another person is associated with the expectation of being liked by the other, which in turn suggests that interactions will be smooth and enjoyable. If Matt, who strongly identifies with his religion, meets Eric, who faithfully follows the same religion, it is easier for Matt to anticipate being accepted by Eric. Expecting to be liked, Matt will feel more comfortable with Eric, treating him in a sociable, friendly manner, making it easier for Eric to respond likewise. Thus, knowledge of similarity is likely to help interactions go well, and such pleasant interactions lead people to experience greater liking.

Similarity is also validating. Many values and interests can be ambiguous; individuals are often unsure whether the things that matter the most to them are acceptable or worthwhile. According to social comparison theory, people obtain information about the validity of their beliefs and opinions by comparing them with the beliefs and opinions of others, particularly similar and highly regarded others. Thus, being around others who hold similar positions can help people feel positively about themselves, and such rewarding interactions lead to liking.

Proximity and Familiarity

Proximity, or the physical presence of others, attracts people to one another and can contribute to greater liking. One study, examining friendships among individuals living in a college dormitory, found that those who lived next door to one another were more likely to become friends than those who lived on the same floor, but farther away. The principle of proximity suggests that when another person is frequently nearby, there are more opportunities to observe and interact with the individual. Proximity has its effect, therefore, by establishing familiarity. Merely being exposed to another person leads to a sense that the other is likable. For instance, research assistants in another study sat in on a large lecture class 0, 5,

10, or 15 times throughout one semester. Students in the class rated the research assistants who attended the most classes more positively and more desirable as friends presumably because they were more familiar with these assistants. Essentially, proximity gives individuals the opportunity to become familiar with others; as long as that familiarity occurs in a positive context (i.e., the individuals have reasonably common interests and values and their interactions are pleasant), feelings of comfort and liking are likely to result.

Although proximity and familiarity may increase liking, regular interaction is needed to maintain liking. Stated differently, in general, absence may *not* make the heart grow fonder. If two individuals do not spend time together, they lack the enjoyable interactions that foster liking. Another qualification is that proximity and familiarity do contribute to greater liking, but only if two individuals are initially favorably disposed toward each other. More time spent with partners who are experienced as unpleasant or with whom there is outright competition and hostility is likely to contribute to further dislike. Social psychologists explain this qualification by arguing that proximity makes the “dominant response”—that is, the most likely response in that situation—even more likely.

Physical Attractiveness

Physical attractiveness is a valued trait in a romantic partner. What may be more surprising is that physical attractiveness can also foster attraction among nonromantic friends. One reason is that good looks often lead to the impression that a person has other desirable qualities. Research on the “what is beautiful is good” stereotype suggests that people presume that attractive individuals are more socially competent, intelligent, moral, selfless, and successful. Given this expectation that beauty is linked to positive qualities, it is clear why people would want to develop relationships with attractive others—they anticipate satisfying and rewarding interactions.

Several studies suggest that in the social domain, attractive people may indeed possess more positive qualities such as greater social skills. It may be that the “what is beautiful is good” stereotype operates in the manner of a self-fulfilling prophecy: People’s expectations that an attractive person has good

social skills may evoke exactly the positive characteristics that they expect. In one influential study, men were shown a photograph of either an attractive or unattractive woman and were led to believe they would interact with that woman over an intercom system. Although the photograph was not actually of their partner, men who saw the attractive photograph were more friendly, warm, outgoing, and funny in their conversations with the woman than men who expected to interact with the unattractive woman. It may be, then, that attractive individuals exhibit positive qualities because others give them opportunity after opportunity to do so.

Although physical attractiveness is associated with characteristics that benefit social interactions, the appeal of attractiveness may go beyond this, especially when selecting a romantic partner. A primary goal of any living organism is to pass on its genes. In sexually reproducing species, individuals have choice when selecting mating partners. Reproductive success can be maximized by choosing partners with the highest quality genes. Some theorists suggest that the physical attractiveness is an indication of a potential partner’s “good genes.” According to this hypothesis, attractiveness provides a cue to an individual’s genetic fitness because poor genes show themselves in deformities and poor health, which are considered unattractive. Attractiveness, therefore, may be an advertisement of an individual’s genetic quality.

Finally, beauty may also contribute to liking because it is valued in most cultures. In part, individuals like attractive people because they are seen positively by society, and associating with valued others may allow individuals to bask in reflected positivity.

Reciprocity of Liking

As mentioned earlier, awareness of being liked by another person often leads to liking. In one dating study, only 3 percent of men reported a willingness to ask out an attractive woman if they did not know what her response would be, preferring instead to wait for indications that the attraction was mutual. Researchers, led by Mark Leary and Roy Baumeister, have theorized that humans have a need to belong—a desire to be included and valued by others. Perceiving that another person likes

the self connotes an opportunity to be included, which is desirable and leads the individual to reciprocate liking. According to this theory, because relationships are tied to feelings of self-worth, individuals are motivated to participate in satisfying close relationships that bring about positive self-evaluations. However, initiating and participating in relationships always carries some risk of rejection. New acquaintances may be rejecting, and friends may behave in ways that foster hurt feelings, intentionally or unintentionally. The pain of such negative interpersonal experiences, which in one important study was linked to activation in the same neural regions as physical pain, may induce people to distance themselves from the situation and seek out supportive others. Knowing that one is liked and accepted by others suggests that they will be attentive to one's needs, interested in one's experiences and perspectives, and willing to make the relationship a priority. Further, interacting with others who express liking for the self is enjoyable and thus positively reinforcing. Essentially, confidence about another person's liking creates expectations of gratifying future interactions, providing an incentive to like that individual in return.

These principles of attraction describe several common processes that contribute to the development of liking. Of course, they also suggest that there are individual differences in who is liked. Interactions that are experienced as rewarding by one individual may be viewed by another as dull or frustrating. People are motivated to self-enhance, to see the self positively. As a result, individuals want to associate with those who validate the self because such interactions make people feel good about themselves. Of course, validating interactions are also inherently pleasurable. Thus, although the processes associated with attraction and liking unfold in all relationships, the specific content of similarity, proximity and familiarity, physical attractiveness, and reciprocity of liking are unique to each dyad.

A Social Relations Analysis of Liking

David Kenny's Social Relations Model attempts to distinguish between the various contributors to liking—the actor, the target, and the relationship. When considering an individual's liking of another, the actor effect refers to how much the individual

likes all interaction partners (i.e., how much does Theresa like all people with whom she interacts?). The target effect assesses how likable the interaction partner is to people in general (i.e., how much is Andrew liked by all people with whom he interacts?). The relationship effect represents how much a partner is liked over and above these general tendencies, presumably reflecting the dyad's distinctive manner of relating to each other (i.e., over and above Theresa's liking for people in general and Andrew's likability, how much does Theresa like Andrew?). Kenny's research suggests that, although actor and target effects have some impact on liking, to a great extent, liking is due to characteristics unique to a given relationship. That is, although an individual may believe that he or she likes another because of that person's qualities or because he or she likes most people, liking is more attributable to a pair's characteristic pattern of interacting.

One of the more interesting questions to emerge from the Social Relations Model analysis of liking is whether people are aware of how much others like them. Several studies have shown that perceptions of liking are attributable to the different components of this model. That is, in terms of target effects, people do seem to have a reasonably accurate sense of how much others like them in general. But in terms of relationship effects—knowing how much a particular person likes the self—people tend to be much less accurate.

Liking and Self-Disclosure

When two people self-disclose to each other, they like each other more as personal disclosures communicate trust and interest in the other person. In addition, self-disclosure is also used by those who like each other to share information about the self and thereby draw closer. Although self-disclosure does strengthen closeness and intimacy, this process must be gradual, or at least proceed at a pace acceptable to both members of the dyad. If either individual discloses too much too soon, the other person is likely to feel that the disclosure is excessive and inappropriate, inhibiting the developing closeness. Similarly, if either individual discloses too little, the other individual may feel a lack of trust or interest in forming a relationship, which also diminishes liking.

Liking in Long-Term Romantic Relationships

Some basic form of liking is necessary for the formation of any type of relationship. Acquaintance and friendship relationships are based primarily on liking, whereas intimate romantic relationships are initially characterized by a great deal of passionate love and physical attraction. However, passionate love generally wanes as time passes, and couples' needs become sated and the partners habituate to each other. If romantic relationships are based only on arousal and desire, they are likely to deteriorate alongside the decreasing passion. In more successful romantic relationships, as passionate love peaks and begins to taper, companionate love tends to grow. Companionate love, which goes beyond the warmth, positivity, and caring associated with liking to also include commitment, is associated with long-term well-being in romantic relationships, including marriage. Although passionate love is a mechanism to get two romantic partners together, it is the affection and dedication associated with companionate love that keeps romantic relationships going long term.

Conclusion

The social world is replete with opportunities for interaction. However, given limited time and energy, individuals prefer others with whom they anticipate fulfilling experiences. The processes associated with liking allow individuals to differentiate between rewarding interaction partners and those who are less interesting or who are disliked. In effect, then, liking is the gatekeeper to forming and maintaining relationships.

LISTENING

The average person does not actually speak for long periods in each day, and listening is the predominant interpersonal activity. It is crucially important in the formation, development, and maintenance of relationships. The child learns to listen before learning to speak, learns to speak before learning to read, and learns to read before learning to write. Listening is therefore a fundamental prerequisite skill on which other skills are predicated. Yet many relationship problems are caused by ineffective listening. Reading and writing skills have a low correlation, and the same probably holds for speaking and listening skills.

Indeed, we often listen with the intention of responding rather than with the intention of understanding. To respond appropriately, we need to give concerted attention to the speaker's communications. It is through listening that we accumulate the information and insights required for effective relational decision making. This entry examines listening in terms of its conceptualization, measurement, typologies, behavioral manifestations, and covert techniques.

Conceptualization and Measurement

The term *listen* is derived from two Anglo-Saxon words: *hylstan* (hearing) and *hlosnian* (wait in suspense). However, there is considerable debate about the exact meaning of the term. Different definitions emphasize either the covert cognitive aspect, or the overt behavioral dimension, associated with listening. Thus, some definitions focus on the cognitive auditory processes involved in sensing, storing, and interpreting oral messages. This perspective distinguishes hearing from listening. Hearing is perceived as a physical activity, whereas listening is a mental process. Just as most of us use our visual pathways to see but read with our brains, so we use our aural pathways to hear but listen with our brains. Similarly, although we do not have to learn how to see but have to learn to read, so too we do not need to learn how to hear but need to learn to listen. But cognitive understandings of aural information ignore non-verbal cues, which contribute significantly to the actual meaning of a message. For this reason, broader definitions conceptualize listening as an inclusive relational process in which the listener attempts to assimilate, understand, and retain both the verbal and nonverbal signals emitted by the speaker.

Listening begins when our senses register incoming stimuli. Our sensory register receives a large volume of data but holds this for a short time. Auditory data are held for up to 4 seconds, whereas visual data are held for just a few hundred milliseconds. For information to be retained, it has to be transferred to memory. Social data can be coded and stored in both episodic memory (remembering what people did) and semantic memory (remembering what they said). In working memory

(WM), both the memory/storage and attentional/processing functions combine to create meaning. People with greater WM capacities are better listeners because they can assimilate and process information swiftly and respond more appropriately. Research has shown a link between capacity for short-term listening (STL) and listening success. Good short-term listeners give more effective oral presentations, ask more questions in interviews, are more likely to secure promotion, and are rated as being better managers. However, although the importance of short-term memory for listening has been demonstrated, the exact nature of any causal relationship among listening ability, overt listening behavior, and STL is unclear. It is evident that there is more to listening than simply recall and more to recall than just listening. Further research is needed to tease out the exact nature of these relationships.

There are two broad categories of instruments used to measure listening: recall tests and perceptual instruments. Recall tests measure effectiveness based on the accuracy of message recall or comprehension. They involve presenting subjects with a filmed or audio sequence and requiring them to answer fixed-choice questions based on what has occurred. Although these tests may have high face validity, they have been criticized on four main grounds. First, they tend to measure retention or basic comprehension, rather than listening per se. Second, they conceptualize listening as a passive process in that, unlike actual social encounters, in these tests the listener is an observer who does not actively engage in the interaction. Third, they have been found to have low validity, with factor analysis tending to reveal that the only common factor is indeed memory. Fourth, these tests also to some extent measure literacy skills because they rely on reading and writing abilities.

Perceptual instruments involve either the completion of self-reports that measure one's perceptions of oneself or another as a listener or tests of ability to decode meaning from vocal or visual messages. Again, however, these are at least one step removed from real interactions. The former, self-report measures, offer a subjective insight into how respondents perceive themselves or others to have acted, as opposed to an objective record of how they actually performed. A problem with this type of measure is that self-report instruments

often have low reliability. Tests of decoding ability tend to focus on either vocalic messages (intonation, pitch, volume, etc.) or visual cues (facial expression, posture, etc.). These reveal that visual cues are more accurately decoded than aural ones, and that females are better at decoding nonverbal information than males. A difficulty in extrapolating these findings to human relationships is that, although there are instances in which single-system decoding may be required (e.g., the telephone), in most circumstances these cues are combined during listening.

Thus, there are difficulties with both types of measurement. To compound matters, correlations between different types of assessment have been low, indicating that these may assess different aspects of the listening process.

Typologies, Behavioral Manifestations, and Covert Techniques

There are five main types of listening. *Appreciative listening* occurs when we select messages from which we will gain pleasure, such as when attending a concert. *Comprehension listening* involves attempting to understand what others are telling us. *Evaluative listening* moves beyond comprehension to delineate the central propositions being put forward and assess the supporting evidence. *Empathic listening* occurs when we listen to someone who needs to talk and be understood and involves trying to see the world from the frame of the speaker. It is therefore at the heart of helping or counseling contexts. Finally, in *dialogic listening*, meaning is jointly generated and shaped through interaction, and for this reason it is also known as relational listening. The term *dialogue* is a combination of the Greek words *dia* ("through") and *logos* ("meaning" or "understanding"). Here, listening is transactional because those involved search for mutually agreed understandings that are beneficial for both parties. This is crucial in negotiations of all types, where for effective outcomes the goals and needs of each side must be jointly explored.

A distinction is also made between *active* and *passive* listening. It is possible to listen passively without indicating that we are paying attention. In contrast, active listening involves responding

in such a way as to show that we are attending. In terms of interpersonal relationships, it is important to listen actively. Although verbal responses are the acid test of successful listening, if accompanying nonverbal behaviors are not displayed by the listener, the speaker will infer a lack of interest.

A central verbal indicator of active listening is response development, where the listener follows on and builds on what the speaker has said. Although basic reinforcers (e.g., "That's excellent") can be useful in the short term, these are often employed in pseudolistening, where the listener is not really paying attention, and so can quickly lose value. For reinforcers to be fully effective, reasons should be given ("That's excellent. You have shown real courage in confronting him . . ."). Two other potent forms of verbal following are, first, probing questions, which follow up specific issues raised by the speaker with related questions, and, second, reflecting, where the listener summarizes in his or her own words the essence of what the speaker has just said. It is difficult to listen, assimilate what is being said, and immediately reflect this back using different terminology. The ability to do so is evidence of careful listening. Another listening indicator is reference to past statements made by the speaker, and in particular intermittent summaries of the main issues raised. During discussion, the speaker should avoid noncoherent topic shifts, which are abrupt changes of conversation that are not explained. Rather, coherent topic shifts should be negotiated, with disjunct markers used to signal the topic change (e.g., "That has been useful. . . . Can we now move on to discuss . . .").

The two most prevalent manifestations of active nonverbal listening are head nods and guggles ("Mmm-hmm," "Uh-huh"). This is well-known by TV producers, who cut separately recorded interviewer nods and guggles into interviewee responses to portray a natural conversation. Another crucial nonverbal listening indicator is eye contact, which conveys a desire to attend and participate. However, cultural expertise is required here because, although in Western society listeners look more at speakers than vice versa, in some cultures, this is not the pattern, and direct gaze may be viewed as disrespectful or challenging. Other nonverbal listening indicators are relevant facial expressions (e.g., showing concern), appropriate paralanguage (e.g., interested tone of voice), attentive posture (e.g., forward lean

on a chair), and sympathetic communication (e.g., mirroring the speaker's posture, facial expressions, and paralanguage).

Although the average speech rate is between 125 and 175 words per minute, the average thought rate (for processing information) is between 400 and 800 words per minute. This means that when listening, we have spare thought capacity, which needs to be used positively or unrelated mental processes can intervene (e.g., daydreaming). Because there are simply too many stimuli to attend to in any situation, we are equipped with a selective perception filter, so that certain information is consciously perceived and other material ignored. Thus, we usually filter out stimuli such as the ticking of a clock, hum of air conditioning, or weight of our arms on the chair. Effective listeners actively scan for important information, whereas poor listeners filter much of it out. Indeed, on average, we have forgotten about half of what we hear immediately after hearing it. This is because we are busy doing other things. When we listen, we not only evaluate the speaker's message, but plan a response, rehearse, and then execute it. It is important to ensure that the evaluating, planning, and rehearsing processes, which mediate between listening and speaking, do not actually interfere with the listening process. For example, we may decide what we are going to say before the speaker has finished and so stop listening.

A range of techniques can be employed to heighten receptivity. Information received may be organized into main themes and a chronological sequence. It can also be visualized by creating mental pictures of what the speaker is saying. Intrapersonal dialogue, or self-talk, also facilitates listening. This encompasses perspective taking (attempting to see the world as the speaker sees it), covert self-coaching ("My mind is beginning to wander. I must concentrate more"), self-reinforcement ("I'm listening well and understand her position"), and self-questions ("How does this relate to what she said earlier?").

Another problem in listening is that we assimilate information so as to make it fit with our mental set. Our previous experiences, attitudes, and values influence our expectations. We also evaluate others based on their appearance, initial statements, or their responses during previous encounters. These influence the way the speaker is

heard, in that statements may be interpreted in such a way as to fit with prior expectations. When attempting to interpret the motives and goals of the speaker, listeners need to be cognizant of their own possible preconceptions and biases.

LONELINESS

The most broadly accepted definition of *loneliness* is the distress that results from discrepancies between ideal and perceived social relationships. This so-called cognitive discrepancy perspective makes it clear that loneliness is not synonymous with being alone, nor does being with others guarantee protection from feelings of loneliness. Rather, loneliness is the distressing feeling that occurs when one's social relationships are perceived as being less satisfying than what is desired. This entry describes how loneliness is conceived and measured; how loneliness is mentally represented;

how loneliness influences thoughts, feelings, and behaviors; and the consequences of loneliness for health and well-being.

Conceptualizations

Despite general agreement over its definition, loneliness is conceived in a number of ways. One theory of loneliness holds that deficiencies in specific provisions of social relationships contribute to specific types of lonely feelings. For instance, lack of engagement in a social network is associated with feelings of social loneliness such as aimlessness, boredom, and exclusion. In contrast, the absence of a reliable attachment figure (e.g., spouse) is associated with feelings of emotional loneliness, such as anxiety, desolation, and insecurity. More recent studies have shown that these types of lonely feelings are not uniquely associated with certain relationships, however. Marriage, for example, serves a broad social integrative function that diminishes feelings of both social and emotional loneliness, especially for women.

Another theory holds that loneliness arises from social skill deficits and personality traits that impair the formation and maintenance of social relationships. Social skills research has shown that loneliness is associated with more self-focus, poorer partner attention skills, a lack of self-disclosure to friends (especially among females), and less participation in organized groups (especially among males). Personality research has shown that loneliness is associated with shyness, neuroticism, and depressive symptoms, as well as low self-esteem, pessimism, low conscientiousness, and disagreeableness. Associations among these characteristics have sometimes led to conceptual confusion between loneliness and depressed affect, poor social support, introversion, and/or neuroticism. Research indicates, however, that loneliness, although related, is independent of these characteristics both conceptually and operationally (i.e., the measurement tools for each of these characteristics are relatively specific for the corresponding traits). Moreover, the effects of loneliness on physical health and physiology are generally not explained by the behavioral and personality characteristics with which loneliness is associated, indicating that loneliness may be a unique psychosocial

risk factor whose effects are distinguishable from some combination of poor social support, depression, and personality traits.

Loneliness is aversive, but that is not necessarily a bad thing. An evolutionary conceptualization of loneliness holds that the aversive feelings are adaptive because they motivate the repair or replacement of social connections. Human offspring are born to the longest period of near total dependency of any species. Simple reproduction, therefore, is not sufficient to ensure that one's genes make it into the gene pool. For one's genes to make it to the gene pool, these offspring must survive to reproduce. Social connections and the behaviors they engender (e.g., cooperation, altruism, alliances) enhance the survival of the parents; consequently, their children are more likely to survive to reproduce.

In early human history, hunter-gatherers whose genetic predisposition encouraged social/family "togetherness" and the offering of food and protection to mother and child would have increased offspring survival odds, whereas hunter-gatherers who felt no compunction about ignoring social/family bonds would have reduced the survival odds of their offspring. The latter may have survived to have another family, however, suggesting that no single genetic predisposition is superior. The consequences of such an evolutionary scenario would be heritable individual differences in loneliness, and adoption and twin studies among children and adults support this view. Approximately 48 percent of the variability in loneliness levels can be explained by inherited tendencies to experience loneliness.

The genes underlying loneliness do not act alone. Interactions with the environment bring the expression of an individual's genes to the fore. The genetic biases that account for people's differing sensitivity to the social pain of isolation or rejection, and/or their differing propensity to extract social "nutrients" from the environment, help to determine whether a given social context will dampen or intensify a tendency to feel lonely.

Some social circumstances are fairly uniformly associated with an increased tendency toward loneliness. Marriage is associated with the lowest levels of loneliness; loneliness is greater among those who have experienced divorce and widowhood. Situational factors that influence the availability of social opportunities are also associated

with loneliness (e.g., geographic relocation). Social relationship quality is a more potent predictor of loneliness than the existence or quantity of social contacts, however. Relationships that offer security, comfort, trust, and pleasure, even if interactions are relatively infrequent, are much more effective at preventing feelings of loneliness than are more friends or more frequent interactions that fail to meet these standards. Even in marriage, the quality of the relationship determines the degree of protection against loneliness.

Measurement

Lonely feelings are typically measured using a variety of items that assess the degree to which respondents endorse thoughts and feelings characteristic of loneliness (e.g., “I feel alone,” “I lack companionship,” “I do not feel part of a group of friends”). The result is a continuum in which the intensity and/or frequency of lonely feelings can range from very low (i.e., equivalent to feelings of social connectedness) to very high. On average, lonely feelings are low to moderate in the general population, with only a relatively small percentage of individuals experiencing intense lonely feelings at any given time. When asked simply whether they are currently feeling lonely, approximately 20 percent of the population will respond affirmatively.

Social Cognition

Mental Representations

An axiom in the study of human relationships is that we are highly social animals. A sense of social connectedness is as vital to our survival as food and drink, yet is so taken for granted that only the absence of that sense has been assigned a unique term. This suggests that “not lonely” is the normal or default state required to maintain a healthy and balanced life and that loneliness is the problematic state. Indeed, people’s mental representations of their sociality conform to the importance of social bonds at every level of human endeavor.

Studies of loneliness have shown that mental representations of our connections with others are characterized by individual, relational, and collective

dimensions. These dimensions correspond to individual, relational, and collective selves posited by theories of the self. At the individual level, feelings of isolation and low self-worth are precluded when people feel comfortable with themselves and their fit in a social world. At the relational level, feelings of interpersonal connectedness are fostered in close dyadic relationships. At the collective level, feelings of group identification and cohesion satisfy a need for belonging. This three-dimensional representation of loneliness holds in young adults and across gender and racial/ethnic lines in middle-age adults, suggesting a universality to this representational structure of the social self.

Mental Processes and Behaviors

Loneliness can be experienced acutely, as a temporary state that resolves when life circumstances resolve (e.g., new friends are made in a new community), and chronically, as a trait-like characteristic that results from an interaction between life circumstances and a genetic bias to experience feelings of isolation. Once loneliness is triggered, it generates a defensive form of thinking—a “lonely” social cognition—that can make every social molehill look like a mountain. Lonely people tend to be more anxious, pessimistic, and fearful of negative evaluation than people who feel good about their social lives, and they are therefore more likely to act and relate to others in ways that are anxious, negative, and self-protective, which leads paradoxically to self-defeating behaviors. For instance, lonely and nonlonely individuals were equally likely to cooperate with a stranger at the outset and during the early trials of a prisoner’s dilemma game in which the stranger was playing a tit-for-tat strategy (i.e., cooperation met with cooperation, betrayal with betrayal). This strategy resulted in increased cooperation across trials among nonlonely subjects, but not among lonely subjects. Similarly, self-reports showed that, relative to nonlonely individuals, lonely individuals were less trusting of others and believed that they were less trusted by others. In essence, lonely individuals exercised self-protective behaviors that prevented them from enjoying the positive, cooperative interactions that were theirs to be had.

Not only do the lonely contribute to their own negative reality, but others begin to view them

more negatively and begin to act accordingly. One study showed that individuals told that an opposite gender partner they were about to meet was lonely subsequently rated that partner as being less sociable. The individuals primed to have these expectations also behaved toward their partners in a less sociable manner than they did toward partners whom they expected to be nonlonely. Once this negative feedback loop starts rolling, the cycle of defensive behavior and negative social results spins even further downhill. The lonely not only react more intensely to everyday hassles (e.g., misplacing or losing things), they experience less of an uplift from everyday perks (e.g., meeting one's responsibilities) than the nonlonely. In essence, lonely individuals inhabit an inhospitable social orbit that repels others or elicits their negative responses. Even when they succeed in eliciting nurturing support from a friend or loved one, they tend to perceive the exchange as less than fulfilling.

Social rejection is a potent cause of loneliness, and the lonely tend to have a heightened sensitivity to cues of social rejection and acceptance in their environment. For instance, after being presented with autobiographical information (i.e., ostensible diary entries) about a number of individuals, lonely participants remembered a greater proportion of information related to interpersonal or collective social ties than did nonlonely participants. It made no difference whether the detail was emotionally positive or negative. In another study, participants asked to "relive" a rejection experience, a procedure that increases feelings of loneliness, showed greater attention to emotional vocal tone (i.e., a cue for social rejection or acceptance) in a subsequent task than did participants asked to relive more neutral experiences.

Greater attention to social cues does not ensure greater social skills, however. Lonely individuals are less accurate than nonlonely people at decoding facial and postural expressions of emotion, for instance. A lack of correspondence between attention and accuracy in responses to social cues has also been demonstrated in a brain-imaging study of lonely and nonlonely young adults. When presented with equally arousing positive and negative pictures of scenes and objects (nonsocial stimuli) and people (social stimuli), activation in a set of brain regions often associated with visual attention and perspective taking varied in response to

negative social (in contrast to matched nonsocial) pictures. Relative to the nonlonely, lonely individuals showed greater visual cortical activation (consistent with greater attention to the negative social than nonsocial pictures) and less activation of the temporo-parietal junction (consistent with less attention devoted to the other person's perspective). Another set of brain regions, associated with reward systems (i.e., ventral striatum), was found to be down-regulated in lonely, compared with nonlonely individuals when viewing positive social (in contrast to matched nonsocial) pictures—results consistent with the idea that lonely individuals derive less pleasure than nonlonely individuals from viewing positive social circumstances. This latter result may bear on the finding that lonely individuals find positive social interactions during the course of a normal day less satisfying than nonlonely individuals.

So although people may become lonely because of a genetic disposition coupled with an unfortunate situation, they remain lonely because of the manner in which they and others think. One might expect that a lonely person, hungry to fulfill unmet social needs, would be accepting of a new acquaintance. However, when confronted with an opportunity to form a social connection, studies show that the lonely are actually far less accepting of potential new friends than are the nonlonely. Similarly, in other studies, lonely students were less responsive to their classmates during class discussions and provided less appropriate and less effective feedback than nonlonely students. Lonely undergraduates also held more negative perceptions of their roommates than did the nonlonely, and this perceptual divide widened as one moved from roommates to suite mates to floor mates to dorm mates.

Time also plays a role in constructing negative "realities." Researchers asked participants to interact with a friend, and to rate the quality of the relationship and the communication (a) immediately, (b) after watching a videotape of the same social exchange, (c) a few weeks later after being reminded of the interaction, and (d) after again watching the videotape. At all four measurement points, lonely individuals rated relationship quality more negatively than did nonlonely individuals. Interestingly, the further in time they were removed from the social exchange, the more negatively they

rated it. Thus, the more time that passed, the more the objective reality succumbed to the “reality” constructed by the lonely individual’s negative social cognition.

The Loneliness Continuum Revisited

When loneliness is considered on a continuum that ranges from *not at all* to *very*, it is easy to assume that social cognitive and behavioral characteristics differ in degree commensurate with the degree of loneliness. However, individuals who experience few or no feelings of loneliness are characterized by a unique and adaptive profile that is not simply the opposite of the profile of highly lonely individuals. This was evident in a study of three groups of young adults selected from a sample of more than 2,500 undergraduate students to represent loneliness scores in the bottom 20 percent (low loneliness), middle 20 percent (average loneliness), and top 20 percent (high loneliness). Individuals low in loneliness differed from individuals average or high in loneliness on four of five personality dimensions (more outgoing, agreeable, conscientious, and non-neurotic) and scored higher in optimism, positive mood, social skills, self-esteem, and social support and lower in anger, anxiety, shyness, fear of negative evaluation, and negativity. However, individuals average or high in loneliness were indistinguishable on these scales.

These results do not mean that those who are low in loneliness possess characteristics that render them immune to ever feeling lonely. Rather, when individuals feel socially connected, they express a constellation of states and dispositions that enriches their lives not only quantitatively, but also qualitatively relative to individuals who are average or high in loneliness. That is, there seems to be something special about being and feeling socially connected. This interpretation is supported by data from a hypnosis study in which young adults were made to feel lonely and then socially connected (or vice versa, in a counterbalanced order) by recalling a time when they felt rejected and as if they didn’t belong, or accepted and as if they did belong. Measures of affect, social factors, and even personality traits mirrored and tracked the acute changes in loneliness induced by the hypnotic manipulation.

Participants induced to feel socially connected, compared with lonely, reported significantly less negative mood; higher self-esteem and optimism; better social skills, social support, and sociability; greater extraversion and agreeableness; and less shyness, anxiety, anger, fear of negative evaluation, and neuroticism. This experimental study suggests that loneliness has features of a central trait—central in the sense that it influences how individuals construe themselves and others, and, by extension, how others view and act toward these individuals. Thus, although objective social circumstances (e.g., bereavement, ostracism) can modify feelings of loneliness, subjective social factors operate to keep people in a lonely or socially connected state of being. Whereas lonely individuals think about and behave toward others in a way that tends to reinforce a isolated existence, socially connected individuals hold a more favorable view of others that in turn tends to reinforce their being perceived and treated positively.

Health Consequences

As this profile reveals, when loneliness takes over someone’s life, they become trapped in a feedback loop of negative expectations, interpretations, and interactions. The challenge is reframing and redirecting social perceptions so that a sense of meaningful social connectedness can be established or recovered. Fortunately, the same feedback loop that allows individuals to construct a negative, subjective reality can be redirected to construct a better objective reality. This could be particularly important given the health consequences of loneliness.

Loneliness has been associated with alterations in the functioning of the cardiovascular, endocrine, and immune systems. A recent theoretical model of the correlates and consequences of loneliness posits that age-related declines in physiological resilience are accelerated by chronic loneliness. Accordingly, in younger adults, loneliness has been associated with early markers of disease processes (e.g., subtle alterations in blood pressure control mechanisms), whereas in older adults, loneliness has been associated with frank disease (e.g., elevated blood pressure) and dysregulation across multiple physiological systems (e.g., impaired immune functioning and

elevated levels of stress hormones). Clearly, the costs of loneliness are too great to ignore.

LONELINESS, CHILDREN

Researchers generally agree that loneliness involves an awareness that one's social and personal relationships are deficient and that this awareness is accompanied by emotions of sadness, emptiness, or longing. In the 1980s, researchers became interested in studying children's cognitive representations of their peer relations and their emotional reactions to relationship difficulties. For example, scholars examined whether children who have difficulty with peers as indicated by objective markers, such as how well liked they are, come to hold negative expectations of others and come to feel lonely, socially anxious, or depressed. Because loneliness stems from dissatisfaction with social relationships, the study of loneliness was a natural line of inquiry. This entry focuses on how children understand and experience loneliness, the influence of family and peer relationships on loneliness, and the role of social-cognitive factors in children's experience of loneliness.

Children's Experiences of Loneliness

When elementary school-age children are asked about their experiences of loneliness, they describe it as “feeling left out,” “feeling unneeded,” “being sad,” and feeling “like you don't have any friends.” Interestingly, even children as young as 5 to 7 years old can report feeling lonely and think of loneliness as consisting of being alone and feeling sad. Still, at this age level, children's understanding of loneliness is considered rudimentary because when asked whether it is possible to be lonely when playing with others, only a small percentage of children this young report that it is possible.

With regard to the formal measurement of loneliness, there is general consensus that loneliness is a subjective, personal experience that is best measured by self-report, rather than by inference from observational or psychophysiological measures. Accordingly, researchers have used questionnaires (multi-item formal scales with excellent internal reliability) to measure loneliness. Most measures contain some items that ask directly about loneliness, but the content of scales is often diverse, with many items assessing perceptions of social support,

self-efficacy, perceived acceptance by peers, or perceived participation in friendship, rather than loneliness per se. New efforts are being made to create highly reliable measures for children that restrict item content to feelings of loneliness. This solves the problem of overlapping content that can result when loneliness is studied in relation to factors such as social support or participation in friendship.

There is evidence that children's feelings of loneliness are moderately stable even over a fairly extended time period (e.g., correlations of .55 over 1 year). Although there is a need for more cross-sectional and longitudinal research, it appears that youth experience more loneliness during middle school than during the elementary school years. Furthermore, there are marked differences in loneliness as a function of developmental problems. Children who suffer from developmental disabilities, such as mental retardation, learning disabilities, or autism, generally report higher levels of loneliness than regular-education students. However, with regard to gender, studies of children in kindergarten through the sixth grade do not show reliable gender differences in rates of loneliness.

Associations Between Loneliness and Children's Family Relationships

Children's relationships with their family may affect how often and how intensely children feel lonely. Research in this area has mainly focused on parent-child interaction style. Degree of maternal warmth and degree of interpersonal control appear to be important predictors of children's loneliness. For example, mothers who tend to give advice about problems to their children in a controlling way and with little warmth have children with increased levels of loneliness.

Insecure attachment to parents early in life may be a risk factor for future loneliness. Longitudinal research has compared the loneliness of children who had different types of attachment patterns during infancy. Attachment was assessed using the Strange Situation, a laboratory paradigm in which the infant's reaction is observed when separated from the mother, when reunited with the mother, and when a stranger appears. Attachment theorists believe that infants who are securely attached to their mothers explore the environment when their

mothers are present, show signs of distress when separated from their mothers, and are comforted on the return of their mothers. Research has found that the loneliest children are those who had insecure-ambivalent attachments to their mother in infancy, meaning that they showed distress when separated from their mother, but were not comforted on reunion. This research suggests that early family relationships may provide an important foundation for how children feel later on in other types of relationships.

Associations Between Loneliness and Children's Peer Relations

Most research on children's loneliness has focused on the association between peer relations and feelings of loneliness at school. The aspects of children's peer relations most widely studied are: (a) peer acceptance, (b) peer victimization, and (c) friendship. Although these constructs are intercorrelated, research has demonstrated that they are distinct dimensions. For example, approximately 30 percent of children who are well liked by their peer group do not have a friend, and, conversely, approximately 50 percent of children who are poorly accepted by their peers have at least one friend. This kind of distinctiveness makes it possible to study the separate contributions of peer acceptance, peer victimization, and friendship to loneliness.

Peer Acceptance

Peer acceptance is the degree to which children are liked by their peer group as a whole. This is typically measured by using either a rating-scale sociometric measure on which children rate how much they like to play with each of their classmates or positive and negative sociometric nomination measures on which children indicate their three most-liked and three least-liked classmates. Research has consistently shown that children who are sociometrically rejected by their classmates report higher levels of loneliness than youth who are better accepted. This finding holds from preschool through high school and is seen in both Eastern and Western cultures. Short-term longitudinal research suggests that peer rejection leads to loneliness, not the other way around.

Of note, there is considerable variability in how much loneliness low-accepted children report. This variability is partially associated with differences in behavioral style. Whereas some peer-rejected youth exhibit aggressive behavior, others tend to exhibit a more withdrawn or submissive style. In elementary school, aggressive-rejected children report increased levels of loneliness compared with average-accepted children, but in middle school they do not. Submissive-rejected children, by contrast, consistently report feeling more lonely than their better-accepted peers. Submissive-rejected children may be at particular risk for loneliness because they receive more overt negative treatment from peers than do aggressive-rejected children. Although peers may not like aggressive-rejected children, they may be too intimidated by them to give these youth negative feedback about their behavior or how they are viewed. Furthermore, aggressive-rejected children are less likely to notice the negative feedback they receive from peers, a kind of self-protective bias that could guard against loneliness. Finally, aggressive-rejected children may feel less lonely in middle school because changing classes each hour makes for a larger pool of available peers and thereby affords them a greater opportunity to affiliate with similarly aggressive schoolmates.

Peer Victimization

Peer victimization can be assessed through direct observation, self-report, peer report, or teacher report. Victimization can take several forms, including verbal insults, social exclusion, negative gossiping, and physical aggression. Approximately 1 in 10 children are repeatedly victimized by their peers. Children who are the chronic targets of peer victimization experience increased levels of loneliness. As with peer rejection, it appears that peer victimization leads to loneliness, not the reverse. More important, once peer harassment stops, feelings of loneliness decrease.

Peer victimization is linked with loneliness in both Western and Eastern cultures. Interestingly, when investigating ethnic group differences within ethnically diverse schools, victimized children who are members of the ethnic majority at their school have been found to report the highest levels of

loneliness, victimized children who are members of the ethnic minority report the second highest levels of loneliness, and nonvictimized children report the least loneliness. One reason that victimized children who are members of the ethnic majority might report the most loneliness is that the victimization may lead them to feel disconnected from their own ethnic group.

Normative perceptions of a child's ethnic group also appear to be important to consider. For example, research has shown that when a victimized child is a member of an ethnic group that is perceived to be aggressive, that child experiences elevated levels of loneliness. It has been proposed that these youth are seen as "social misfits" by other members of their ethnic group and that perhaps these victimized children blame themselves for not fitting in better, an attribution that leads to poor adjustment.

Friendship

Friendship is defined as a close dyadic relationship in which there is a high degree of mutual liking and attachment, as well as a shared history. Loneliness has been studied in relation to two aspects of children's friendships: number of friends (e.g., mutual sociometric friendship nominations) and quality of their best friendships (e.g., reports by the child's best friend about specific qualitative features of the friendship). Children with friends experience less loneliness than children without friends, but the sheer number of friends does not typically make a significant difference. Interestingly, even children whose friends participate in delinquent behavior, such as stealing and drug use, experience less loneliness than children who are friendless. Furthermore, there is evidence that children who cycle through making and losing friends are as lonely as children who make no friends.

Children who are rejected by their peers and who do not have any friends experience significantly more loneliness than children who are rejected by their peers but have a friend. This finding has important implications for intervention work with children who have peer difficulties. If a child can develop a friendship with just one other child, his or her level of loneliness will likely decrease even if the child continues to be disliked by the broader peer group.

The quality of children's friendships is also related to loneliness. Features such as companionship, helping, validation and caring, intimate disclosure, conflict, and ease of conflict resolution predict loneliness above and beyond the prediction that can be made from overall peer acceptance. Children with higher quality friendships report significantly less loneliness than children with poorer quality friendships. The degree of association between specific friendship features and loneliness has been found to be similar for boys and girls, suggesting that boys and girls may have fairly similar needs with regard to what they look for in a friendship.

Social-Cognitive Factors Associated With Children's Loneliness

A small but growing body of literature exists on lonely children's social-cognitive processes. Research on locus of control has focused on the types of attributions that children make for their successes and failures in social situations, and particularly whether they blame themselves or others for social difficulties. Although lonely children are more likely to view their social successes as due to unstable factors that are outside of their control, they tend to perceive their social failures as due to stable characteristics of themselves, such as seeing themselves as difficult for others to get along with and acting in ways that bother other children.

Rejection sensitivity is another type of social-cognitive process that has been explored in relation to children's loneliness. Rejection sensitivity is the tendency to anxiously or angrily expect rejection by others. Youth who are highly rejection sensitive are not only more likely to behave in hostile ways toward their social partners, but are also at increased risk for internalizing problems, including loneliness.

Further research on the social-cognitive processes associated with loneliness may help to explain why some children who are well liked by their peers and have friends nonetheless feel lonely. It may be that children who hold stringent expectations of their social partners are especially susceptible to experiencing high degrees of loneliness. Conflicts and disappointments in relationships are virtually inevitable; as a result, children who

believe that friends should never break commitments or in other ways let each other down may be at increased risk for loneliness.

LONELINESS, INTERVENTIONS

Loneliness is a subjective, negative, and unwelcome feeling of not having a close companion, desirable friends, or social contacts. It is characterized by negative feelings such as not belonging, being left out, boredom, sadness, depression, and anxiety.

Loneliness and social isolation are closely associated but also distinct, with *social isolation* defined as an objective state that can be measured by the number of contacts and interactions between individuals and their wider social network. This entry focuses on loneliness and the types of interventions that are known to be effective in preventing and alleviating loneliness. Because of the close relationship between loneliness and social isolation, some of the interventions will, by default, target both.

Conceptualization of Loneliness

Humans are inherently social beings, needing both supportive social networks and intimate social relationships. Most people have an intuitive notion of loneliness and describe it in different ways. Common to all such descriptions is the subjectivity of the feeling and that it is for the most part an unpleasant and distressing experience. The determining factor is how people feel about or respond to loneliness, rather than in the physical sense of the experience.

An important distinction with regards to the development of interventions is the duration of the experience. Transient loneliness relates to the common everyday swings of mood, which are unlikely to require intervention. Situational loneliness follows a change in life circumstances, such as becoming widowed or moving to an unfamiliar area. Interventions at this stage can be effective in both preventing and alleviating loneliness. Chronic loneliness is an ongoing enduring experience of loneliness, where the nature and quality of the individual's social networks affect their ability to deal with their loneliness. Finally, the term *aleness* is sometimes used to express a serious, long-term, chronic experience of loneliness associated with long spells of lack of any meaningful contact with the external environment. Interventions targeting these two chronic conditions are essential to ensure people's health, quality of life, and life satisfaction.

Factors Associated With Loneliness

For the purpose of developing effective interventions, several aspects of loneliness need to be considered: demographic characteristics such as age, gender, culture, and living alone; people's

perceptions of personal control, coping, and feelings of dependency; the experience of major life events, such as job loss or retirement, loss of friends, relatives and companions, change of residence, and health problems; and personal resources, such as mental health (particularly depression), disability, and decreased mobility. Finally, the stigma of loneliness leads to underreporting of loneliness. Men and older people, in particular, are reluctant to admit feelings of loneliness because of the stigma of what is seen as a social failure and not being able to cope.

Interventions to Alleviate and Prevent Loneliness

A vast array of interventions has been developed over time to alleviate and prevent loneliness in vulnerable groups, ranging from hi-tech Internet or phone-based services to small low-cost self-help groups. Some of these activities and services are theory- and/or evidence-based, whereas others have evolved through practitioners' experience and local knowledge. Interventions intended to alleviate loneliness could be said to have three broad goals: to help lonely individuals establish satisfying interpersonal relationships; to prevent loneliness from evolving into more serious health problems, such as depression or suicide; and to prevent loneliness from occurring in the first place. The majority of these interventions fall into four, sometimes overlapping categories: social support/social activity; education; service provision; and problem solving, as either group or one-to-one interventions.

Social Support and Social Activity

Research has demonstrated that the quality rather than the quantity of social support is of greater importance in alleviating loneliness and reducing social isolation. For example, older people may have frequent contact with family, but the family is not, contrary to what many services seem to assume, the main source of emotional support. However, contacts with adult children are frequently the main source of instrumental support. Long-term, old friends provide support in times of transition (e.g., retirement and bereavement by

providing continuity and an acceptance of aging). New friends, in contrast, are frequently sought through group activities, with the emphasis on shared enjoyable activity rather than on reciprocal support.

Education and Problem Solving

Group-based social support interventions for older people with mental health problems, widows, women living alone, and caregivers are often effective in reducing social isolation and loneliness and in increasing self-esteem and morale. Most interventions include some form of structured activity, such as peer- and professionally led educational programs, self-help support, directed group discussion, or supported social activation (e.g., providing widows with skills to adjust to an independent life and improve their life skills competencies). Groups meet a variety of needs such as enjoyment, activity, and social integration. Membership in a group is a strategy for dealing with loneliness. Participant-planned and participant-led activities seem to improve effectiveness. Some interventions are intended to help the individual identify activities and tasks that can be enjoyed alone. Older men are more likely to participate in task-focused activities than in what they perceive as social support or social network activities. Many interventions use indirect approaches, which are not perceived as social network activities or intended to reduce social isolation and loneliness. Walking and exercise groups are known to improve physical and mental health and reduce loneliness, and there is some evidence to suggest that activities such as gardening projects, healthy eating groups, art, music, and dance are effective, although further evaluation is still required.

It is frequently assumed that if people participate in an activity, it demonstrates that it is acceptable and attractive to them. However, research shows that some older people will make do with activities and services that do not meet their social activity or social support needs simply because there are no other options. Expectations of services and activities vary among individuals, but also among socioeconomic groups, cultures, genders, and generations. It is well known that in all age groups people from higher socioeconomic groups have better access to and participate to a greater degree in relevant services and activities.

Ironically, those who are truly isolated and lonely are the least likely to join a social support or activity group.

Similar activities have been proposed for school children, young people at high risk of dropout, violence, drug and alcohol use, bullying, and other health risk behaviors and first-year college students. In a review of school-based activities to reduce loneliness among children, Evangelia Galanaki and Helen Vassilopoulou identified seven categories of interventions that would help children to deal with their loneliness: (1) identification, understanding, acceptance, and expression of loneliness; (2) social skills training and social problem solving; (3) creating a positive social environment in the classroom and the playground by, for example, changing the physical layout of the environment or establishing buddy and peer support; (4) enhancement of self-esteem; (5) cognitive-behavioral modification; (6) development of coping strategies; and (7) development of solitude skills.

For college students coping with transition and loss, relationship support and friendship development have been suggested as ways of reducing loneliness, especially in the first year. Research has shown an association among loneliness, mental health, and resilience in young people, particularly in vulnerable groups such as the homeless, same-sex attracted young people, young parents, and obese children. However, little is currently known about the effectiveness of interventions intended to enhance resilience in preventing or alleviating loneliness. Preconditions for successful social network and social support development are that the activity is provided regularly, that participants wish to socialize and participate, and that there is someone who leads and takes responsibility.

Use of Technology

The use of technology, such as the Internet or telephone networks to reduce social isolation and loneliness across age groups, has increasingly been shown to be effective. There are indications that telephone and Internet support groups may be effective in reducing loneliness among housebound older people, caregivers, older people living with HIV/AIDS, and people in congregate housing. Research has shown that e-mail and the Internet are used for different purposes: E-mail is mostly

used for social contact, and thereby to reduce loneliness, whereas the Internet is used for practical purposes, such as information and simply to pass the time. It would also seem that mobile technology such as cell phones or social networking sites might help to decrease individuals' feelings of loneliness. However, little is currently known about *how* different groups utilize cell phones or Web sites for this purpose (e.g., texting vs. voice calls, perceptions of purpose of Internet communication). The impact and effectiveness of telephone buddy services and telephone support groups are ambiguous.

For older isolated and housebound older people, telephone befriending and support groups provide the means to have social contacts and to reduce their isolation and loneliness. Some research has also shown that people who choose not to join groups like the anonymity of the telephone group. However, the association between loneliness and telephone interventions remains unclear.

Volunteering

Volunteering is frequently put forward as an effective way of increasing socialization and maintaining mental well-being in later life. Volunteering undoubtedly has beneficial effects mainly because of the social aspects of the activity and because it can give a sense of worth. It may also be that the reciprocity of volunteering adds to a sense of well-being, in that the mutual benefits of providing and receiving support are effective in giving a sense of social support. Intergenerational activities and home visiting have been mentioned specifically in relation to older people, but other voluntary activities may have similar effects.

Qualitative research has shown that older people respond favorably to home visiting because it provides someone with whom to share interests and worries, as well as practical help, social support, and companionship. The importance of reciprocity is emphasized, which may be more likely when the visitor/caller and the recipient are of the same generation, share a common culture and social background, and have common interests. Befriending is therefore of value to both the (older) volunteer and the older person receiving the service.

Indirect Activities

Many widely provided services and activities that are not directly intended to affect loneliness have not been evaluated or evaluated adequately despite anecdotal evidence of their effectiveness in alleviating loneliness. For example, results from research regarding the influence of companion animals have to date been inconclusive mainly due to flaws in the research. Likewise, the impact of the physical and social external environments in terms of interventions has not been evaluated. For example it has been suggested that the provision of adequate public transport and accessible, safe social venues (parks, libraries, Internet cafes, garden centers, and shopping malls) would reduce social isolation and loneliness. It has even been suggested that hairdressers could provide lay support for socially isolated people who might not access other services.

Finally, not everyone wants to participate in groups or have a large social network. Some people choose to be alone and to live alone. It is important for others, including service providers, to recognize and accept the individual's right to this decision because, although they are alone, they are not necessarily lonely.

LONG-DISTANCE RELATIONSHIPS

Long-distance relationships (LDRs) are defined here as occurring among individuals who have an expectation for a continued close connection and their communication opportunities are limited, in the views of the relational participants, due to geographic separation. Long-distance (LD) status has been ascribed based on relational participants' reports of the miles between them, of their residence in different cities, of the number of nights a week they spend apart, their inability to see each other every day if they so desire, or simply if they consider themselves to be in an LDR. LDRs are of interest because they exist and generally thrive in contradiction to assumptions concerning necessity of frequent face-to-face interaction for the maintenance of close relational bonds. Although a large body of research exists on noncustodial fathers and the effects of parental absence on children, such parent-child LDRs will not be covered within this entry. This entry concerns the types of and reasons for LDRs, as well as interaction opportunities, societal support, maintenance, and reunions.

Types of LDRs and Reasons for Their Occurrence

LDRs may occur between marital partners, committed nonmarital partners, the children of such

partners (or ex-partners), extended family members, and friends. The number of LD marriages (or families) is unknown; outside of the military, LD families are not officially recognized.

LD marital relationships occur primarily due to educational or career pursuits, employment demands, military deployment, or incarceration. Military deployment and incarceration account for most LD romantic involvements. In 2005, approximately 60 percent of deployed military personnel were married and/or had children. As of 2000, federal, state, and local prisons held approximately 2 million individuals, the majority of which had children and/or romantic partners.

A distinction is often made between dual-career, dual-residence (DCDR) LD couples and single-career, single-residence LD couples. DCDR couples live apart due to difficulty finding career opportunities in the same location. Estimates indicate that about 1 million married couples are DCDR couples. The number of academics and corporate executives in LDRs is estimated to be higher than that of the general population. An LD, yet single residence, couple or family occurs when one member of the couple (usually the male) is away for extended periods of time due to his work demands, but a separate residence is not maintained. Rather, the traveling individual generally stays in hotels, barracks, company quarters, and the like. Separations might be for routine, relatively short durations, such as weekly travel for business purposes, or for months or years, such as off-shore oil workers.

Nonmarital romantic LDRs exist and occur for the same reasons. Estimates indicate that up to 50 percent of college students will be involved in an LDR. Committed nonmarital LDRs exist beyond college students. Two, committed, career-oriented individuals may cohabit and then become LD for career reasons.

Although most romantic partners share the expectation that they will share a residence, Irene Levine and Jan Trost have identified a couple type labeled *living apart together* (LATs) who are romantically involved, might be heterosexual or homosexual, might or might not be married, might or might not have children, expect a continued romantic involvement, and have no desire to share a residence or necessarily live in the same city. These individuals are sometimes apart due to the same reasons listed previously. Some such couples

are formed later in life and desire to retain two residences in order to maintain proximity to children or grandchildren.

LDRs occur in other forms. They often occur between friends. Laura Stafford has coined the term *cross-residential relationships* to reflect nonromantic family relationships as a type of LDR because a lack of shared residence places restrictions on interaction. Noncustodial parents have more restrictions on their interactions than do custodial parents. When including friendships and cross-residential relationships as forms of LDRs, it is likely that nearly everyone in the United States is in at least one.

Societal Support, Interaction Opportunities, Maintenance, and Reunions

Friendships, Sibships, and Extended Family

Some types of LDRs are expected in Western cultures. It is normative for adult children and their parents, extended family members (e.g., grandparents), adult friends, and adult siblings not to share a residence, and they are sometimes questioned if they do. Nor are they expected to live in geographic proximity. Among nonromantically involved family members and friends, research has largely addressed the strength of ties or the ability of the relationship to meet needs because it is assumed that family or friends who live apart and do not interact frequently cannot be as close as those who do. Participants in such relationships have been found to maintain close relational bonds and positive affect and to meet emotional needs regardless of frequency of interaction or geographic proximity, although proximity is linked to the ability to meet some instrumental needs.

Although LD friendships do not seem to be contingent on frequency of interaction, the type of interaction engaged with proximal friends is different than that of distal friends, but the emotional closeness appears to be similar. As individuals become older, close friendship is defined less by interaction and more by the feeling that the other would “be there” if needed. Mary Rholving found that LD friendships may remain dormant for many years. Nonetheless, the individuals feel close, and if they do interact, they often seem to be able to simply pick up where they left off.

As siblings become adults, they typically engage in less contact with each other than during their childhood. Adult sibships share similarities with adult friendships. Some become dormant. Into middle age and especially as individuals become elderly, siblings take on increased meaning regardless of proximity and contact. Feelings of attachment and the perception of the willingness of a sibling to mobilize during a time of need seem to define successful adult sibships.

Grandparents who live in proximity of their adult grandchildren engage in more frequent interaction than those who do not, yet there is no association between feelings of emotional closeness or personal involvement and frequency of contact between young adults and their grandparents. To what extent this might hold true for younger children is unknown.

Romantic LDRs

The assumption is that a marital couple (and their young children) should live together. Recognized exceptions include the male’s career or military deployment or divorce. Other reasons for cross-residential or LDRs among family members are often met with skepticism.

Scholarly study of military LDRs began with WWII. At that time, interaction opportunities meant the often delayed exchange of letters. Similar to early research, recent research has found that vague positive and supportive letters help maintain ties. Interaction opportunities have increased with the advancement of new communication technologies. However, whether such contact is beneficial for the relationship or for the military operation is undetermined. Concerns that a soldier’s contact with family members might distract her or him from the task at hand have been raised. Individuals sometimes report feeling more depressed, lonely, or helpless after interactions. For the family members at home, stressors include managing the day-to-day roles that the deployed individuals filled, concerns for safety, and difficulty gaining access to information about deployed family members. Economic impact often occurs when reservists are called into duty, leaving a more lucrative financial situation. Military families do have institutionalized support unavailable to most other LDR forms. Societal support is generally

high for military families, although the popularity of a particular war seems to be associated to some degree with support.

Partners must cope with not only the separation, but also the reunion (and often another separation). The most successful families fill in the missing partners' roles during the absence and retain the missing member psychologically and symbolically. Upon reunion, the roles filled by other family members or friends are returned to the previously absent partner. On departure, the family restructures again. Preparing returning military personnel for potential issues encountered with reunion seems helpful. Divorce appears somewhat more likely for military personnel returning from deployment as compared with the general population; this is more so the case for individuals who have seen active combat.

Families separated due to the incarceration of one or more members face perhaps the most stressors and challenges; they encounter extremely limited communication of any form. Some families forbid children from seeing an imprisoned parent. Relationships that are maintained are often done so through few, if any, letters or phone calls. Relationships are maintained cognitively as individuals reminisce about relational partners or family members and look forward to reunions. Sometimes pictures or other reminders play a role in these cognitions. Family members are often stigmatized, invoke little sympathy or societal support, share concerns for safety, have difficulty gaining access to information, and have few resources. Families of incarcerated individuals no longer receive any financial support from the absent member, who was often the primary monetary earner. Pending many factors, marriages and other romantic involvements, and often times active child relationships, do deteriorate during this time. The maintenance of family relationships and successful reunions with those families on release appears to aid in rehabilitation and reintegration into society and decreases recidivism.

The 1970s saw the rise of DCDR marriages or "commuter couples." Their interaction opportunities are likely the greatest of all other romantic LDR types. Flexible work schedules and monetary resources contribute to the success of the LD arrangement. If children are involved, the parent

with the children sometimes feels stressed and overwhelmed, whereas the parent living apart from the child reports missing the day-to-day interaction. DCDR couples report some benefits of the arrangement, such as the ability to segment work and family and higher quality time when they are together. Participants indicate that their relationships are sometimes met with skepticism as to their commitment to the marriage. Research has not examined the long-term viability of such relationships or permanent reunions.

LD dating relationships have been found to be as or more stable than proximal dating relationships. It is this point that most relational scholars have found the most puzzling. LDRs have less face-to-face time. New technologies and unlimited cell phone plans allow students the opportunity for virtually unlimited mediated interaction. Yet they do not seem to engage in more mediated communication than proximal partners. LDRs have been argued to be maintained in part through idealization. A large proportion of everyday talk appears to be intimacy focused.

Student LDRs are thought to be stressful. The extent to which this is the case has been questioned. Like DCDR married couples, LDRs have reported some benefits of an LDR, including the ability to segment work (or school) and the relationship, enjoyment of autonomy, and feeling that their limited time together is qualitatively better. Generally, college student LDRs have less monetary support than DCDR couples. When LDR partners relocate to permanent geographic proximity, the probability of relational dissolution increases; extreme idealization during separation is associated with relational demise upon reunion. Of course, some report few, if any, difficulties moving to the same location.

Conclusion

Most types of LDRs are successful at maintaining close positive bonds during separation (with the exception of incarceration). Relational maintenance mechanisms other than interaction occur. LDRs may supplement their lack of face-to-face maintenance with cognitive maintenance efforts, such as idealization, romanticized beliefs, positive ruminations, anticipation of future meetings,

imagined interactions, and symbolic or ritualistic inclusion. The strength of the relationship prior to separation, the length of time separated, the time between face-to-face visits, and many other factors that vary even within the same type of LDRs surely impact these relationships; however, little research exists. Despite maintenance during separation, reunions bring more questions about relational stability. Although not studied among DCDR couples, military personnel college dating relationships and relationships that survive incarceration are at risk on reunion.

Many forms of LD families (e.g., relationships among immigrants or migrant workers and their families) have yet to be the focus of significant study. Although the violation of norms for living arrangements and interactions may be the primary reason for study among Western relational scholars, LD family relationships are not considered atypical for many cultures.

LONGITUDINAL STUDIES OF MARITAL SATISFACTION AND DISSOLUTION

More than 90 percent of Americans marry at least once. Although the divorce rate has been slowing since the early 1980s, nearly half of all marriages end in divorce or permanent separation—and many people remain in unhappy marriages. Understanding how marriages evolve from the optimistic “I do” to the disillusioned “I want a divorce” is important because marital distress and divorce are associated with significant economic, mental health, and physical health problems among adults and with emotional and behavioral problems among children.

For more than 70 years, scientists have sought to explain why some marriages are more satisfying than others and why some marriages dissolve. Marital satisfaction is a spouse's appraisal of how happy he or she is in the marriage. Marital dissolution refers to whether the couple remains married versus gets separated or divorced. The majority of studies in this field is cross-sectional or conducted at a single point in time. Cross-sectional studies are limited in explaining variability in marital satisfaction and dissolution because they cannot identify factors that cause marital decline. For example, when marital satisfaction is measured at the same time as poor communication, it is not possible to say which is the cause and which is the consequence—or whether a third variable, such as stressful events outside the marriage, caused both.

Longitudinal studies, which assess marriages two or more times, are therefore necessary to identify how marriages change and deteriorate. Longitudinal studies are valuable for addressing a fascinating puzzle about human social behavior, and they are critical for informing interventions that can prevent adverse marital and family outcomes.

Conceptual Approaches to the Study of Marital Satisfaction and Dissolution

To understand how different marriages result in different outcomes, scientists from diverse disciplines have focused on a variety of hypothesized causes, from the broad social and political structure (macroanalytic perspective) to the specific individual characteristics of a spouse (microanalytic perspective). For example, demographers focused on social and political forces have examined divorce rates in relation to World War II, no-fault divorce laws, women's workforce participation, and gender imbalance in the population. To examine marital satisfaction and divorce, sociologists have examined spouses' sociodemographic characteristics such as age at marriage, race, income, education, premarital cohabitation, gender roles, and attitudes toward divorce. Psychologists focused on spouses' behaviors and thoughts have examined communication skills, cognitive appraisals of relationship events, commitment, spouses' personality characteristics and family background, relationship violence, alcohol consumption, the transition to parenthood, and depressive symptoms.

The different disciplines that examine marriage all have theories—that is, reasoned explanations—for why marriages succeed or fail. This entry highlights psychological theories because they focus on behavioral and cognitive components of marriage that can be changed or improved through intervention to relieve marital distress, a significant source of human suffering. There are various psychological theories of marriage; the three theories highlighted here get at the diverse factors that impinge on marriage—behavior in the here and now, family relationships in the past, and stressors outside the marriage. Behavioral models focus on how spouses talk to each other (i.e., the content of their words and the emotional tone with which they are

delivered) when trying to resolve a marital problem (e.g., money, household management) or providing support to one another. Attachment theory focuses on how adult romantic relationships are affected by relationships in childhood, such as the emotional connection with a mother or the quality of the parents' marriage. Crisis theory focuses on how marital outcomes result from a stressful event outside of the marriage, perceptions of the crisis, resources, and coping responses. Each of these perspectives specifies what is likely to be an important aspect of how marriages succeed or fail. Yet there is a growing realization that marital outcomes are multiply determined, suggesting that the most comprehensive approach to understanding marital success or failure will result from examining the interplay among multiple aspects of marriage, rather than just one domain or a string of variables examined in isolation. Thus, informative longitudinal studies will be those recognizing that the outcome of a given marriage is the dynamic product of individual characteristics of the spouse (e.g., history of parental divorce, personality)—how spouses interact with each other (e.g., how they express understanding, resolve disagreements, and allocate chores) as they encounter a broader context of stressful circumstances (e.g., illness, job lay off, dangerous neighborhoods), all within a particular historical cohort. For some couples, the seeds of marital demise will be present in the early months of marriage, even during the newlywed period when satisfaction is at its highest point, whereas for other couples problems emerge later as the product of individual vulnerabilities (e.g., depressed mood, parental divorce), interpersonal deficits (e.g., poor communication skills), and contextual influences (e.g., stressful circumstances).

Factors That Predict Marital Satisfaction and Dissolution

Although numerous variables have been used in longitudinal studies to predict changes in marriage, only a subset of these have replicated across studies. Based on Benjamin Karney and Thomas Bradbury's review of 115 longitudinal studies of marriage that were conducted from the 1940s to the 1990s, two broad observations summarize this subset of replicated variables. First, a given variable

(e.g., expressions of strong negative emotion) typically has the same effect on dissatisfaction as it does on dissolution, with one notable exception: The presence of children tends to increase dissatisfaction while reducing the likelihood of dissolution. Second, interpersonal variables—that is, the interactions between spouses, such as conflict resolution behavior and sexual satisfaction—are stronger predictors of change in satisfaction and stability than external stressors, spouses' psychological characteristics, and spouses' demographic characteristics. Based on similar results across a number of studies, we can be reasonably certain that spouses' marital satisfaction is higher and divorce is less likely when spouses evidence the following: display more positive and less negative behavior when resolving marital conflicts, are sexually satisfied, are older at the time of marriage (ages 25 and up), have more education, did not cohabit before marriage, had a happy childhood, exhibit less neuroticism, are not depressed, report less stress, and do not live in poverty. It should be noted that these results are based primarily on studies of White middle-class spouses and may not hold for more diverse populations.

More compelling is research that captures generative processes in more complex ways. For example, evidence suggests that newlyweds go on to achieve higher marital adjustment (i.e., higher marital satisfaction, fewer depressive symptoms) when spouses report more negative life events *and* have more adaptive communication skills, but adjustment declines when more negative events are combined with poorer communication skills. Thus, negative events are not uniformly damaging to marriage, but their effect depends on the skill with which couples communicate or approach conflict resolution. Studies suggest that newlyweds' physical aggression predicts divorce 4 years later, whereas poorer conflict-resolution skills predict lower satisfaction. Thus, some variables have a stronger effect on divorce, and some have a stronger effect on marital satisfaction. Last, John Gottman showed that, over 14 years of marriage, higher rates of negative emotional expressions during conflict resolution predict divorce in the first 7 years of the study, but lower rates of positive emotional expressions predict divorce in subsequent 7 years. It appears that heated fighting corrodes marriages quickly and that emotional detachment becomes

more salient and damaging after marriages pass through the intense early childrearing years.

Karney and Bradbury's review of 115 longitudinal studies of marriage yielded a long list of variables, studied largely in isolation from each other, that predict satisfaction and stability. These studies give us limited information on how marriages are transformed over time. They also yield important lessons about how the next generation of longitudinal studies can be more effective. The typical longitudinal study of marriage samples a heterogeneous group of 500 to 600 spouses two times and examines a circumscribed set of predictors as main effects. A number of changes can yield stronger research designs to yield more comprehensive information about how marriages evolve.

Longitudinal Studies of Marriage: The Next Generation

If the goal is to understand how marriages change, both gradually and abruptly, then the "perfect" study would be to follow thousands of couples over 25 years with daily measures. Clearly, the perfect study is not so perfect in terms of the burden on the participants, the burden on the researcher, and the expense. Short of perching in a couple's living room observing them day in and day out, there are ways that longitudinal studies of marriage can be improved conceptually and methodologically to capture more of the complexity of marital development. We have already noted the importance of comprehensive, theory-driven research as a strategy for refining future studies. Moreover, studies that use two times of measurement to assess couples with varying lengths of marriage and have a limited focus on a single arena are of limited value. The following three suggestions for improving longitudinal research on marriage represent an illustrative, but not exhaustive, list of tactics likely to achieve greater precision in predicting when and explaining how marriages develop and deteriorate.

First, comprehensive understanding of marriage will be achieved by integrating multiple arenas relevant to both spouses, including marital communication skills, individual characteristics the spouse brings to the marriage, and stressful events and circumstances outside the marriage. Considering

that communication is the route through which most marital experiences unfold, and through which most couples will try to improve their relationship, a strong theoretical case can be made for assigning communication a central role. However, contrary to some claims made in the literature, simple models ascribing primary importance to communication processes are unlikely to be particularly powerful if only because communication is shaped by characteristics of the individual spouses and their development through adulthood, by their prior history together, and by the environments that couples inhabit.

Second, basic demographic characteristics about marriage tell us which couples we should study to maximize the probability of observing variability in adverse marital outcomes. Half of couples divorce within the first 7 years of marriage, and a significant proportion of those divorces occur in the first 4 years. By the 10th anniversary, marital satisfaction is fairly stable, and the risk of divorce is relatively low. Because a greater risk in divorce occurs in the early years of marriage, there is unique value to beginning a longitudinal study of divorce with newlywed couples to observe how couples go from being satisfied to dissatisfied. Studies that include couples with heterogeneous lengths of marriage run the risk of not observing change because satisfaction fluctuates less as marriages progress. Also, studies that examine couples with longer marriages will miss couples who already divorced. Whereas studying newlyweds increases the likelihood of capturing changes in marital satisfaction and divorce, studying other key marital transitions will also likely capture changes in satisfaction. For example, a replicated finding is that the transition to parenthood shows declines in marital satisfaction during that time. Investigation of other transitions, such as the transition of children to school, to the empty nest, and to retirement, are also likely to capture changes in marital dynamics and satisfaction and will fulfill the need to study marriages in different contexts.

Third, understanding different patterns of marital satisfaction over time requires more than two assessments, which yield an oversimplified linear view of change in marital satisfaction. Two assessments of marital satisfaction only allow researchers to say that a given marriage improved, declined, or stayed the same. Three or more assessments, say

every 4 to 6 months, can begin to capture the arc of, and fluctuations in, marital satisfaction that cannot be estimated with two measurements. More assessments also mean that researchers can ask interesting questions about what variables predict initial levels of satisfaction versus the rate of change over time. For example, one replicated finding is that the personality characteristic of neuroticism is related to overall levels of satisfaction, but not to change of marital satisfaction over time, whereas marital problem-solving skills are related to change in satisfaction over time, but not to initial levels.

Understanding marriage requires research designs that capture the core phenomena of two people, over time, responding to one another and their circumstances and personal histories. Research designs have evolved greatly and away from looking at one spouse at a single point in time without regard to context. The newest era of longitudinal designs is helping us to see and represent the complexity in marriage, and no doubt that continued refinement of longitudinal designs will allow us to penetrate this important relationship even further still.

Loss

Loss is a central concept in the social and behavioral sciences and is relevant to a vast array of phenomena, including chronic illness, death and dying, relationship dissolution, injuries of various types, and assaults on the self (e.g., rape). Loss is a general concept that subsumes more specific concepts such as trauma and stress. Trauma refers to extreme psychological and physiological reactions to loss situations, such as those involving violence or the death of close others. Stress refers to an unpleasant state of emotional and physiological arousal that people experience in situations that they perceive as dangerous or threatening to their well-being. Loss or anticipated loss of something valuable is the key underlying condition in the experience both of trauma and stress.

Loss may be defined first as a reduction in a person's resources that involves a degree of emotional involvement. For example, people may not feel loss when they lose a drinking buddy with whom they talk about sports. However, the loss of a drinking buddy with whom they discuss intimate aspects of their marriage may be perceived as emotionally debilitating and as a major loss. In addition to the reduction of resources, a second and perhaps more basic part of the experience of loss is that of missing something. For example, a high school girl falls madly in love with a popular male classmate,

only to discover within a few months that he has many girlfriends who he is attempting to juggle. The girl may feel that something that was a part of her life is gone. Her great expectations are dashed, her hopes are lost, and her plans are ruined. Loss is a central, common experience in all human relationships. The present entry discusses characteristics of loss and its relevance to relationships.

Objective and Subjective Qualities

Loss may have both a subjective and an objective quality. Subjectively, a person's own attribution of meaning to a situation is critical to her or his response to the situation and coping with negative consequences. For example, some people may minimize the loss of a home to a tornado, focusing on the fact that no people were killed or hurt. Others may stress the importance of this loss, considering practical hassles, the loss of keepsakes, and the loss of a place containing many positive memories. These are subjective features of the experience of loss.

There also are important objective aspects to the experience of loss. When a person has lost mental functions in a brain injury or disease, including memory, the person may not necessarily perceive her or his situation as a major loss. An outsider, such as a neuropsychologist, however, may readily conclude that a major loss has occurred. Thus, it is essential to consider both subjective and possible objective markers of loss when considering whether a person has experienced a loss of some magnitude.

Fields Involved in the Study of Loss

The study of loss usually flows from work in many other subfields in the social and behavioral sciences, including: death and dying, traumatology, suicidology, dissolution and divorce, stress and coping, aging, violence and war, chronic disease, life-threatening accidents and injuries, homelessness, and economic hardship. Within these subfields, the concept of loss often is treated as an implicit underlying condition for the phenomenon under study. As an illustration, mental illness and substance abuse often are cited as central factors in a person's progression toward homelessness.

However, the earlier causal condition in that progression may have been the person's reactions to a divorce and romantic loss, and loss experiences in the family of origin and in the process of growing up and forming relationship bonds.

Loss and Adaptation

One of the most important concepts in the study of loss pertains to how people cope, and a key approach to coping is that of account-making, which often involves storytelling to a trusted confidant about one's loss and its implications, or emotional expression. Behind these approaches are ideas that emphasize the feelings of control, acceptance, and hope that are engendered by forming and expressing aspects of one's account, and the notion that the expression of pain nullifies the inability to take some constructive action associated with the loss that has led to the pain. By "opening up," whether sharing directly with others or simply writing in a diary, individuals can start the process of allaying the pain. In addition, creating an account may also start the process of doing something effective about the pain, such as seeking the advice or support of a caring other.

A popular but perhaps dubious idea is that in adjusting to loss it is important to achieve "closure." Closure does not occur in the sense that people stop thinking about, feeling about, or behaving in reference to major losses. People would have to lose their memory for closure to be a reality. Instead, a more effective perspective about loss and closure is to recognize, respond to (including learning the lessons of a loss), and remember losses. The goal of these activities is to achieve an acceptance of the loss and of the new realities for which adaptation is required. Survivors of loss need to adjust and continue on with life's important tasks while incorporating major losses into their identities and honoring and respecting the lessons of loss.

This active approach to grieving and adjustment may be stymied by a tendency to ruminate excessively about the loss and its consequences. Rumination, in the form of persistent commentary about the loss, also may cause supportive others to withdraw. Grieving people need to recognize what these untoward social effects of rumination may be and work toward a settled acceptance of the loss.

Research on people's ranking of types of losses suggests that major losses are perceived as relative. They are relative to other losses that a person has experienced and to losses experienced by others. By viewing losses on relative continua, people are better able to attribute meaning to them and adjust. As an example, a young person experiencing the end of a first love may feel suicidal in the wake of this loss. Later, when encountering another loss in love, this same person, now with more relationship experience, may be better able to handle the pain and know how to grieve and find support from caring others. Critical to long-term adjustment is learning the lessons of major losses. What, for example, has a person learned about how to make future close relationships stronger or be more careful before entering into them?

Relativity also occurs as people learn to view their losses in the context of human loss and that many types of loss (e.g., the sudden unexpected death of a child) are more devastating than others in their impact on our coping and meaning-making.

Major losses have cumulative effects. Whether in terms of psychology, physiology, or sociology, the impacts of major losses tend to accumulate over time. As with the prior example of relativity and relationship loss, a person may become cynical after several big disappointments in his or her love life. The person may turn to drinking or other forms of substance abuse. As a further consequence of this chain of events, the person may lose a good job, become financially destitute, and have to rely on family for help in future difficult circumstances. All told, the impacts over time may pile up and affect numerous dimensions of an individual's life. The idea of a pile up of losses is related to the cumulative impact principle. It is not uncommon in studying the ingredients of suicide to find that, just before committing suicide, a person may have experienced multiple major losses (e.g., the loss of a relationship, the loss of a job, a pet's death, a loss of health, an insult by a coworker). Learning to deal with each major loss separately and effectively, and recognizing that there will be relief at some point, is part of the developmental progression in becoming a thoughtful, mature person.

Major losses often contribute to new aspects of identity. When a couple has been married many years and one member dies, the surviving spouse

may have a major adjustment to make in terms of her or his identity because that person is no longer the husband or wife of a cherished partner. Rather, the person's identity is now that of a widow or widower, maybe reaching out as a single person searching for some new sanctuary for heart and mind. Developing an approach that both recognizes (and memorializes) the value of a past loved one, but that also recognizes the imperative to form a new identity and new relationships, seems to be central to effective adjustment.

Major losses involve adaptations related to a sense of control. Just as the idea of "missing something" is a core feature of loss, the perception of a loss of control is critical to most loss situations. Whether a person loses a relationship, a valued possession, an athletic skill, or an optimistic attitude about life, each loss reflects a feeling that he or she cannot control some part of life that previously was under control. People want and need a sense of control, and major loss reduces the feeling of control.

Loss in Relationships

Loss in the domain of relationships concerns dissolution and divorce, death of close others, and various forms of psychological injury, especially including infidelity and sexual assault. With the latter types of psychological injury, a person may feel that there has been a significant loss of trust in another person and possibly in people whom that person represents. All of the ideas and principles that have been discussed as germane to the general sense of loss also pertain to loss in the arena of close, personal relationships, both romantic and familial. People sometimes experience pileups of these losses (e.g., the death of a close other, such as a child, followed closely a divorce), the loss of control over key features of their lives (e.g., the marital or parental identity around which much life activity is structured), and the need to create new identities. If a person lives a long life, he or she may even have a history of these loss sequences in the realm of close relationships. People also usually cope best with relationship loss by developing accounts, confiding, and being open about their feelings of loss and pain.

A particularly important area of work that links loss and the endings of close relationships is referred

to as "children of divorce." This vibrant area of work focuses on both negative and positive effects for a child (including adolescents and people in their 20s) being in a family that experiences one or more divorces. Negative effects may include difficulties in interpersonal relations, schoolwork, employment, psychological and physical health issues, and confidence and trust in others. Positive effects may include growth as a person and in a family situation, becoming more mature and responsible about life's important missions, and gaining valuable perspective about the vices and virtues of close, romantic relationships. Although the negative effects of divorce are major and daunting for most children, research suggests that young people are better off when parents in highly conflicted or cold marriages end the marriages and do their best to take care of their children in their postdivorce, binuclear families.

Study of Loss as a Valuable Perspective

As has been documented in many literatures in the social and behavioral sciences, the effects of loss are pervasive. They occur in the dissolutions of or difficulties in close relationships, in post-traumatic stress disorders, in chronic grief reactions, in the loss of valued possessions, in becoming unemployed, in becoming homeless, in the loss of bodily functions after injuries or disease, and in aging.

A better appreciation of the aspects and dynamics of loss will continue to be one of the most important steps in the understanding of the human condition, both by the general public and by scholars of the social and behavioral sciences.

LOVE, COMPANIONATE AND PASSIONATE

Most people eagerly seek out love and believe that forming a successful love relationship is essential for their personal happiness. Although each individual is likely to experience various types of love and enter into a number of different kinds of love relationship over the course of his or her lifetime, scientists have tended to focus on two varieties of love that commonly occur in long-term romantic relationships. These two important types of love—stable, affectionate, *companionate love* and exciting, intense, *passionate love*—are linked with several significant personal, interpersonal, and societal outcomes, including marriage and long-term pair bonding, sex and reproduction, and social support. This entry discusses how companionate and passionate love are commonly defined and measured, reviews existing research about each type of love, and explores current steps scientists are taking to further our understanding of both love varieties.

Companionate Love

Definition and Measurement

Companionate love refers to a variety of love that is durable, fairly slow to develop, and characterized

by interdependence and feelings of affection, intimacy, and commitment. Various described as affectionate love, friendship-based love, attachment, and conjugal love, companionate love reflects the abiding affection, trust, and tenderness we feel for people with whom our lives are deeply interwoven and connected. Because it requires time to develop fully, this kind of love is often seen between close friends or romantic partners who have been together for a long time.

To study any variety of love, scientists must have a way of accurately measuring it. Researchers typically measure companionate love using self-report methods, which involve asking people to respond to questions about their feelings for a specific other person (e.g., a friend, dating partner, or spouse). There are two basic self-report methods available to scientists—single-item measures and multi-item scales. Single-item measures typically ask respondents to report on the amount of companionate love they experience for their partner (“How much warm, caring, affectionate love do you feel for your partner?”). These kinds of global single-item measures are easy to use and appear to be relatively valid. However, many researchers choose to use multi-item scales that have been developed specifically to measure the various elements of companionate love. On these scales, people answer a series of questions about how much intimacy, affection, respect, trust, commitment, and so on that they feel for their partner, and the researcher sums up their responses and calculates a total companionate love score.

Research

Research provides evidence that companionate love is an almost uniformly positive experience. For example, when people are asked to think about companionate love and identify its important features, they specify positive feelings like “trust,” “caring,” “respect,” “tolerance,” “loyalty,” “supportiveness,” and “friendship.” In addition, most men and women mention “trust,” “mutual respect,” “communication,” “sharing,” “honesty,” “affection,” and other positive emotions and experiences when describing the qualities and characteristics that they believe are important in a companionate love relationship. Similarly, when asked how they can tell the difference between loving (as opposed

to being in love with or merely liking) someone, the majority of people point to deeper levels of trust and tolerance as being characteristic of the state of loving another.

Research conducted with dating couples substantiates these findings and reveals that positive emotions are strongly associated with the amount of companionate love that the couples experience. Specifically, the greater the amount of companionate love that partners feel for each other, the more trust, liking, and respect they have for each other, the more contented they are with each other and with their relationship, and the more satisfying they find their relationship to be. In addition, companionate lovers tend to feel high degrees of emotional intimacy and warmth. They also report stronger feelings of sexual intimacy than do people who love less companionately; that is, the higher a couple's companionate love scores, the more the partners indicate being able to communicate openly and honestly with each other about sexuality. Thus, feelings of intimacy—emotional and sexual—are a hallmark of the companionate love experience.

Scientists also have found evidence that companionate love is strong and durable. Not only do companionate lovers report feeling extremely committed to each other and desirous of maintaining their relationships, but levels of companionate love tend to remain stable over time. In other words, it often makes no difference how long a couple has been together—the partners generally continue to report feeling the same high level of affectionate, companionate love for each other. Thus, companionate love appears to be relatively impervious to the effects of time. Indeed, companionate love may even grow stronger over time because it is based on intimacy processes (such as caring and attachment) that require time to develop fully. The ability to withstand—and perhaps grow stronger over—the passage of time is one feature that distinguishes companionate love from other, more fragile varieties of love, including passionate love.

Current Directions

Recently, researchers have begun to explore the biochemistry of companionate love. Two peptide hormones have come under scrutiny—oxytocin and vasopressin. These substances are released as neurotransmitters (peptides) in the brain and as

hormones from the pituitary gland, and they have multiple biological functions involving the kidneys and the cardiovascular and reproductive systems. For example, vasopressin increases blood pressure and facilitates the flow of blood through the kidneys, and oxytocin acts on smooth muscle cells and stimulates uterine contractions during childbirth and the release of milk during lactation. These hormones are associated with reproductive and caregiving behavior in nonhuman mammals. In addition, decreased oxytocin levels (along with other alterations in the endocrine oxytocin and vasopressin systems) have been observed in children diagnosed with autism, a developmental disorder characterized by severe social impairment and the inability to form interpersonal connections and lasting emotional attachments. Based on these two lines of evidence, some scientists have hypothesized that oxytocin and vasopressin are involved in the ability to form deep attachments to others and to experience feelings of affection, intimacy, and companionate love. As of yet, however, this supposition has not been thoroughly tested and therefore remains speculative.

Passionate Love

Definition and Measurement

Passionate love (also known as erotic love, romantic love, or the state of being “in love with” another person) is a much more fragile, sexualized, and emotionally intense experience than companionate love. In addition, passionate love tends to occur fairly rapidly (people can and do fall in love “at first sight”), and people who are passionately in love often idealize the loved one and become mentally preoccupied with thoughts of the partner and the relationship. Physiological arousal and its associated bodily sensations (such as racing pulse, heightened breathing, and “butterflies” in the stomach) represent another feature of passionate love. This variety of love also generally produces an exclusive focus on one particular individual; that is, it is unusual (although not impossible) for someone to fall in love with two people at once.

Passionate love has received much more scientific attention than have other varieties of love, including companionate love, for a number of reasons. First, passionate love appears to be a universal—and

universally sought-after—human experience. By young adulthood, most men and women report having been in love at least once, and researchers have found evidence that passionate love is actively sought and experienced by people living in all cultures all around the world. Second, passionate love has become an essential part of marriage in many human societies. Most people say they will not get married if they are not in love with their intended partner. Third, the absence or loss of passionate love seems to be a factor in relationship termination. Many people end their marriages or leave their romantic relationships when they fall “out of love” with their partners.

Like companionate love, passionate love can be measured using global, single-item, self-report measures (“How deeply are you in love with your partner?” or “How much passionate love do you currently feel for your partner?”) or multi-item scales that are designed to capture the important emotional, behavioral, and cognitive or mental features of the passionate love experience. A number of multi-item scales have been developed. The Passionate Love Scale constructed by social scientists Elaine Hatfield and Susan Sprecher represents one of the most complete and commonly used measures of passionate love currently available. The items were developed based on a review of previous theory about love, existing measurement scales, and in-depth personal interviews with couples, and they reflect the various components of the passionate love experience, including physiological arousal (“Sometimes my body trembles with excitement at the sight of _____”), emotional intensity and turbulence (“Since I’ve been involved with _____, my emotions have been on a roller coaster”), idealization of the beloved (“For me, _____ is the perfect romantic partner”), cognitive preoccupation (“_____ always seems to be on my mind”), and sexual attraction (“I possess a powerful attraction for _____”).

Research

Research reveals that passionate love is a highly emotional experience. However, whether the emotions associated with it are positive or negative depends to some extent on whether the love is reciprocated. *Required* (reciprocated) passionate love is an almost uniformly positive experience.

Men and women who are asked to identify the essential features of passionate love tend to cite many more positive emotional experiences—including happiness, joy or rapture, closeness, warmth, giddiness, and tenderness—than negative ones. Similarly, partners who are in love with one another report feeling positive emotions to a greater degree than negative emotions. In fact, jealousy appears to be the only negative emotion that is consistently associated with the experience of required passionate love; most people believe that jealousy is a natural part of being in love, and people who are passionately in love also tend to report feeling or having felt jealous at one time or another in their relationships. *Unrequited* or unreciprocated passionate love has many of the same positive emotional features as required passionate love, but at the same time it is a much more intensely negative experience. For example, people who have been in love with someone who did not return their affection generally report that the experience was emotionally painful and that it caused them to feel disappointment, suffering, jealousy, anger (usually directed at the loved one’s chosen partner), and a sense of frustration. In addition to these unpleasant feelings, however, unrequited lovers also tend to experience many pleasant emotions, including happiness, excitement, the blissful anticipation of seeing the beloved, and sheer elation at the state of being in love. Thus, passionate love—regardless of whether it is required—is a deeply emotional kind of love.

Scientists also have found evidence that passionate love has a relatively brief life span. Although feelings of passionate love initially may increase as a couple progresses from earlier to later courtship stages (e.g., as they move from casual dating to steady dating or engagement), research generally reveals that passionate love declines over longer periods of time in most romantic relationships. In fact, several investigations have found a strong negative correlation between the number of months that a couple has been dating and the amount of passionate love they report feeling for one another; specifically, the longer a couple has been together, the lower their passionate love scores. Among married couples, levels of passionate love tend to decline both over time and after major relationship transitions. For example, couples who make the transition from being childless to becoming parents

may experience a decrease in their levels of passionate love (although levels may rise once children leave home). Although passionate love is clearly more fragile than companionate love, it is important to keep in mind that these results do not imply that passionate love is completely lacking between partners involved in long-term romantic relationships. Rather, these findings simply provide evidence that the intense feelings and sensations characteristic of the first stages of “falling in love” tend to gradually stabilize over time.

Passionate love is also a more sexual kind of love than is companionate love. In fact, sexuality appears to be one of the hallmarks of the passionate love experience. People who are more passionately in love report experiencing higher levels of sexual excitement when thinking about their partners and also engaging in more frequent sexual activities with those partners than do people who are less passionately in love. In addition, interviews conducted with couples who are in love reveal that sexual activities, including hugging, “petting,” and “making love” or engaging in intercourse, represent one of the primary ways in which many of them express and communicate their feelings of passionate love. The motivational component of sexuality—sexual desire or sexual attraction—has a particularly strong association with passionate love. Research indicates that people consider sexual desire to be one of the essential features of passionate love; moreover, they believe that dating partners who are very sexually attracted to one another are more likely to be passionately in love than are dating partners who do not desire each other sexually. This belief appears to be accurate. Most men and women report experiencing sexual desire for the people with whom they are passionately in love, and the more passionately in love they are, the greater their feelings of sexual attraction. In summary, there is solid evidence that passionate love is a sexualized experience that is strongly associated with feelings of sexual desire or attraction for the partner, tends to result in the occurrence of sexual activity, and appears to be linked with sexual excitement.

Current Directions

Just as they have with companionate love, scientists have begun to explore the biochemistry of

passion with a particular emphasis on neurotransmitters (electrochemical messages released by neurons or the cells of the nervous system). Although a number of different types of neurotransmitters exist, the monoamines (in particular, serotonin, dopamine, and norepinephrine) have received the most attention due to their strong relationship with mood and generalized arousal. Several scholars have speculated that passionate love is associated with high levels of dopamine and norepinephrine and low levels of serotonin because of similarities between the experience of being in love and the action of those particular monoamines. For example, people who are passionately in love often report feelings of euphoria and exhilaration coupled with heightened energy, loss of appetite, and sleeplessness. These same experiences are associated with increased concentrations of dopamine in the brain. Similarly, people who are in love report focusing on specific events or objects associated with the beloved and remembering and musing over things that the beloved said or did. Increased levels of dopamine are associated with heightened attention, and increased levels of norepinephrine are associated with enhanced memory for new stimuli. In addition, people in the throes of passionate love often report thinking about the loved one obsessively, and low levels of serotonin are implicated in the type of intrusive thinking that is associated with obsessive-compulsive disorder.

The similarities between the experience of being in love and the psychophysiological effects of dopamine and the other monoamines may be coincidental. However, one research study demonstrated that a group of healthy people who were in the early phases of “falling in love” had approximately the same level of serotonin as did a group of people who had been diagnosed with obsessive-compulsive disorder. In addition, the serotonin levels of both of these groups of people were significantly lower than those of a control group of healthy individuals who were not currently in love. Researchers also have discovered that people who are passionately in love show increased activity in dopamine-rich areas of their brains when they gaze at a photo of their beloved. Although additional research is needed, these findings certainly suggest that the experience of passionate love may be associated with brain neurochemistry.

Conclusion

Virtually all theorists who have written about the topic of love agree that love is intricately associated with the quality of human life, that different varieties of love exist, and that at a minimum there are two commonly experienced types of love—a passionate variety that is intense, emotional, fragile, and sexually charged, and a companionate variety that is durable, stable, and infused with warmth, intimacy, affection, and trust. These theoretical suppositions are largely supported by empirical research on people's beliefs and conceptions of love and their reports of their ongoing experiences in romantic relationships. Of course, it is important to recognize that other types of love also exist and are experienced by men and women over the course of their lifetimes, ranging from the vague liking felt for casual acquaintances to the intense devotion often experienced for family members, children, and beloved pets. An important task for future researchers is to determine the unique features and consequences of these other important varieties of love.

LOVE, PROTOTYPE APPROACH

What is love? This question, posed in Shakespeare's *Twelfth Night*, is one that also has intrigued social scientists. In recent decades, many definitions and theories of love have been generated. In addition, research has been conducted to illuminate how ordinary people understand this concept. The purpose of this entry is to describe how ordinary people think about love (in general, as well as specific kinds of love), address whether women and men hold different views of love, and briefly discuss relationship implications of people's conceptions of love.

Most of the research on ordinary people's conceptions of love has been conducted from a prototype perspective. According to Eleanor Rosch, the founder of prototype theory, many of the concepts that are used in everyday language lack explicit, precise definitions. Instead, such concepts are

organized around their clearest cases, or best examples, which Rosch referred to as *prototypes*. For example, when asked to list types of fruit, most people mention apples and oranges—these are the prototypical cases. Figs and papayas are considered less prototypical. Tomatoes and avocados lie at the periphery of the concept and shade into the neighboring category of vegetables. Rosch demonstrated that the organization of concepts in terms of prototypes influences how people process information. For example, people are faster to confirm that a robin is a kind of bird than that a chicken is a kind of bird.

Other researchers subsequently explored whether more abstract concepts, such as love, might also be structured as prototypes, such that some kinds of love are seen as more representative of the concept than others. In one series of studies, people were asked to list the attributes or features of the concept of love. Features such as honesty, trust, and caring were listed with the highest frequency. Characteristics such as dependency, sexual passion, and physical attraction were listed relatively infrequently. In all, there were 68 features listed by more than one participant, suggesting that ordinary people have rich, complex knowledge of this concept. In follow-up research, other people rated these features in terms of prototypicality (goodness of example). Features such as trust, caring, and intimacy were considered central to love. These features map onto what social psychologists refer to as companionate love—a kind of love characterized by friendly affection and deep attachment to someone. Features such as sexual passion, gazing at the other, and heart rate increases received the lowest ratings. These features map onto social psychologists' definitions of passionate love. This prototype structure was confirmed using a variety of methods. For example, there was evidence that prototypical features of love, such as trust and caring, were more likely to be recalled in memory tests than were nonprototypical features, such as physical attraction and sexual passion.

The initial studies on the prototype of love were conducted in British Columbia, Canada. In subsequent studies, other researchers tested whether similar findings would be obtained on the East Coast of Canada and on the West Coast of the United States, using university students and

members of the public as participants. There was a remarkable degree of consistency across studies. Five features of love were listed frequently and received the highest prototypicality ratings in each of these data sets: trust, caring, honesty, friendship, and respect. The feature, intimacy, also received high ratings in each data set. Thus, at least within North America, among university students and nonstudents alike, there appears to be consensus that it is the companionate features of love that are seen as capturing the true meaning of the concept. Passionate features are seen as part of the concept, but on the periphery.

Prototypes of Specific Types of Love

The next development in prototype analyses of love was to focus on types of love, rather than the concept of love in general. The most extensive prototype analyses have been conducted on romantic love, "being in love," and compassionate (altruistic) love. Other varieties of love, such as familial kinds of love (e.g., maternal love, brotherly love), friendship love, platonic love, and sexual love, have received more limited attention. These investigations have revealed that the features of the different varieties of love tend to overlap with the features listed for the concept of love in general. More specifically, features that are prototypical of love also are generated for specific kinds of love and rated as high in prototypicality. For example, features such as trust, caring, and honesty—which are central to love in general—are also rated as highly prototypical of romantic love. In addition, people list features such as candlelit dinners, going for walks, and kissing, but these are considered nonprototypical. Similarly, for the concept of compassionate love, features such as trust, caring, and honesty are regarded as prototypical. People also generate features such as make sacrifices for the other and put the other ahead of self, but these are regarded as nonprototypical.

Other research in this vein has examined which kinds of love are considered most prototypical of the concept of love in general and which are considered nonprototypical. Similar to the findings for features of love (discussed earlier), companionate kinds of love, such as familial love and friendship love, receive the highest prototypicality

ratings. Passionate kinds of love, such as romantic love, passionate love, and sexual love, are considered nonprototypical. Thus, research on the features of love and research on types of love point to the same conclusion—namely, that ordinary people regard companionate love as the essence of love; passionate love is considered less central.

Gender Differences/Similarities in Prototypes of Love

Do women and men hold different conceptions of love? Research has been conducted in which women and men are presented with descriptions of various prototypes of love (portraying companionate and passionate kinds of love) and are asked to rate how well these prototypes reflect their own view of love. Consistent with research on love experiences, men are more likely to think about love in terms of passion and romance than are women. Women are more likely to think about love in terms of its companionate varieties (e.g., familial love, friendship love, affection). However, these gender differences are not large—both women and men rate the companionate love prototypes highest (although women's ratings are higher than men's), and both women and men rate the passionate love prototypes the lowest (although men's ratings are higher than women's). Based on these findings, it has been concluded that women and men actually are more similar in their conceptions of love.

Relational Implications

So far, the relational implications of people's conceptions of love have not received extensive attention. However, the limited research to date suggests that people who conceptualize love in terms of its prototypical cases (i.e., a companionate conception of love) report greater relationship satisfaction as well as greater love and liking for their partner than those who think about love in terms of its nonprototypical cases (i.e., a passionate conception of love). Further, thinking about love in terms of its prototypical, rather than nonprototypical, cases is associated with relationship longevity.

In conclusion, the answer to the question "What is love?" is that, in the minds of ordinary people, love is a multifaceted, complex concept. At its core are companionate features such as trust, caring, and honesty. Passionate features such as romance and sexual attraction also are part of the concept, but reside on the periphery.

LOVE, TYPOLOGIES

If one or more types of love or any similar construct can be described in a systematic way, we can say that it forms a *typology* or categorization. In fact, there are many types of love, and this entry deals with how these various types are organized into typologies, primarily typologies of romantic love. A typology of romantic love is a description that divides love into two or more qualitative categories. Each category of a typology has its own verbal description, and the category may have properties that can be measured. The differences between the categories can in most cases not only be given verbal descriptions, but also quantitative descriptions. Thus, categories within a typology may be discriminated from one another and therefore compared with each other. Further, typologies may be compared with other typologies.

During the past few decades, several typologies of romantic love have been developed. The first relevant social-psychological scientific work distinguished loving from liking. The next approach proposed two types of romantic love: passionate and companionate. From the 1970s to the present, typologies in most cases became more complex, with each new one generally proposing several categories.

It may be helpful to contrast a typology of love with a process theory of love. As an example of the latter, Arthur and Elaine Aron proposed that people have a basic need to grow or expand the self. As life's journey proceeds, self-expansion may include such things as obtaining physical possessions, attaining occupational success, and forming close relationships. For example, falling in love provides a pleasurable, rapid expansion of the boundaries of self. As two people fall in love, they each metaphorically expand the self to include the other, creating a new entity called "us." The self-expansion theory, as applied to romantic love, is quite versatile in generating testable predictions. It is a theory about the process of change in the self in response to love or how love *proceeds*. A typology of love is rather about types or categories of love or what love *is*.

The following are some of the most researched typologies of love. The concluding section of the entry provides some comparisons of the typologies, as well as a few applications of the typologies to couples in real life.

Passionate and Companionate Love

Most people can relate to the idea of falling head over heels in love. In this state, the lover is at first totally absorbed with the loved one. Thoughts of the beloved intrude frequently, the heart may race at the sight of the loved one, and the couple attempts to be together as much as possible. This describes in capsule form the concept of passionate love. Additionally, there is usually sexual desire and perhaps intense love-making. However, it is possible to fall passionately in love with and have sexual desire for someone without the other person's awareness. Such a state is called *unrequited love*. A passionate love affair requires some reciprocity on the part of both persons. Lust is a

strong sexual "wanting," but it is typically not equated with love, even passionate love.

The first flush of falling in love cannot endure forever. Eventually the intensity must cool because other areas of life require attention. It is common for a relationship to evolve into companionate love, the type of love that involves strong affection, trust, and closeness. This state is also called *friendship love*.

Both types of love are readily recognized within our cultures. Early theorizing viewed passionate love as coming first. If a relationship endured, passionate love evolved into companionate love. More recent thinking and research has shown that one type of love does not have to succeed another; couples can have both types of love at the same time. There are research data indicating that young couples want friendship with their partner as well as strong passion. Relatively strong passion may be maintained indefinitely for many couples across the years.

A balanced mix of friendship and passion appears to be the modern ideal. People want to "love" their partners (friendship) and be "in love" with them at the same time (passion). Theorists now agree that the early hot embers of passion need not inevitably cool into quiet, unexciting companionate love. It is possible to have both passion and friendship and maintain both over time.

Love Styles

At first thought, the passionate/companionate typology appears to exhaust the possibilities for romantic love. Such is not the case. One typology proposed six different types (or styles) of romantic love. These love styles may be considered as attitudinal categories of romantic love. The Love Attitudes Scales developed by Clyde and Susan Hendrick measure how much of each love style a person possesses, and each person is given a score on all six styles. Usually, one or two styles will be dominant, so that person can be assigned to one or two love categories.

The six love styles have interesting names and characteristics. The *eros* style is similar to passionate love. An eros lover has definite preferences for a partner's physical characteristics and may fall in love at first sight. Eros desires deep and rapid intimacy,

both emotional and physical. In contrast, the *ludus* style treats love as a game to be played for fun, preferably with more than one partner at a time. Commitment and deep intimacy are avoided. Ludus has no preferred physical type. At its best, ludus is a playful love style with no intent to harm a partner emotionally. The *storge* style is closest to companionate love. Storge is friendship love: steady, reliable, and trustworthy. The intensity of eros and the detachment of ludus are missing from storgic love. The *pragma* style is practical love. A pragma lover looks for a desired list of traits in a partner and is content when a match is found. Perhaps computer dating and mating (with a shopping list of qualities desired in a partner) most aptly describes pragmatic love. The *mania* style encompasses both possessiveness and dependence. The manic lover alternates between emotional highs and lows and is possessive, jealous, and prone to dramatic breakups and reconciliations. Manic love is both ecstatic and painful. The *agape* style represents “gift” love. Agapic love is freely bestowed and asks nothing in return. The agapic lover is focused on the welfare of the partner. In the real world, there are few pure cases of agape because enduring love between partners depends strongly on reciprocity in word and deed, rather than love flowing in just one direction. However, our last typology will be an enlarged version of agape named compassionate love. It includes both romantic love and love of “humanity.”

Much research supports the validity of the typology as a set of six different approaches to romantic love. There are gender differences in some of the styles. Men typically score higher on both ludic and agapic love than women, and women score higher than men on storgic and pragmatic love. Eros is associated positively with relationship satisfaction, and ludus is negatively associated with relationship satisfaction.

Prototypes of Love

A prototype is the best example or best set of defining features of some concept. A prototype is not rigidly fixed in definition and will usually have fuzzy boundaries. This approach examines people’s mental *representations* of an object, such as love, instead of studying the object directly. Several researchers have taken a prototype

approach to the study of love. Early work attempted to distinguish between features of love and features of commitment. This research tradition has people list the characteristics of love that occur to them. Results have revealed features of both passionate and companionate love, and companionate love was clearly rated as most typical of the meaning of love. Features named consistently included caring, trust, respect, honesty, and friendship. In fact, passion and sexuality were ranked quite low on the list of defining features.

This research concerned “love in general.” Later research explored a prototype analysis of romantic love. Results showed that passion and sexual attraction were now listed as central features, but these features still ranked below such features as trust, happiness, and honesty, along with the companionate features.

Why does passion seem relatively less central in prototype research? More than 60 attributes of love have been named with some frequency. Other researchers performed a complex statistical analysis of these many features and discovered the 60-plus attributes could be sorted into three dimensions: passion, intimacy, and commitment. However, the features that defined intimacy were rated as more central to the meaning of love than the features that defined passion or commitment. The research suggests that intimacy is intrinsically more important than passion in defining love.

The methods used to study prototypes of love consistently show that companionate love is the most general type of love. This outcome makes sense because companionate love applies to all sorts of relationships (e.g., parents, children, friends). However, this approach basically reduces romantic love to companionship plus passion. There may be something about the method used in these studies that reduces the apparent power and importance of passion. Other theorists have argued that passionate love is universal across all cultures. It may be that when people are asked to make a list of the features of love, they are reluctant to list passion or lust at the top, although these might on occasion occur to them right away. It is clear that companionship is also a central component of romantic love, and it may be universal as well. In fact, throughout history, people in some cultures have gone through a betrothal period during which a couple becomes acquainted, perhaps developing

some companionate/friendship features before physically consummating their marriage. Prototype research reduces the relative importance of passionate love. The relative importance of passionate and companionate love features will be clarified by further research.

Love Triangles

The previous section noted that the prototypes research approach uncovered three basic components of love: intimacy, passion, and commitment. Another researcher, Robert Sternberg, working independently of the prototype tradition, proposed the same three components. If one visualizes a triangle with the three vertices labeled intimacy, passion, and commitment, one can immediately visualize a “triangular theory of love.” One interesting aspect of this approach is that the three dimensions can be mixed in different amounts, and each mixture yields a different type of love.

This conception can best be understood by assuming that a given component is either completely present or completely absent. The mix of present/absent yields a typology of eight kinds of love:

1. Nonlove: absence of all three components
2. Liking: intimacy without passion or commitment
3. Infatuated love: passion without intimacy or commitment
4. Empty love: commitment without intimacy or passion
5. Fatuous love: passion and commitment (no intimacy)
6. Companionate love: intimacy and commitment (no passion)
7. Romantic love: intimacy and passion (no commitment)
8. Consummate love: presence of all three components

Perhaps most people would say that only the last three types (6, 7, and 8) represent “real love.” Further, when companionate love overlaps romantic love, all three components occur, yielding consummate love. As noted earlier, there is evidence that couples want both friendship and passion (or

companionate and romantic love, in the terminology of the triangular typology). Thus, most serious couples want consummate love. Because intimacy is high for liking (type 2) and for the three types of “real love,” it is easy to see that intimacy underlies a wide range of close relationships. The prototype research tradition suggested that intimacy and commitment may be more important than passion for a loving relationship. A *romantic* loving relationship is incomplete without passion, but passion alone is only infatuation. Even passion with commitment but no intimacy is merely “fatuous love” (type 5). In this way, the seemingly simple eightfold typology, composed of three basic elements, can account for a wide range of the types of love relationships.

Compassionate Love

Compassionate love is a single type of love. It is most similar to the love style of agape, but is much broader in scope. The scholars who proposed this type of love viewed it as an attitude toward several types of other people: a romantic partner or friend, close others generally (e.g., family), and strangers or all of humanity. Compassionate love is focused on care and concern for another and is oriented toward empathic understanding, supporting, and helping the other, especially in times of need.

The broad range of persons encompassed by this type of love required three slightly different types of rating scales: one for close others, another for strangers or humanity in general, and the third specifically for friends or a romantic partner.

Research showed that compassionate love is a viable category of love. This type of love was related positively to empathy, helpfulness, social support, volunteer activities, and religiosity, depending on who was rated. For example, when a specific romantic partner or friend was the focus, only social support was associated with compassionate love. When the focus was close others or strangers/humanity, social support, volunteerism, and religiosity were all related to this type of love.

Other interesting results were found. Women were higher than men on compassionate love. The average love ratings were higher for close others and romantic partner/friends than for strangers/humanity, and the highest compassion score was for a romantic partner.

As the world moves toward becoming a “global village,” the concept of compassionate love acquires an urgency for full understanding and implementation. The research data indicate that people show more compassion for specific and close others than for strangers. Much more research is needed, but one application is clear. Somehow, people must learn to extend compassionate love more fully to strangers and humanity generally. Quite simply, human survival may depend on it.

Typologies in Real Life

The typologies described in this entry offer several different ways to view romantic love. Love may be companionate, passionate, or both. Or love styles may be passionate, companionate, game-playing, practical, possessive and dependent, or giving. The prototypic kind of love may be companionate, with passion included when love is of the romantic variety. Love may be composed of intimacy, passion, and commitment and may reveal itself in eight different guises. Or love may be an outpouring of attention and support to a romantic partner, close others, or humanity as a whole.

These different views of love are really more similar than they are different. Two guiding themes that appear in most of the love typologies are “passion” and “companionship.” Research has shown that young couples in the Western world describe their love partner as their “best friend” and that for older couples both passionate and companionate love are highly related to satisfaction with their relationships. Other research that compared several of the most frequently used measures of love found that, indeed, when these measures were analyzed together, the most dominant themes that emerged were passion (accompanied by intimacy and similar constructs) and caring (also accompanied by intimacy and an absence of negativity).

Does this mean that there are really only two types of love after all, passionate and companionate? Probably not! Given the complexity of our human species, and the many ways in which such factors as gender, age, race/ethnicity, culture, socioeconomic status, and a myriad of other factors affect the emotions, thoughts, and actions of a romantic couple, it is unlikely that one or two or six or eight types of love could capture love’s infinite variety.

For example, suppose that a married couple has young children, and both parents have demanding jobs. These parents want to work hard and parent well, and they view themselves as a team. They are each other’s best friends, and they both participate wholeheartedly in their companionate marriage. Two other people, each reconciled to being alone because they had not yet found the “right person,” find themselves together in the most emotionally intense and physically exciting relationship they have ever experienced. They thought passion would forever elude them, but it did not. Yet another couple has experienced both passionate and companionate love in their few years together, but a life-threatening illness in one of the partners has required them to reach into their deepest reserves of caring and compassion so as to comfort and console each other as they face the biggest obstacle their relationship has ever encountered. Their evident agapic love for each other inspires the people who know them. Another couple, older and partners for many years, decide that they will no longer buy presents for each other except under unusual circumstances. They both dislike shopping and don’t want to distress themselves or each other by doing that. They have also agreed to take the money they would have spent on presents and contribute it to a charity they both regard highly. Are these partners companionate, agapic, compassionate, or some combination of these or other types of love? Each couple portrays a somewhat different picture of love, yet each set of partners is connected by a bond that can best be called love.

The love typologies presented are representative of ideas about love, but are certainly not exhaustive of the ways in which love may be expressed. At some level, love is shown by what is *not* expressed as much as by what *is* expressed. For example, closeness without negativity, as noted previously, is important in love. So also is the absence of game-playing, exploitation, and disrespect. Indeed, love and respect have been put forth as key qualities that romantic partners seek from one another. Love may be necessary but not sufficient for a romantic relationship to endure, yet few of us would want to be in such a relationship without love. Humans seek connection, and love is one of connection’s most profound forms.

LOVE, UNRECIPROCATED

Most people believe that love is one of the most significant events that a human being can experience. Thus, it is not surprising that the majority of men and women spend a good portion of their adolescence and adulthood seeking a partner with whom to fall in love and form a long-term, committed relationship. The eagerness with which many people search for love is certainly understandable when one considers the growing amount of scientific evidence indicating that love is associated with a variety of positive outcomes. For example, partners in love relationships report feeling intimacy, contentment, and satisfaction; experiencing passion, joy, and excitement; and providing and receiving significant levels of emotional and social support from one another. All of these experiences, in turn, can enhance and promote the partners' psychological and physical

well-being. Love between two people whose feelings are mutual and reciprocated—that is, who love or are in love with each other—can be a fulfilling and rewarding experience. But what if one person loves another who does not return his or her feelings? What if the object of one's affection spurns one's romantic overtures? This entry considers the topic of *unreciprocated love*, with an emphasis on defining the experience and considering its frequency and consequences.

Definition

Unreciprocated love (also known as *unrequited love*) refers to romantic love that is not mutual or shared by two people; it is defined as the experience of loving or feeling strong romantic attraction toward another person who does not return that particular feeling. Scholars who study this phenomenon point out that it is not necessary for people who are the objects of unreciprocated love to be actively hostile toward or openly rejecting of their lovelorn admirers; sometimes they may feel quite affectionate toward those individuals or the two may share a long history of friendship. The objects of affection may even have experienced some initial attraction to their admirers or were involved in a romantic relationship with them; however, at some point, their feelings changed or failed to develop into the deeper passion felt by their would-be suitors. The key issue is that, regardless of their personal history or the current state of their relationship, the objects of unreciprocated love do not feel the way their admirers do—they do not feel the same kind of passionate attraction, longing, and intense desire for intimacy that their admirers feel for them.

How Common Is Unreciprocated Love?

There is little research that can provide a definitive answer to the question of how often unreciprocated love occurs. This is partly due to the fact that some people are likely to experience unreciprocated love fairly frequently, whereas others may never experience it at all. However, studies generally indicate that most men and women (close to 95 percent) have found themselves on both sides of unreciprocated love—that is, they have loved in

vain and have been loved in vain by another—by the time they reach their late teens or early 20s. Thus, unreciprocated love appears to be a common life event. Interestingly, women report having been in the “rejector” role more often than men, and men report having been in the “would-be lover” role more often than women. Some researchers speculate that this may stem from the fact that men tend to fall in love more readily than women (and therefore find themselves more frequently in the position of would-be lover), whereas women tend to fall out of love more readily than men (and consequently find themselves more often in the role of rejector).

Consequences of Unreciprocated Love

Although folk wisdom (actually, Victorian poet Alfred Tennyson) tells us that “it is better to have loved and lost than never to have loved at all,” the reality is that unreciprocated love can be, and often is, an extremely unpleasant experience for both the unrequited lover and the object of his or her affection. Autobiographical accounts provided by would-be lovers and rejectors reveal that negative emotion is the most common consequence of unreciprocated love. For example, would-be lovers often report that their unreciprocated passion caused them to feel intense pain, suffering, heartbreak, and disappointment. Additionally, they report having experienced extreme bouts of jealousy and anger, which were often directed at their beloved’s chosen partner. Frustration and fears of rejection are also common consequences of loving another person in vain. However, unreciprocated love is not an entirely unpleasant experience for the lovelorn suitor. In addition to the unpleasant emotions they experience, unrequited lovers also report a variety of pleasant emotional outcomes. For example, happiness, excitement, the blissful anticipation of seeing the beloved, sheer elation at the state of being in love, and other positive emotions are commonly reported by most would-be suitors. Many also look back on their unreciprocated love experiences with fondness and an appreciation for the opportunity they had to experience passion and other intense emotions.

Rejectors, however, do not usually experience positive outcomes. Although some rejectors report

feeling flattered by the attention of their admirers, most report feeling annoyance at having to endure unwanted advances, discomfort and guilt at having to deliver rejection messages, and a host of other negative emotions, including anger, frustration, and resentment. The intensity of these negative reactions depends in part on the behavior of the would-be lover. For example, a person dealing with an extremely persistent suitor who continues in his or her pursuit despite repeated requests to cease is far more likely to experience rage, hostility, disgust, and other strong negative emotions than is a person whose unwanted suitor is content to love unobtrusively from afar.

In summary, unreciprocated love is a common occurrence that primarily produces emotional distress. Unfortunately, there is no easy way to recover quickly from the experience of unreciprocated love. Time is perhaps the only cure.

LUST

Lust (also called *sexual desire*, *sexual interest*, or *sexual attraction*) is the motivational component of human sexuality. Lust is experienced as an interest in sexual activities, a drive to seek out sexual objects, or a wish, need, or craving for sexual

contact. Although people can feel and express a variety of sexual responses within their interpersonal relationships, lust appears to play an especially important role in the attraction process and in the early stages of romantic relationships, particularly as people fall in love. This entry distinguishes lust from other related sexual responses, examines its origins and correlates, and explores its consequences in ongoing, romantic relationships.

Conceptualization and Measurement

The experience of lust is presumed to be distinct from other sexual responses, including *sexual arousal* (which involves physiological arousal, genital excitement, and the subjective awareness of genital and physiological arousal), *sexual activity* (which consists of overt sexual behaviors, such as masturbation, “petting,” or intercourse), and *sexual feelings* that are associated with these responses (such as satisfaction, fulfillment, and pleasure). Of course, these sexual responses frequently co-occur and thus are experienced relatively simultaneously. For example, the sight of an attractive person may cause an individual to feel an urge to engage in sexual activities with that person and to fantasize about what sex with that person might be like; these lustful feelings may subsequently produce physiological arousal and genital excitement. The subjective awareness of this sexual arousal may, in turn, increase the desire to engage in sex with the other person and may result in actual sexual behavior. After orgasm or sexual satiation, the individual’s body will return to its prearoused state, and sexual desire also may decrease. Thus, the interrelationship among desire, arousal, and activity is complex; each response can influence the others, and they may co-occur. Researchers nonetheless consider each experience to be a separate component of the human sexual response cycle.

Lust or sexual desire varies along at least two dimensions. The first dimension is quantitative and concerns the magnitude of the desire that is experienced. Both the intensity and the frequency with which lust is experienced can vary within one individual over time. For example, a person may experience sexual desire on numerous occasions one week, only to feel no desire at all the following

week; similarly, he or she may possess a powerful sexual urge at one point in time and then a much less-intense sexual need at another. In addition, people differ in the chronic amount of lust that they experience; some individuals generally have a low level of sexual appetite, whereas others habitually experience high levels of desire.

The second dimension along which sexual desire varies is qualitative and concerns the specificity of the desired sexual goal and sexual object. A person in the throes of lust may wish to engage in a specific sexual activity (e.g., intercourse) with a specific other individual (e.g., the partner). Alternately, he or she may simply have an urge to engage in some form of sexual activity with an unspecified partner; in this situation, both the sexual goal and the sexual object are diffuse rather than specific.

Because lust is a subjective, internal experience, rather than an overt physical or behavioral event, scientists generally measure it with self-report methods. These involve asking people to respond to questions about their feelings in general or for a specific other person (e.g., a dating partner or spouse). People might rate their overall level or amount of desire (“How much sexual desire or lust do you experience?”), the frequency of their sexual urges (“How often do you experience sexual desire or lust?”), or the intensity or degree of their sexual attraction to their romantic partner (“How intensely do you desire ____ sexually?” or “How sexually attracted are you to ____?”).

Causes and Correlates

Research indicates that lust is associated with a variety of factors. Some of these factors involve the partner or the desired object. Certain partner characteristics appear to excite desire more than others. For example, most people consider an attractive appearance, good overall personality, sense of humor, kind disposition, self-confidence, and intelligence to be particularly sexually appealing attributes for someone to possess. In addition, individuals with symmetrical facial features, an average body weight, and a sex-typical distribution of body fat or “shape” (for women, an hour-glass shape; for men, a straighter shape) are typically considered sexually desirable.

Although variables associated with the partner are undoubtedly important, the majority of researchers interested in understanding the dynamics of lust have focused on person or individual-level factors. For example, men and women with serious physical illnesses, including cancer, diabetes, and Parkinson's disease, typically report decreases in their overall level of sexual interest following the onset of their illness, and their desire levels are usually lower than those reported by healthy adults. Depression and other forms of major mental illness are also associated with decreased desire, as is excessive and chronic use of alcohol and other recreational drugs. Another person factor that is related to the ability to experience lust is age. Although most healthy older adults continue to experience desire and other sexual responses, research reveals that both men and women report a decline in their level of sexual interest with advancing age.

One of the most important individual-level factors that scientists have identified is the hormone *testosterone* (an androgen, or masculinizing hormone, that is synthesized primarily in the testes and the adrenal cortex, and to a lesser extent in the ovaries). A growing body of research reveals that the ability to experience lust is associated with the action of this particular hormone. For example, levels of testosterone are positively correlated with self-reported levels of sexual desire and frequency of sexual thoughts in healthy adults. That is, the higher the level of active testosterone in a person's bloodstream, the more sexual desire he or she reports experiencing and the more often he or she indicates having sexual thoughts. In addition, people who have undergone surgical procedures (such as removal of the adrenal glands) that result in a sudden decrease in their levels of testosterone report decreased feelings of sexual desire. Similarly, treatment with synthetic steroids that suppress the synthesis of testosterone produces diminished sexual desire. This result has been observed in three groups of individuals: male sex offenders who are treated with the anti-androgenic substances cyproterone acetate or medroxyprogesterone, cancer patients who receive anti-androgenic treatment in combination with surgical castration as part of their therapeutic regimen, and people who are given androgen antagonists to treat androgen-dependent hair and skin problems such as acne,

alopecia, hirsutism, and seborrhea. In all three groups, treatment often is associated with a reduction in sexual desire, fantasies, and urges. Finally, the administration of testosterone has been noted to result in an increase in the strength and frequency of sexual desire among men and women complaining of diminished sexual interest, men with hypogonadism or eugonadism (medical conditions that result in abnormally low levels of testosterone), and women with androgen deficiency syndrome (an androgen deficiency caused by chemotherapy, hysterectomy [removal of the uterus], or oophorectomy [removal of the ovaries]). These findings suggest that some minimum level of testosterone is necessary for the experience of lust.

Are Men or Women More Lustful?

Biological sex or gender is another individual-level factor that appears to be associated with the experience of sexual desire. Certainly the question of whether men or women are the more "lustful" sex has long interested scientists. Current research suggests the following conclusions. First, both sexes, particularly in adolescence and young adulthood, feel sexual desire fairly frequently. Second, men typically report experiencing sexual desire more often than do women. Third, when asked to rate their level or amount (as opposed to frequency) of desire, men tend to report a greater amount than do women. Thus, although lust is a common experience for both sexes, at first glance, men appear to be more lustful than women. However, women experience greater variation in hormone levels than do men and, as a result, are particularly prone to fluctuations in desire. For example, many women report increases and decreases in their feelings of sexual interest as their bodies go through the various phases of the menstrual cycle. Pregnancy, menopause, and other hormonally mediated life events may also alter a woman's levels of sexual desire. Consequently, in any given span of time, there will be occasions when a woman's intensity or frequency of desire exceeds that of her male counterpart. There will also be times when his desire exceeds hers and times when the two experience roughly equal frequencies or levels. Thus, the question of which sex is more lustful is a difficult one and can only be answered by future

research that examines the pattern of men's and women's levels of desire over time.

Relational Consequences

Lust appears to play a key role in the process of romantic attraction and relationship development. Feelings of sexual desire for another individual may propel a person to initiate interpersonal contact, thus leading to the beginning of a romantic relationship. Intense sexual attraction also is associated with, and may even produce, feelings of passionate love. In fact, most people believe that sexual desire is part and parcel of the state of being in love. For example, when asked to describe the difference between "being in love with" and "loving" a romantic partner, the majority of men and women spontaneously mention sexual desire as creating the essential difference between the two experiences (and as being much more reflective of the state of being in love than of loving). Similarly, when asked to identify the basic features or ingredients of passionate love, most people list sexual desire or lust (along with other positive experiences). Moreover, dating partners who report a high level of sexual attraction for each other tend also to report being passionately in love, whereas partners with lower levels of desire for one another are correspondingly less "in love" (although they may like or love each other a great deal).

Although sexual attraction is often present during the initial stages of a romantic relationship, particularly when the partners are falling in love with one another, it may not remain at the same high level throughout the entire relationship. Over time, partners commonly experience decreased sexual desire for each other. Because the ability to experience lustful feelings is associated with the partners' physical and mental health, age, hormonal variations, and other factors (including the loss of novelty that occurs as partners become habituated to each other), a reduction in their sexual desire is to some extent inevitable and does not necessarily mean that their relationship is dysfunctional. However, a sudden dramatic loss of desire or a sustained feeling of sexual repulsion

for the partner may sometimes indicate that some degree of emotional conflict or interpersonal difficulty exists in a couple's relationship. If that is the case, treatment administered by a qualified therapist may prove beneficial. Clinical research suggests that the most effective treatment programs for sexual desire problems are those that combine traditional cognitive-behavioral techniques that target the low-desire partner (such as sexual fantasy exercises and cognitive restructuring) with techniques that target the interpersonal dynamics between the partners, including training in verbal communication skills, emotional communication, and sexual intimacy.

M

MAINTAINING RELATIONSHIPS

Scholars often have insights about how people maintain their close relationships, as many entries in this volume indicate. However, the purposeful, direct examination of various factors that specifically address how people maintain their relationships is a recent enterprise. Still, a substantial number of scholars have now converged on behaviors directly relevant to the domain of relationship maintenance.

This entry focuses on research that has directly sought to reveal how people maintain their close relationships—emphasizing both stability and quality. First, *relational maintenance* is defined. Next, two metaphors that several scholars have used to portray maintenance processes—centripetal force and centrifugal force—are described. This entry concludes by observing that maintenance processes occur at several levels, from the individual to the cultural.

Defining Relational Maintenance

Five definitions of *relational maintenance* have been offered in the literature. (1) Perhaps the most obvious definition concerns *stability*, or *how people keep the relationship intact*. Here, relationship maintenance refers to those behaviors that keep a couple together over time—the longer, the better. (2) A second definition involves sustaining desired features of the relationship. From this view, it is not

enough to have a stable relationship; *relationship maintenance means retaining a high-quality involvement*. Accordingly, relational maintenance refers to engaging in actions that promote important relationship features, such as satisfaction, commitment, trust, love, and so forth. (3) Third, relationship maintenance refers to *how people repair their close involvements that have been somehow damaged*. In this sense, maintenance behaviors are reactive; people do not engage in maintenance until the relationship needs repair. (4) Fourth, relational maintenance concerns *keeping a relationship in a specified condition*. That is, a particular type of relationship and level of intimacy are maintained. For instance, platonic friends engage in maintenance behaviors to keep the friendship as nonsexual. (5) Finally, from a dialectical perspective, *relational maintenance refers to how partners adapt to change that is inherent in relationships*. In other words, relationships do not have a static status quo; rather, relational partners experience ebbs and flows of various tensions that need to be managed for the relationship to be sustained.

Researchers tend to adopt one definition in preference to others. However, these definitions are probably more mutually informative than mutually exclusive. That is, relational maintenance most likely occurs in all forms but at different times. At a minimum, people need to keep their relationships in existence, and at times, that is the critical goal. But in addition, people work at maintaining important characteristics of the relationship—as one that involves commitment, trust, and so forth. And when partners have a

falling out, they then need to repair the damage done. During periods when both parties are content, they work at sustaining those times of continuity, although the status quo of relationships is not static but involves change.

Forces That Push and Pull on Relationships

Some people believe that relationships are easy to get into but difficult to get out of, whereas other individuals hold that people must work to maintain their relationships or they will fall apart. The idea that relationships are hard to leave invites a *centripetal* analogy, and the idea that relationships fall apart unless some force holds them together suggests a *centrifugal force* at work. Research shows that both centripetal and centrifugal forces function to maintain close involvements, such that one should leverage the forces that keep relationships intact and combat the forces that pull relationships apart.

Emphasizing Centripetal Forces

One clear centripetal force concerns the barriers that people face when they attempt to dissolve a relationship. Both internal barriers and external barriers have been examined. One internal barrier concerns how individual identities are constructed in the partner's presence. The extent to which one's identity connects to the relationship is a centripetal force that keeps people together. Such personal identities can become so enmeshed that people cannot imagine their lives without their partners, for example, what to do in the evenings or on weekends. Also, external barriers keep partners together; for example, financial interdependence, legal constraints, societal norms, and children represent obstacles to leaving one's partner.

Another centripetal force, communication, maintains relationships. Mundane, predictable, and routine interactions define and perpetuate relationships. According to Steve Duck, talk—in and of itself—conveys a symbolic vision of the relationship that promotes its continuance every time partners engage in it. Accordingly, mundane communication patterns solidify the relational system such that altering communicative patterns requires no small effort. Communication patterns also establish

expectations about how each person should behave in relation to the partner. Communication patterns refer to repeated exchanges of messages, for instance, in the ways partners greet each other after a day at work (“Hi Honey, how was your day?” / “Not bad, you know, the usual craziness”). Once patterns establish expectations, alternative behaviors appear unusual and perhaps inappropriate (“Hi Honey, how was your day?” / “Why do you ask?” / “What?”).

Combating Centrifugal Forces

Recall that a centrifugal analogy implies that relationships tend to break apart unless people do something to keep the relationship together. In this view, maintenance behaviors represent the “do something” actions that people undertake to keep the relationship intact and of high quality. For example, Laura Stafford and Dan Canary's Relational Maintenance Strategy Measure (RMSM) comprises five strategies that have been found to predict relational stability and quality. First, *Positivity* refers to conscious attempts to make interactions positive and upbeat, including acting cheerful, being spontaneous, performing favors for the partner, and so forth. *Openness* involves direct discussion about the relationship, including talk about its history, rules made, and self-disclosure. *Assurances* concern showing support for the partner, comforting the partner, and stressing one's commitment. *Social Networks* refer to relying on friends and family to support the relationship (e.g., having dinner every Sunday at the in-laws), involving network members to solve relational problems, and the like. Finally, *Sharing Tasks* concern performing one's responsibilities (e.g., doing household chores). Although people can use each strategy alone or in combination with others, these five strategies are moderately and positively associated. For example, positivity might be used to increase partner rewards and one's likability, whereas in a different interaction, openness could be used to increase time spent together. Moreover, researchers have expanded the original five RMSM strategies, including such behaviors as *Joint Activities* (e.g., spend time together) and *Not Flirting* (to maintain a platonic relationship) among others.

In one important program of research, Caryl Rusbult has identified variations in how people

respond to their partners during troubled times, or *tendencies to accommodate*. Tendencies to accommodate are the product of two dimensions: passive versus active and constructive versus destructive. Active and destructive behaviors involve *Exit*, which includes threats to leave the partner or actually leaving. *Voice* is an active and constructive strategy that involves discussing the problem without hostility. *Loyalty* constitutes a passive and constructive tendency that entails acquiescence to the partner; for example, conceding to the partner's point of view. Finally, *Neglect* is a passive and destructive approach that involves indirect and negative behaviors (e.g., no kiss goodnight).

These tendencies to accommodate the partner are predicted by one's personal commitment to the relationship, which is itself constituted of three factors: satisfaction, where one experiences positive outcomes from the relationship and the partner meets or exceeds one's expectations; comparison level of alternatives, where one's partner is seen as superior to other potential partners and activities (including being alone); and investments of time and resources into the relationship. Moreover, the three factors that promote commitment affect the tendencies to accommodate. For instance, voice behaviors most likely occur when satisfaction, investment, and alternatives are high, whereas loyalty is preferred when satisfaction and investments are high, but one has few alternatives.

Combining Centripetal and Centrifugal Analogies

Responding to both centripetal and centrifugal factors helps maintain relationships. Research suggests that centripetal factors and behaviors are more relevant to relational stability, whereas centrifugal forces and behaviors work to maintain the quality and important characteristics of the relationship (e.g., satisfaction, commitment, liking). Stated differently, relationships remain intact when barriers and communication patterns appear consistent and strong. However, maintaining relationship quality requires efforts at being positive, showing one's commitment, engaging in one's fair share of responsibilities, and so on.

As mentioned, several scholars have adopted a dialectical perspective on relational maintenance. This perspective holds that change is inherent in relationships, such that attempts to maintain a

stable status quo are impossible. Change occurs because people experience recurring dialectical tensions that result from poles of experience that contradict each other but exist in tandem with each other. Common dialectical poles include *autonomy/connection*, *openness/closedness*, and *predictability/novelty*. From this perspective, then, to maintain their relationships partners must balance competing forces of wanting to hold an individual identity with wanting to be interdependent with one's partner (autonomy/connection), of desiring to disclose one's concerns and beliefs while retaining privacy boundaries (openness/closedness), and of needing to have a sense of continuity while enjoying new experiences (predictability/novelty).

Adopting a dialectical perspective that attends to both centripetal and centrifugal forces, researchers have reported several responses to dialectical tensions. These responses involve *denial* (reject the existence of a tension), *disorientation* (partners ignore attempts to actively manage tensions), *spiraling inversion* (partners respond to first one, then the other pole), *segmentation* (partitioning the relationship by topic or activity), *balance* (compromise is achieved by partially fulfilling the demands of each pole), *integration* (both poles are responded to simultaneously), *recalibration* (a temporary synthesis of the contradiction such that opposing forces are no longer seen as opposites), and *reaffirmation* (a celebration of the stimulation that contradictory tensions provide). Alternate lists of dialectical responses exist.

Levels of Relational Maintenance Activity

Maintaining relationships occurs at different levels. First, at the individual level, certain cognitions help keep the person in the relationship. Second, at the dyadic level, partners engage in the maintenance routines and strategies that were discussed previously. Next, social networks can promote relational stability and quality. Finally, the broader culture indicates appropriate behavior for people in close involvements.

Individual Level: The Role of Cognitions

How people think about their partners and their relationship can promote relational stability

and quality. Generally speaking, holding positive thoughts about one's partner leads to perceptions of the partner that reinforce one's positive bias. For instance, highly idealized people remain in their relationships through times of trouble more than do people who are less idealized; and over time, idealized partners experience increases in satisfaction and decreases in ambivalence about the relationship. Moreover, individuals sometimes use tactics that increase ambiguity when a potential relational threat arises. For example, when one's partner has a lunch date with a former lover, one would not use the term *date* but instead call it a *meeting* to increase the ambiguity of the event and thereby reduce its relational consequences.

Other specific cognitions serve maintenance functions. For instance, Rusbult has identified cognitions that reflect people's commitment to their partners. The first is *deciding to remain* in the relationship, a fundamental decision that is pivotal to other thoughts and behaviors. Second, *perceived relational superiority* references the belief that one's relationship is better than all other relationships. Third, the *derogation of alternatives* involves devaluating attractive alternatives, thereby promoting the partner's comparative relational worth. Finally, a *willingness to sacrifice* one's personal interests for the relationship involves focusing on the partner's welfare more than on one's own. If one acts on a willingness to sacrifice, then this cognitive maintenance activity becomes behavioral. Regardless, willingness to sacrifice remains an individual level behavior that can be performed independently of the partner.

Dyadic Level: The Role of Maintenance Behaviors

At the dyadic level, people enact routines and strategies with each other to maintain their relationships (as discussed earlier). Researchers have found strong support for the effects of these behaviors. For example, the five RMSM strategies have accounted for as much as 80 percent of the variance in commitment and other indicators of relational quality. Also, people who do not engage in the RMSM behaviors are more likely to terminate their relationships than are people who use maintenance strategies. Moreover, the research shows that these maintenance strategies affect relational outcomes differentially. For example, commitment

to one's partner is most strongly predicted by use of assurances, whereas liking the partner is most strongly predicted by positivity.

Importantly, the effects of maintenance strategies on relational features are short-lived. One panel study found that the strong associations between maintenance behaviors and relational quality have a short half-life. Accordingly, dyadic maintenance behaviors need to be continually used so they will affect relational quality. Cooking dinner or saying "I love you" once a week will not be effective for most people; rather, one needs to engage in maintenance behaviors continually for them to be effective.

Social Network Level: The Relevance of Friends and Family

Social networks play an important role in the stability and quality of romantic relationships. Research indicates that social networks can facilitate or inhibit the stability of dating relationships. That is, one's social network system can promote relational stability and satisfaction in intended ways or in ways that boomerang. If the relationship is satisfying, support from network members as well as lack of support from them can each function in different ways to strengthen the relationship. In other words, people interpret both positive and negative evaluations of their relationships in ways that support their selection of partners. However, if the relationship is dissatisfying, then social network disapproval of the relationship works against the stability of the relationship. Research shows that if one is seriously thinking about ending a romantic involvement, then friends and family members who endorse the termination help to speed up the termination.

This research is sometimes counterintuitive. In one study, perceptions of the *partner's* parental support and friendship support of the relationship promoted relational stability, but one's own parental support did not add to relational stability. Instead, friendship support in combination with *disapproval* from one's parents promoted relational stability. Researchers have offered two alternative explanations for this so-called Romeo and Juliet effect: (1) people engage in psychological reactance when a parent disapproves of the relationship; and (2) parental disapproval motivates

partners to discuss relational troubles they have that are raised by family members, and this problem-solving interaction works to strengthen the relationship.

Culture and Relational Maintenance

Relationships do not exist in a vacuum. Rather, the cultural context affects whether and how relationships are maintained. Little research has examined the manner in which culture affects relational maintenance processes. Still, the evidence suggests that maintenance strategies are more salient and important in cultures where people have latitude in selecting mates and where individual expression is valued. When people can determine who their partners are and when the culture endorses the direct expression of ideas, then people assume more responsibility for developing their romantic relationships and maintaining them with explicit and direct messages.

For example, Korean values regarding relationships are largely based on Confucian principles. Koreans have reported less use of explicit and direct relational maintenance behaviors than have U.S. participants. The decreased use of such maintenance behaviors by Koreans probably reflects their cultural values and traditions. For instance, the Confucian concept *eur-ri* (pronounced *oo-ree*) presumes a long-term, obligatory association. As long as people perceive that their partners engage in *eur-ri*, then they should remain in the relationship regardless of their satisfaction levels. Also, Koreans tend to be less direct in attempting to appease their partners. Rather, Koreans prefer the practice of *noon-chi*, which roughly means that one should anticipate what the partner wants and behave accordingly. Instead of asking whether one's partner wants a second cup of coffee, for example, one should pour the second cup when appropriate. Such cultural principles make the use of explicit and direct maintenance behaviors moot and the use of indirect and implicit maintenance behaviors, such as *noon-chi*, important.

In individualistic cultures, people tend to maximize their personal rewards by selecting partners they find rewarding. In such cultures, social exchange factors, such as equity, become salient when deciding how much effort to put into maintaining the relationship. Studies have shown that

people in Western cultures engage in more direct efforts to maintain their relationships when they are treated fairly. However, in East Asia, where people do not attempt to maximize their personal rewards, people enact fewer direct maintenance behaviors. Also, maintenance behaviors in East Asia do not depend on how fairly people believe they are treated. Instead, maintenance behaviors tend to be used to the extent one finds the relationship personally rewarding, regardless of fairness.

MARITAL SATISFACTION, ASSESSMENT OF

During the last 60 years, marital satisfaction—or the related constructs of marital adjustment and marital quality—have been the target outcome variables for almost all marital research and couple therapies. These have been assessed via epidemiological research, treatment outcome research, and basic marital research and are the field's measures of whether couples are happy and whether our couple therapies are working. Marital satisfaction and adjustment are strongly associated with the 50 percent divorce rate in the United States, individual distress (e.g., depression, anxiety, and alcohol abuse), physical health, and children's well-being. This entry reviews various terms used to describe marital satisfaction, examines ways of assessing marital satisfaction and adjustment, reviews the reliability and validity of the most widely used measures, and concludes with an overview of emerging efforts to standardize the assessment of marital satisfaction and related constructs.

Terminology

For as long as marital satisfaction has been assessed, there has also been considerable confusion and controversy regarding the differences among

the terms *marital satisfaction*, *marital adjustment*, and *marital quality*. Marital satisfaction refers to global marital sentiment or marital happiness as a unitary construct. Marital adjustment is broader in scope, and includes a consideration of marital processes such as conflict management skills and marital outcomes such as marital satisfaction. Marital quality refers to marital processes alone, such as the quality of a couple's conflict management skills, supportive transactions, sexual relations, or emotional intimacy. Additionally, several terms have been used to describe low marital satisfaction or adjustment, including *marital discord*, *marital dissatisfaction*, *marital distress*, and *marital dysfunction*. Low marital satisfaction is also distinguished from marital dissolution, which refers to separation or divorce.

Ways of Assessing Marital Satisfaction and Related Constructs

Historically, marital satisfaction and adjustment have been assessed by administering questionnaires to husbands and wives and then calculating sum scores for spouses (or couples) based on their responses. Scores are typically placed on a continuum from low to high satisfaction. Starting in the 1950s, marital adjustment was assessed with omnibus measures in which spouses evaluated multiple aspects of their marriage, such as the amount of disagreement across different areas of conflict, global evaluations of the marriage, and frequency of sexual relations. Harvey Locke and Karl Wallace's Marital Adjustment Test (MAT) and Graham Spanier's Dyadic Adjustment Scale (DAS) are two widely used measures of marital adjustment.

In the 1980s, researchers and clinicians also began assessing marital satisfaction with shorter, unidimensional measures of global sentiment toward one's marriage. Robert Norton's Quality of Marriage Index (QMI) and Walter Schumm and colleagues' Kansas Marital Satisfaction Scale (KMSS) are widely used measures of global marital satisfaction. Researchers and clinicians also began to assess marital satisfaction using a semantic differential approach, a way of quantifying spouses' evaluations of their marriage by having them rate their perceptions on scales between two opposite

adjectives (e.g., satisfied to dissatisfied, good to bad). Charles Osgood and colleagues, and Ted Huston and Anita Vangelisti, have developed and validated versions of semantic differential measures to assess marital satisfaction.

Since the mid-1990s, there has been a move toward assessing marital satisfaction and adjustment with multidimensional approaches. For example, Frank Fincham and Kenneth Linfield developed the Positive and Negative Quality in Marriage Scale (PANQIMS), on which spouses evaluate the positive and negative qualities of their partner and marriage, yielding scores for two distinct aspects of marital satisfaction. Global measures collapse these two domains, making it impossible to determine whether it is lack of positive or high levels of negative evaluation that reduces marital happiness. Alternatively, the PANQIMS allows spouses to be categorized as happy (high positive and low negative marital quality), distressed (low positive and high negative), ambivalent (high on both positive and negative marital quality), or indifferent (low on both positive and negative marital quality). Douglas Snyder's Marital Satisfaction Inventory (MSI) is a multidimensional measure of marital adjustment that differentiates among levels and sources of distress. Dimensions include assessments of family of origin conflict, sexual satisfaction, and problem-solving communication strategies.

Reliability and Validity of Commonly Used Measures

Marital adjustment. The MAT is a 15-item self-report measure of overall relationship functioning, with questions about couples' relationship satisfaction, activities, and levels of agreement on issues such as demonstrations of affection and philosophy of life. Yielding scores from 2 to 158, the MAT is typically the instrument against which other marital assessments are validated. The MAT demonstrates adequate cross-sectional reliability (split half = .90) and discriminates between non-distressed spouses and spouses with documented marital problems. The DAS is a 32-item self-report measure of relationship distress with a variety of response formats. An overall score of relationship

distress is obtained from items assessing dyadic differences, interpersonal tensions, dyadic satisfaction, dyadic cohesion, and consensus on matters important to dyadic functioning. The DAS is internally consistent and stable over brief intervals, with reliability estimates ranging from .58 to .96. Total DAS scores converge substantially with other marital adjustment measures, discriminate between distressed and nondistressed couples, and identify couples who are likely to divorce.

Marital satisfaction. The KMSS is a 3-item measure of marital satisfaction that demonstrates good concurrent validity, correlating at .83 with the DAS, and good discriminant validity when compared with measures of life satisfaction. The KMSS also demonstrates good criterion validity, distinguishing women living with their partners from women who are separated, and good test-retest reliability and internal consistency. The QMI is a 6-item measure that demonstrates good convergent validity, correlating above .80 with the DAS, good discriminant validity when compared with measures of individual psychopathology, and strong internal consistency, with estimates above .90 across several studies.

Multidimensional measures. The PANQIMS is a 6-item scale with strong internal consistency (estimates above .87) on each dimension. It also demonstrates good convergent validity when compared with the MAT, and good incremental validity, explaining significant variance over the effects of the MAT. The MSI is a 150-item self-report measure with 10 scales assessing specific dimensions of relationship functioning. Internal consistency for the individual scales ranges from .70 to .93, and test-retest reliability coefficients range from .74 to .88. The MSI scales correlate with the MAT and DAS, and with a broad range of affective and behavioral components of marital interaction.

Emerging Efforts to Standardize Assessment

In the last few years, researchers and clinicians have begun to move beyond self-report questionnaires of marital satisfaction, adjustment, or quality. Semistructured interviews have been developed

to conduct multidimensional assessments of these important constructs. For example, Richard Heyman and colleagues developed a structured interview to provide a diagnostic measure of relationship distress. Erika Lawrence and colleagues developed a multidimensional interview to assess marital quality across five key relationship domains, including emotional intimacy, interpartner support, sexual relations, interpartner respect and control, and communication and conflict management. There is also an emerging, conceptually framed, empirically derived, integrated effort to develop a standardized assessment protocol for assessing marital satisfaction and adjustment. This protocol will include assessments of cognitive, affective, behavioral, interpersonal, and structural or developmental domains, and will include self- and partner-report questionnaires, clinical interviews, and analog behavioral observations.

MARITAL SATISFACTION AND QUALITY

Marital satisfaction (also called *marital quality* or *marital happiness*) typically refers to the subjective

attitude that individuals have toward their marital relationship. Marital quality may be used synonymously with marital satisfaction, but it also has been used to refer to marital adjustment (see later) or to refer to marital satisfaction in conjunction with marital conflict. Marital happiness is typically used synonymously with marital satisfaction.

The marital relationship occupies a privileged status among adults in our society, and as Peter Berger and Hansfried Kellner noted, it is a primary means through which individuals construct and maintain social reality. Satisfaction in the marital relationship is of interest to those who study interpersonal relationships because of its centrality to the meaning-making process in the lives of many adults and because satisfaction in this key relationship is shaped by and shapes aspects of other human relationships (e.g., parent–child). This entry provides an overview of the debate regarding the conceptualization and measurement of marital satisfaction and a summary of the investigation into causes and correlates of marital satisfaction.

Conceptualization and Measurement

Marital satisfaction is perhaps one of the most frequently studied variables in marital research. Despite the wealth of literature examining this construct, there is a continuing lack of consensus among marital researchers about how to conceptualize and measure marital satisfaction, as well as an absence of a unifying theoretical approach to studying this construct. During the past several decades, scholars have engaged in lively debates about how to conceptualize marital satisfaction. There have been two major approaches: looking at the relationship itself (examining patterns of interaction, such as the amount and type of communication and conflict) and looking at individual feelings of the spouses (subjective judgments of satisfaction or happiness). According to those scholars who focus on the interactions in the relationship, rather than on the subjective evaluations made by individuals in the relationship, marital satisfaction is an interpersonal characteristic. Proponents of this approach treat marital satisfaction as a process, the outcome of which is determined by interaction patterns between spouses. Scholars who take this approach, which was dominant during the 1970s,

generally favor the terms *marital adjustment* or *marital quality*, although some do use the term *marital satisfaction* as well. These scholars also view marital satisfaction as a multidimensional construct. Multidimensional measures of marital satisfaction typically assess a number of specific types of interactions between spouses (e.g., time spent together/companionship, conflict, and communication). In addition to measuring reported behavioral characteristics of the dyad, some multidimensional measures also include global subjective evaluations of the relationship (such as happiness, satisfaction, or distress). These items are then typically summed. Frequently employed multidimensional measures of marital satisfaction are the Locke-Wallace Marital Adjustment Test (LWMAT), the Dyadic Adjustment Scale (DAS), and the Marital Satisfaction Inventory (MSI).

During the 1980s, the interpersonal approach to the study of marital satisfaction or marital quality, and the multidimensional measures used by those who adhered to this approach, came under severe attack. Criticisms can be grouped into two general categories. First, many multidimensional measures, such as the LWMAT and the DAS, were criticized for combining scales assessing objective reports of interaction, which are dyadic measures, with subjective evaluations of the relationship, which are individual measures. This is problematic because it combines two different units of analysis. Additionally, it combines two different types of reports (objective and subjective). This presents serious threats to the validity of such scales. Second, multidimensional measures were criticized because the components that are frequently included may actually be determinants of subjective evaluations of marital satisfaction. These factors, such as communication or couple interaction, also could be considered as independent variables that might influence marital satisfaction. Critics pointed out that by including both evaluative judgments about marital quality and reports of specific behaviors and general interaction patterns, multidimensional measures also may inflate associations between marital satisfaction and self-report measures of interpersonal processes in marriage. This is particularly problematic when dealing with cross-sectional data. The criticisms of multidimensional measures raised in the 1970s led many researchers to conclude that scales assessing

different dimensions of marital quality should not be summed up and to develop new measures.

In response to the criticisms of the interpersonal and multidimensional approach to conceptualizing marital satisfaction, scholars began to take an intrapersonal and unidimensional approach in the 1980s. This approach also was prompted by the fact that many of the large nationally representative data sets that were available in the 1980s contained only unidimensional measures of marital quality. According to the intrapersonal approach, marital satisfaction should be conceived of as reflecting a person's subjective evaluation of the marital relationship, rather than the reported quality of interaction between two spouses. Scholars who take this approach typically employ the terms *marital satisfaction*, *marital happiness*, or *marital quality*, rather than *marital adjustment*.

Scholars who take the intrapersonal approach to marital satisfaction most often use unidimensional, global evaluative assessments of the relationship. Unidimensional measures take the individual (rather than the dyad) as the unit of analysis and are subjective reports of attitudes (rather than objective reports of behaviors). Frequently used unidimensional measures include the Kansas Marital Satisfaction Scale (KMSS), the Marital Satisfaction Scale (MSS), and the Quality of Marriage Index (QMI).

Although unidimensional measures have not suffered the same degree of criticism as multidimensional measures of marital quality, two major shortcomings have been identified. First, unidimensional measures are criticized for being subject to considerable social desirability response bias. There have been some attempts to measure the extent to which these measures are contaminated by social desirability response bias and to control for it, but there is not yet agreement about the best way to do that. A second criticism of global measures is that they tend to be significantly skewed toward a positive evaluation. This makes analysis of the dependent variable difficult because there is often little variance.

During the 1990s, the lack of consensus regarding how to conceptualize and measure marital satisfaction persisted. At this time, many scholars began to employ the term *marital quality*. Some researchers used this term interchangeably with *marital satisfaction* or *marital happiness*. However, other

scholars began to use *marital quality* in a broader sense and included multiple measures (e.g., both marital satisfaction and marital conflict), but treated them as separate dimensions rather than creating a summary index as earlier scholars had done. Frank Fincham and colleagues suggest that marital quality contains separate positive and negative dimensions. Drawing on recent research in the areas of attitudes and affect, they argue that people may feel both positively and negatively about their marriages and that these feelings may change independently over time. These scholars use the terms *positive marital quality* (PMQ) and *negative marital quality* (NMQ) to distinguish between these two dimensions and create a fourfold typology of marital quality: satisfied (high PMQ and low NMQ), ambivalent (high PMQ and high NMQ), indifferent (low PMQ and low NMQ), and distressed or dissatisfied (low PMQ and high NMQ). It remains to be seen whether this two-dimensional approach will be widely adopted by marital researchers, though. The debate regarding how to conceptualize and measure this important construct has not been resolved.

Disagreement regarding how to conceptualize and measure marital quality and the diversity of academic disciplines represented among those who study marital satisfaction, have both contributed to the failure of scholars to develop a guiding theoretical perspective while studying marital satisfaction. Early theoretical attempts consisted primarily of drawing propositions from existing, general theories, such as Attachment, Social Exchange, or Role Theories, or of developing middle-range theories, such as Robert Lewis and Graham Spanier's Exchange Theory of Marital Quality. In the 1980s, marital quality research tended to be atheoretical, as scholars struggled to resolve the controversies surrounding how to measure and conceptualize marital satisfaction. In the 1990s, scholars began to expand their areas of inquiry beyond individual and interpersonal factors that may influence marital satisfaction to take a more ecological approach, considering the contexts in which individual and interpersonal processes occur as well.

Causes and Correlates of Marital Satisfaction

The investigation of determinants of marital satisfaction and marital quality has occupied a central

place in marital research for many decades. However, over time, the focus of such research has changed. In the 1940s, much of the work investigated how personality characteristics might influence marital satisfaction. In the 1950s, scholars shifted their attention to interactional styles, which spurred the development of the multi-dimensional measures of marital satisfaction (or marital adjustment) described earlier. The movement of women out of the home and into the workplace shaped the work of scholars in the 1980s and 1990s, when factors such as role conflict, the division of household labor, women's employment, and power were widely investigated for their relationship to marital satisfaction. Conflict resolution and violence also emerged as factors investigated during this time.

More recently, scholars have begun to take a more complicated approach to understanding the factors that may be related to marital satisfaction by trying to identify both mediating and moderating variables. A moderating variable is a variable upon which a relationship between an independent and dependent variable is contingent. For instance, the link between marital satisfaction and certain factors, such as conflict and sexual satisfaction, appears to be contingent on the gender of the spouse. Other factors, such as race/ethnicity, age, and relationship stage also have been considered as possible moderators. Recent research also has attempted to understand the role of mediating, or intervening variables, on marital satisfaction. For instance, depression may lead to more negativity in relationships (a mediating variable), thereby impacting marital satisfaction indirectly.

Because of the vast number of studies into the causes and correlates of marital satisfaction and marital quality, it is impossible to summarize all their findings. However, several excellent reviews have set out to accomplish this task. Each decade since 1970, the *Journal of Marriage and the Family* has published such a review, offering an overview of findings from the previous decade. This entry offers only a brief introduction to some of the key findings regarding causes and correlates of marital satisfaction.

One of the most intensely studied topics in marital satisfaction research has been the influence of children, family stage, and duration of the marriage on marital satisfaction. In a review of studies

conducted during the 1960s, scholars reported that one of the most surprising findings of that decade was that children appear to detract from the marital quality of their parents. The transition to parenthood continued to be a popular topic of study during the 1970s. Several cross-sectional studies identified a curvilinear relationship between family stage and marital satisfaction, whereby the average quality is higher in the preparental and postparental stages. The most common interpretation of this finding was that it reflected the addition of children to the family, their maturation, and their departure. However, longitudinal studies have suggested that changes often attributed to the transition to parenthood are duration-of-marriage effects instead. Some of these studies suggest that rather than being curvilinear, marital quality declines sharply during the first few years of marriage and then tapers off more slowly. The impact of children on marital satisfaction continues to be a topic of inquiry among scholars. A recent meta-analytic review of research into the link between parenthood and marital satisfaction concluded that parents report lower satisfaction than do non-parents, that the effect of parenthood is stronger for women than for men, that this effect is particularly strong for women with infants, and that the effect is stronger for more recent generations. The number of children and levels of satisfaction were also negatively correlated. This review offered support for the notion that children are linked to lower levels of satisfaction because of role conflict and restricted freedom.

The link between premarital cohabitation and marital satisfaction also has been the subject of a great deal of investigation in recent decades. A negative relationship between cohabitation and marital quality has been established, but it is unclear whether it is the living together or the type of people who tend to live together before marriage that is responsible for this effect. Research on remarriage also has increased sharply in the past 20 years and much of it has focused on marital satisfaction. This research indicates that the average marital satisfaction is slightly greater in first marriages than in remarriages after divorce. It also appears that the average satisfaction in remarriages is somewhat higher for men than for women.

Wives' employment, spouses' gender role attitudes, the division of household labor, and perceived

equality also have received a great deal of attention recently. It seems that congruency between spouses' attitudes toward gender roles, as well as congruency between attitudes and behaviors, are related to marital satisfaction. A shared division of household labor and perceived fairness of the division of household labor also seem to enhance marital satisfaction, especially for wives.

Thomas Bradbury and colleagues organized their review of marital quality research conducted in the 1990s around two themes: interpersonal processes and sociocultural contexts within which marriages operate. These authors stated that research conducted during the 1980s and 1990s supported the conclusion that spouses' attributions (or causal statements) for marital events are linked to marital satisfaction. Spouses that employ maladaptive attributions for negative partner behaviors have lower levels of marital satisfaction and use more negative behaviors during marital problem-solving discussions. Maladaptive attributions emphasize stable, internal, global characteristics rather than temporary, situational, specific characteristics. For instance, a wife who attributes her husband's late arrival to dinner as reflective of a stable personality characteristic, such as thoughtlessness or a lack of organization, rather than to a temporary, situational issue, such as heavy traffic or a busy day at work, is more likely to engage in negative behaviors during problem-solving discussions. The 1990s also saw a dramatic surge in research on the affective, or emotional, dimension of marital interaction. Although this research has demonstrated that affect is linked to marital quality, the exact nature of the relationship is not clear yet. For instance, some studies show that negative affect is harmful to marital quality, but other studies suggest that it enhances marital quality. Interaction patterns (especially the demand-withdraw pattern), physiology (e.g., the degree of physical arousal during marital interaction), social support, and violence also were identified as factors that are linked to marital satisfaction. In the latter half of their review, Thomas Bradbury and colleagues focus on contextual factors that are linked to marital quality. In particular, they discuss ways in which children, spouses' background and characteristics, life stressors and transitions, and neighborhood characteristics are related to marital quality.

The importance of understanding and measuring marital satisfaction and its influences stems primarily from the assumption that it is a key determinant of other important marital outcomes, such as marital stability (divorce and separation). Early marital researchers often assumed that marital satisfaction was predictive of marital stability. However, it became clear that given a certain level of marital satisfaction, some marriages would end in divorce and some would not. Spanier and Lewis identified four types of marriages: high quality/high stability, high quality/low stability, low quality/high stability, and low quality/low stability. Following the work of these scholars, several researchers have tried to identify factors that may moderate the relationship between marital quality and marital stability. External pressures (e.g., social pressure to remain married) and alternative attractions (e.g., availability of other mates) have been the focus of several studies.

Studies also show that marital satisfaction is positively related to other measures of individual well-being (e.g., life satisfaction, physical health). In the 1980s, some studies used marital satisfaction as an independent variable to predict the global well-being of married people, illustrating a strong positive link between the two. Although there has been some debate regarding the causal direction between these two variables, recent longitudinal research suggests that low marital quality is linked with lower levels of overall happiness, life satisfaction, self-esteem, and overall physical health. The authors of these studies suggest that marital satisfaction is a predictor of individual general well-being (rather than the other way around). Additionally, findings indicate that one spouse's marital satisfaction is linked to the well-being of the other spouse as well as the children's well-being.

Finally, in recent years, scholars have begun to examine how the concepts and findings from research on marital satisfaction might relate to the study of satisfaction within nonmarital relationships, such as unmarried heterosexual couples or same-sex couples. Thus far, it seems that many of the concepts and findings derived from studies of marital satisfaction also can be applied to satisfaction within other types of committed sexual relationships.

In conclusion, despite the continuing debate about how to conceptualize and measure marital

satisfaction and the difficulties constructing a unifying theory of marital satisfaction, a great deal has been discovered about what factors are linked to marital satisfaction. As scholars continue to explore moderators and mediators of these links, and to engage in longitudinal research identifying the directions of effects, our understanding of this important component of human relationships will become even clearer.

MARITAL STABILITY, PREDICTION OF

Studies predicting marital dissolution generally assess couples within a few months of marriage

and then follow them over the next 2 to 14 years, assessing their relationship status throughout the study. Around the time of marriage, relationship researchers assess many different types of factors, including demographic variables, personality variables, and variables capturing the quality of interaction between the couples in hopes to determine which factors best predict divorce. Because 40 percent of all divorces occur within the first 4 to 5 years of marriage, studies tend to follow couples during this high-risk period to identify the factors predicting divorce. Accurate prediction can identify factors that put couples at risk for divorce and can be used to help target interventions (such as relationship workshops) to the couples that need them most. Although many variables have been assessed for their potential ability to predict divorce, this entry focuses on those factors that have been found to contribute the most to predicting marital separation and divorce as well as the methods researchers use to assess these factors.

Demographic Predictors

One set of factors that researchers have used to predict divorce is demographic variables. Demographic variables categorize individuals into certain groups or populations and include characteristics such as occupation, geographic location, religion, age, and marital status. Researchers have found that race, gender, and levels of education are significant predictors of the risk of divorce over time. Specifically, research has found that African-American couples are more than twice as likely as are Caucasian couples to divorce. In addition, couples with lower levels of education, lower levels of income, couples starting marriage at younger ages, and couples starting marriage with children are also at significantly greater risk for divorce. As these demographic variables often go hand in hand with one another, the results with these various demographic markers highlight the risk associated with general socioeconomic disadvantage.

Personality Traits

Researchers have also focused on how the individual personalities that husbands and wives bring to relationships affect marital outcomes. Studies

have consistently found that husbands and wives who have very negative and irritable personalities (a trait called *neuroticism*) tend to be less happy in their marriages and are more likely to divorce over time. Although neuroticism has shown the strongest long-term effects on relationships, a number of other personality traits have also been linked to relationship outcomes over time. Divorce tends to be slightly more likely for couples who have highly impulsive husbands (husbands who are more likely to act without thinking or are less able to inhibit themselves). Divorce tends to be slightly less likely in couples where spouses are highly agreeable (easy going and amiable) and conscientious. Thus, the personality traits that spouses bring into their relationships can sometimes place those relationships at greater risk for discord and divorce.

Feelings

Researchers have also examined affective factors such as passion, liking, trust, and emotional distress in predicting relationship outcomes. Specifically, high levels of emotional distress (a variable including many areas of psychological health including depression, anxiety, and hostility) around the time of marriage predict separation and divorce. Low levels of liking (positive impressions of a romantic partner) and low levels of trust at the time of marriage also predict more rapid relationship dissolution. Low levels of passion for one's partner at the time of marriage also predict earlier separation, but this result has only been found for women. This gender difference suggests that feeling passionate about one's spouse early in marriage might have different meaning for men and women. Drops in feelings of liking, trust, or love during the first 4 years in marriage also help to predict subsequent separation and divorce. Thus, feelings toward a relationship and toward one's romantic partner early in marriage can help to identify the couples who will separate and even end their relationships.

Communication and Support

Of all the factors examined, the factor most strongly linked to relationship outcomes is spouses'

behavior toward each other—specifically, the quality of their communication skills and the degree to which their discussions of everyday problems either remain constructive and supportive or become negative, hostile, and attacking. Research has consistently shown that high levels of self-reported hostile conflict behavior and frequent conflict in the relationship around the time of marriage are signals that a marriage may be heading toward divorce. Furthermore, husbands feeling validated (feeling listened to and understood by his wife) around the time of marriage is associated with lower risk of divorce. Similarly, spouses being emotionally supportive and compassionate toward each other—particularly during stressful periods—has been linked to better outcomes. Although many studies assess couples' communication using self-report questionnaires, researchers also often assess communication skills by videotaping couples discussing relationship problems in the laboratory. Research teams then code these discussions for the amounts of positive (e.g., warm, affectionate, empathic) and negative (e.g., defensive, angry, critical) behavior exhibited by each spouse. Coding of conflict behavior has been strongly linked to adverse marital outcomes (marital discord and divorce) across a series of studies from a variety of research labs. High levels of angry and hostile emotions during conflict discussions predict divorce during the first 7 years of marriage. In addition, a notable lack of positive emotions during conflict discussions has been found to predict divorce during 14 years of marriage. Both lower levels of positive and higher levels of negative conflict behavior have been linked to significant drops in relationship satisfaction during the first 4 years of marriage. Thus, becoming hostile and attacking when dealing with relationship problems potentially erodes relationships during the early years of marriage.

Physical Aggression

Mild forms of physical aggression (e.g., pushing, slapping, shoving) are known to occur in as many as 35 to 50 percent of all newlywed marriages, and another line of research has examined how such common couple violence is associated with marital outcomes. Physical aggression reported around the

time of marriage is a strong predictor of divorce in the first 4 years of marriage, even after controlling for the effects of hostile conflict behavior. These findings suggest that while both factors erode relationship quality, physical aggression has more immediate effects, eroding relationships more quickly. Researchers have also assessed drinking behaviors and alcohol-related problems in studies looking at relationship aggression, inasmuch as these often co-occur. Alcohol problems and excessive heavy drinking have been found to increase the risk of divorce two to three times during a 5-year period. However, even after taking alcohol problems into account, the presence of physical aggression in the relationship continues to more than double the risk of divorce, demonstrating a strong association with marital outcomes that rivals the prediction demonstrated for communication behavior.

Predicting From Interviews

Although many studies use either coded behavioral observations of conflict discussions (to assess the quality of communication behavior) or self-report questionnaires (assessing a range of factors including relationship communication, personality traits, and feelings about one's partner or relationship), another line of research has used ratings obtained from face-to-face interviews with couples to assess these same constructs. For example, the Oral History Interview asks partners about the history of their relationship, their attitudes toward marriage and the quality of their current relationship. In a series of studies, researchers have demonstrated that interviewer assessments of high husband disappointment (the husband seeming disillusioned about the marriage or seeming to have given up) and low levels of fondness (affection toward a spouse) predicted divorce during a 3-year period. In addition, assessments of poor marital bond (a general sense of closeness and a visible emotional connection between spouses) predicted divorce during a 5-year period even after accounting for self-reported levels of initial relationship happiness.

Retrospective Studies

Other marital researchers have attempted to examine the issue of prediction by collecting large

numbers of successful and failed marriages (after these outcomes have already occurred) and then using archival data collected from those couples just before marriage (obtained in the context of religious marital preparation) to identify differences between the two “outcome” groups. Although the data used for prediction was indeed collected prior to marriage, selecting couples for inclusion based on the ultimate outcome of their marriage differs markedly from including all willing couples and then tracking their outcomes. This sample-selection procedure typically resulted in samples made up of mostly extreme outcomes (very happy marriages vs. very bitter divorces) as the researchers eliminated more typical couples from their studies. This technique also limits the sample to religious couples as well as limiting the study to the religion-based compatibility inventories used to screen couples for marital readiness. Couples are often required to obtain sufficiently high compatibility scores to obtain permission to marry, so there is clear pressure on couples to adjust their responses accordingly—leading one to question the validity of such data. Despite these caveats, such studies have shown that higher levels of similarity on domains such as preferred leisure activities, life style expectations, religious values, and approaches to problem-solving and finances are associated with better marital outcomes.

Predictive Algorithms

In sum, evidence in the current literature points to a diverse group of factors that contribute to the risk of divorce including race, gender, education, aversive personality traits, hostile and attacking communication, social support, physical aggression, and compatibility. The results suggest that these factors can be measured by self-report scales, observational coding of couples’ behavior, interviewer ratings, or compatibility inventories without affecting the predictive information they provide. Just over a dozen studies have attempted to examine sets of these factors simultaneously to develop predictive algorithms. Although each of these factors makes a unique contribution to the process of prediction, results suggest that the bulk of the prediction can be achieved by including the factors representing partners’ behavior toward

each other—specifically, their communication, social support and aggressive behaviors. The current models can predict between 68 to 84 percent of marital outcomes during the first 3 to 6 years of marriage. This suggests that by simply giving engaged or newlywed couples a short packet of questionnaires to complete, it is possible to accurately predict the outcomes of three or four couples out of every five during the volatile early years of marriage, offering the possibility of targeting couples at the greatest risk for discord and divorce with preventive interventions to improve their interaction and thereby strengthen their relationships. However, it is also apparent from these findings that there is still much to be learned about how marriages succeed and fail. It may be that some factors involved in the dissolution of relationships have yet to be identified or included in prediction studies. It is also possible that marital discord and divorce are such complex, changing, and highly individual phenomena that it may never be possible to achieve perfect prediction.

MARITAL TYPOLOGIES

Marital typologies represent attempts of scholars to simplify the study of marriage by grouping together, and essentially treating as equivalent, those marriages that are similar and to distinguish, and treat separately, those that are different. This entry reviews basic assumptions underlying different marital typologies and their roles in theorizing about interaction processes and outcomes relevant to marriage.

Marital typologies, like other typologies of human relationships, provide a cognitive framework that primarily serves two functions: to organize observations and to systematically relate knowledge to explain and predict behaviors and outcomes. As such, they are the inventions of observers (scholars and laypersons alike) rather than the reflection of an actual or natural state of the marital relationship. Although often related, these two functions are theoretically orthogonal. Typologies that do a good job of fulfilling the first function (i.e., organizing observations) often make intuitive sense and are based on some easily recognizable attribute of the marriage that makes identification of the type easy. However, because marital outcomes usually are dependent on processes and dynamics that are not linked to easily observed attributes, typologies based on such attributes are not necessarily good at explaining and predicting behaviors and outcomes.

Typologies that are good at fulfilling the second function (i.e., explaining and predicting behaviors and outcomes) are frequently based on what scholars and researchers have learned to be relevant and important for the internal processes and dynamics

of marriages that lead to different behaviors and outcomes rather than some easily recognizable attribute. Consequently, it is not easily apparent what type a marriage falls into and, therefore, it is not uncommon to find that typologies of marriages are more meaningful to researchers than to laypersons or even the married couples themselves. Most scholars favor typologies that fulfill the function of explaining and predicting.

Assumptions Underlying Marital Typologies

Determinations about similarities and differences that allow marriages to be assigned a certain type are usually based on assumptions about similarities in experiences and external factors or on assumptions about similarities in internal dynamics and processes of marriages. Examples of the former include typologies based on stability (e.g., enduring vs. divorced), satisfaction and adjustment (e.g., satisfied vs. dissatisfied), or structure (e.g., first vs. second marriage; heterosexual vs. homosexual marriage; intra-ethnic vs. mixed-race). The underlying assumption of these typologies is that the individuals within marriages and the marriage dyads themselves essentially function similarly and that differences between marriages are the result of the different challenges and circumstance that couples confront.

Examples of typologies based on internal dynamics and processes include those based on conflict behaviors (e.g., validating, volatile, and avoiding couples), problem solving (e.g., competitive, collaborative, accommodating, neglecting, and compromising couples), and marriage beliefs (e.g., traditional, independent, and separate couples). The underlying assumption of these typologies is that individuals and couples constitute systems with unique properties who respond to similar challenges and circumstances quite differently, but that among these responses, there are regularities that can be used to classify couples into different types.

Marital Typologies in Social Science

As a consequence of social scientists' concern for explanation and prediction, most marital typologies developed in the social sciences focus not as

much on structural differences or differences in external circumstances as on differences in internal dynamics and processes.

Typologies of Couples in Specific Circumstances

For some typologies, these dynamics and processes are considered in the context of specific external circumstances only, such as newlyweds, couples with young children, or remarried couples. One classic example of such a typology is the work of Lawrence Rosenfeld and his colleagues, who developed a typology of dual-career marriages. Here, couples are classified based on spouses' involvement in family- and work-related activities. Collapsing couples are those in which wives adjust poorly to demands at work and home and husbands adjust poorly to demands at work and only moderately to demands at home. Work-directed couples, as the name implies, are those in which both spouses adjust well to work-related demands, but the wife adjusts only moderately and the husband poorly to demands at home. Finally, traditional-role couples are those in which the wife adjusts well to demands at home but poorly to demands at work, whereas the husband adjusts well to demands in both areas. In terms of satisfaction, wives were most satisfied in work-directed couples, whereas husbands were most satisfied in traditional role marriages, suggesting that challenges of dual careers require some sort of trade off between spouses.

Typologies of Couples Based on Specific Interpersonal Processes

Other typologies are also similarly narrowly focused, but rather than focusing on particular circumstance, they focus on specific processes, such as problem solving or parenting. A good example is John Gottman's seminal work on couple conflict. His typology is based on conflict behaviors and identifies three functional and two dysfunctional types. Of the functional types, the most intuitive is the validating couple. In this type, both partners openly communicate their needs and desires and are receptive of those of the other. They are supportive of one another, engage in collaborative problem solving, and maintain largely positive affect throughout conflict episodes. They are also able to repair

any damage caused to their relationship as a result of expressed negative affect by apologizing and expressing positive affect for the other.

Less intuitive is the volatile type. Couples who are volatile are those in which both partners are more competitive rather than collaborative and also freely express their negative affect. These couples, however, are able to compensate for hurt and negative emotions by also expressing a surplus of positive affect that allows them to maintain their relationship. Equally counterintuitive are avoidant couples, in which both partners avoid even acknowledging their divergent interests and, as a result, do not engage in any form of problem solving or openly express their negative affect. Although avoidant couples typically fail to explicitly resolve their differences, partners individually accommodate each other and, because they do not create a lot of hurt feelings, are able to maintain their relationship even in the absence of expressions of positive affect for each other.

Gottman also identified two dysfunctional types, the hostile and the hostile-detached couple. Conflict in these couples is characterized by the open expression of negative affect, often with the intent to hurt or denigrate the other. Because of the significant negative emotional toll that these interactions incur, couples with these conflict styles are unlikely to stay together for very long.

Typologies of Couples Based on Cognitive Representations and Behaviors

There are also a few typologies of marriages that are broader in scope in that they do not focus on marriages in specific circumstances or on only one or two interpersonal processes. Of these typologies, one of the earliest and most influential was developed by Mary Anne Fitzpatrick. Fitzpatrick's typology categorizes marriages based on how they are represented cognitively by spouses in terms of relevant beliefs about marriage and how these beliefs are expressed through behavior. Specifically, spouses' reports of their marital *ideology* are assessed, including beliefs spouses have about the sex-roles of husbands and wives, whether wives should take husbands' names, and how married couples should relate to their communities. Also measured is the behavioral *interdependence* of couples. Couples report on how they coordinate

their individual schedules and how they share their physical and psychological space, by, for example, having separate bedrooms or offices and maintaining privacy about financial matters and personal correspondence. Finally, *communication* is assessed and, in particular, whether couples engage in or avoid conflict and what they do, say, and feel during conflict interactions.

Based on these three dimensions, individuals can be categorized into one of three marital types: traditional, independent, and separate. Traditionals are very interdependent in their marriages, have conventional ideological values and beliefs about marriage and family life, and report an expressive communication style with their spouses. Independents are moderately interdependent in their marriages, have nonconventional values and beliefs about marriage and family life, and report a very expressive communication style with their spouses. Separates are not very interdependent in their marriages, have conventional ideological values and beliefs about marriage and family life, and report very little expressivity in their marital communication. In about two-thirds of marriages, both spouses have the same marital type; the remaining marriages fall into a mixed type (most frequently a traditional wife and a separate husband).

In addition to being more broadly applicable to investigations of marriage in a number of circumstances and concerns for various interpersonal processes, this typology has several other strengths. First, it is based equally on theory (the three underlying dimensions were identified based on prevailing marital theories) and empirical observation (the three types represent naturally occurring clusters in the conceptual space defined by the three dimensions). This typology also recognizes that different marriages achieve similarly satisfactory or functional outcomes in different ways that produce different sets of advantages and disadvantages for each type. That is, different types of marriages confronting the same set of challenges may respond differently and achieve similar outcomes; by contrast, similar ways of responding may lead to different outcomes based on marriage type. For example, independent and separate spouses both cultivate close relationships outside of marriage that are sources of emotional support for them, whereas traditional spouses and, in

particular husbands, focus almost exclusively on the spouse as a source of emotional support, often at the expense of external friendships. Thus, spouses in all marriage types are generally able to receive emotional support in times of need, although the loss of a spouse from death or divorce is more challenging in traditional marriages, whereas the stress of moving to a different town and building a new social network are more challenging in independent and separate marriages.

Despite these obvious strengths, there are also weaknesses in Fitzpatrick's typology. Probably the greatest weakness is that the typology fails to provide a comprehensive account of about a third of all couples (i.e., those that fall into the mixed category). Although there are six different types of mixed couples that likely vary in their communication, researchers usually treat mixed couples as a single group and contrast them to traditional, independent, and separate couples. This is an oversimplification and represents a lost opportunity to study the consequences of divergent perceptions of relationship among married couples.

MARKETPLACE APPROACHES TO COURTSHIP, LOVE, AND SEX

Marketplace approaches to romance and sexuality seek to analyze these phenomena using economic concepts and terms. This entry describes how romance and sexuality can be analyzed in economic terms. A marketplace approach involves several basic assumptions, as follows. First, exchange is involved. Second, exchanges are to some extent beneficial to both sellers and buyers, though not necessarily equally beneficial. Third, the transactions of each pair of buyer and seller are intertwined, so that they affect each other, and are in accord with basic economic principles.

Human romantic and sexual relationships can be analyzed in marketplace terms for several reasons. Forming a romantic attachment, whether for one night or a lifetime or something in between, is a kind of exchange in which the two people offer each other something that each wants (though not necessarily the same things). In modern Western cultures, the strong tradition of exclusivity and laws against polygamy entail that these transactions involve two persons. The most common form involves one man and one woman, although same-sex pairings do occur with some regularity and present theoretically interesting variations on the marketplace model.

In psychology, the foundation for marketplace analyses is social exchange theory, which has sought to analyze human interactions in terms of what each person offers the other and what benefits each person gets from it, as well as the costs to each. A basic assumption is that people will only participate in such interactions (and relationships) as long as their benefits outweigh their costs. For example, people may remain in relationships that cause them some degree of pain and distress as long as they derive other, valued benefits from

remaining. A social exchange theorist might also consider that the two persons derive different benefits. One may find sexual satisfaction or emotional support to be paramount; the other person may feel that financial support or having a stable family is the main benefit.

Supply and Demand

Marketplaces respond to fluctuations in the relative amounts of supply and demand. This is true for romantic and sexual relationships also. In the market for heterosexual romance, the relative numbers of men and women available are important because an oversupply of either gender relative to the other means that not everyone will be able to find a mate.

In this respect, economic marketplaces are the opposite of democracy. In a democracy, the majority rules and can by its superior voting power insist on having conditions that favor it. In a marketplace, however, the minority has more power than the majority. If your gender is in the minority, then you have many romantic options, and the marketplace is likely to negotiate terms favorable to your gender. If your gender is in the majority, things will go less smoothly. For example, because men tend to die younger than women, elderly widowed men have many more potential romantic partners than do elderly widowed women.

The impact of the sex ratio (i.e., the number of men per hundred women) on sexual and romantic behavior was explored in a classic interdisciplinary book by Marcia Guttentag and Paul Secord called *Too Many Women?* Comparing across different cultures and times, Guttentag and Secord noted that patterns of sexual and romantic behavior fluctuated in step with the sex ratio. When there were more men than women (because more men immigrate to a place, or because selective infanticide or selective abortion reduces the female population), norms tended to conform to what many women prefer. Long-term committed relationships were typical, whereas premarital and extramarital sex were relatively rare. In contrast, when there were more women than men (such as after a major war in which many men have been killed, or today in some low-income minority populations from which many men are killed or arrested), the norms

seemed more suitable to what many men like: less commitment, more turnover in relationships, and much more premarital and extramarital sex.

Sexual Economics

Sexual economics theory was proposed by Roy Baumeister and Kathleen Vohs to analyze sexual interactions in marketplace terms. They invoked another basic principle of social exchange theory, the so-called Principle of Lesser Interest, which suggests that whoever wants something more is at a disadvantage. This principle has often been applied to relationships: Whichever partner is more in love is at a disadvantage because he or she wants the relationship to continue more than the other does, and so this person must typically offer the other extra inducements.

Applied to sex, the Principle of Lesser Interest puts men at a disadvantage because typically men want sex more than women. The greater desire entails that men must typically offer women additional inducements to persuade them to have sex. These may take the form of paying for dates and dinner, giving jewelry and other gifts, making a commitment, giving the woman respect and commitment, or in the case of prostitution, giving her money.

Sexual economics theory is decidedly unromantic, which has created some resistance to it, but it explains a broad variety of findings and observations. It treats sex as a resource that women possess and that men want, and so female sexuality has exchange value whereas male sexuality usually does not. Thus, women have been able to trade sex for career advancement, reduced punishments, privileges, drugs, and money, whereas men usually do not have that option. Among ordinary people, both men and women fantasize about having sex with celebrities, but only women are able to enact these fantasies because a man who offers sex to a celebrity is likely to be rejected whereas comparable offers by women are more likely to be accepted.

One application of sexual economics theory invokes basic economic principles about how monopolies can increase prices by restricting the supply. Many cultures have imposed restrictions on female sexuality. These have sometimes been

interpreted as efforts by men to control women, but a large amount of evidence indicates that, on the contrary, restraints on female sexuality are mainly supported and enforced by other women. Even the most extreme of these restraints, namely the female genital surgeries that impair women's sexual responses, are culturally maintained by women who make the decisions, put pressure on each other to continue the practice, and carry out the operations, generally to the complete exclusion of men and in many cases contrary to men's preferences. Women benefit from restrictive sexual norms insofar as the reduced supply of sex makes men willing to offer more (e.g., faithful long-term commitment, respect, financial support) for sex. Cross-cultural evidence indicates that sexual norms are most restrictive when women lack economic and political power, presumably because women need the price of sex to be high. When women have more opportunities, they can allow more sex.

Homosexual Marketplaces

Same-gender romance and sex also have marketplaces, although these differ in important ways from heterosexual marketplaces. Because both persons are of the same gender, the roles (corresponding to buyer and seller) may be less well defined than are gender roles. The minority status of homosexuality means that it is often relatively difficult to find potential partners, and so the prospects of finding an ideally matched partner are lower than for heterosexuals. Homosexuals may find it appealing to relocate to places where there are more potential partners, simply to have more prospects.

Love triangles likewise present additional complications among same-gender couples. In a heterosexual marriage, for example, a man may be upset to learn that his wife is attracted to another man, but he does not usually feel personally offended that the interloper is sexually pursuing his wife rather than himself. In same-gender triangles, any two of the three could potentially form the stable couple.

MARRIAGE, BENEFITS OF

Given the preponderance of divorce in developed nations, most people realize that a Cinderella wedding does not guarantee living happily ever after. Even so, most couples in the world get married, and many same-sex couples are fighting for the right to get married. For some, marriage is a sacred vow that must be enacted before having sex and children. For many others, it is a voluntary choice, entered into regardless of religious significance. In short, most people want to get married. With the well-known fact that many marriages do not last, one might wonder why people want to get married. Are there real benefits to marriage beyond those imagined through rose-colored glasses? This entry addresses this question. To answer it, the entry will also address two other questions. First, to whom do these benefits go? It can be argued that marriage benefits culture, society, the family, the couple, and the individual. Second, do benefits accrue differently for men and women? Research has shown that, at the individual level, marriage bestows benefits differently to men and women.

All legal marriages impart legal benefits, but other, less visible and direct benefits vary from couple to couple. The preponderance of research demonstrates that the most of the social, physiological, and psychological benefits of marriage accrue to those couples whose marriages are going well.

Culture and Society

It has been argued that marriage provides the best type of family structure within which to raise,

nurture, and socialize children to become productive members of society. On the practical side, spouses combining two incomes can, more easily than single parents, maintain a household and raise children. In addition, families are one way in which cultural and religious traditions are transmitted to the young. Being married also gives couples a connection to their community, and are recognized as spouses bound by law. Although our society tolerates and sometimes accepts cohabitation, such an arrangement is not given legal rights or as much legitimacy as marriage. More often, cohabitation is seen as a step toward the goal of getting married.

Family

Marriage creates a bond between one person and his or her spouse's family. Such a connection may be detrimental when, for example, in-laws interfere with the marital relationship or the socialization and discipline of children. However, the benefits that accrue when families are supportive are clear. The family group to which a couple belongs automatically becomes larger when they marry. The spouses are seen as family, and as such, have access to the resources of two families instead of one. Older family members can provide teaching functions for the new couple. Couple that have children also benefit from interactions with other family members, learning to socialize and become members of a larger family unit, not to mention the tangible benefits that other family members can provide.

Couple

Married couples have legal benefits that unmarried couples generally do not have. Legally, a spouse has access to the health insurance of the other and is allowed to make decisions for an ill partner when he or she is unable to make those decisions independently. In many nations, a spouse is also entitled to the retirement benefits of the deceased spouse, and married couples are given tax benefits. Married couples are also seen as more desirable parents to adopt children. In addition, in a court of law, spouses are not required to testify against each other. These benefits of

marriage are not given to unmarried cohabiting couples. Although marriage provides many other benefits, the legal benefits, in large part, are those that same-sex couples are fighting for.

There are other, less tangible benefits to marriage. Marriage gives couples a way to demonstrate their commitment to each other publicly. Being married bestows a sense of legitimacy, recognition as a couple, and inclusion into the larger society, which are other reasons that some same-sex couples want the right to marry.

Although the benefits of raising and nurturing children can far outweigh the costs, the changes children bring a couple's life are daunting at first. Day-to-day routines must change drastically to adjust to a new baby who is dependent on parents for every aspect of living. The joys of raising children, as well as the strains, can be shared by spouses, and may expand their "couple identity" as they become parents. However, if a marriage is troubled, having children usually does not solve problems. Research indicates that couples' interaction patterns generally do not change after having children. For example, spouses who engage in destructive patterns of interaction before having children continue to behave in destructive ways after having children. Research also shows that for most marriages, marital quality declines after having children, but stability increases. This downturn in marital quality occurs especially in younger couples who have children early in marriage. Thus, having children can be a double-edged sword for many couples.

Marriage can also be a source of social support in the sense that spouses help each other in times of need. Marital support is exemplified by having someone to confide in when upset, being taken care of when ill, and being valued as an individual. Marital support engenders the sense that one is not alone when facing stressful situations. One person's problems become *our* problems and can be faced together, fostering the attitude of "you and me against the world." Thus, problems may not seem as bad when someone can be counted on to help and reassure.

Individual Well-Being

U.S. society is considered to be individualistic compared with many Asian countries that are

considered to be collective societies. Therefore, it is not surprising that many of the benefits of marriage in Western society accrue to the individual. Individuals who are married are better off in many ways—physically and psychologically—than are people who are not married.

Physical Health

In Western society, married people are healthier than unmarried people. There are two major hypotheses for the health advantage of marriage. The first is selection. That is, healthier people choose (are selected or self-select) to be married. People who choose to be married often have more financial resources, less stress, more social support, and better health habits than do those who choose to be single. These advantages, at first glance, are not benefits to the individual because they exist before marriage. However, when two people with these same advantages combine resources, marriage can enhance their existing healthy lifestyle.

The second hypothesis for the health advantage of marriage is protection from ill health. Protection (as opposed to selection) is a benefit of marriage because it accrues after marriage. Interestingly, the health advantage after marriage is stronger for men than for women. One reason married men are healthier than unmarried men is that women are more likely than men to attempt to influence their partner's health-related behaviors (such as taking medication, visiting doctors, eating healthy foods). As such, wives are more likely than husbands to urge their spouses to seek medical help and even make their appointments with physicians. Further, men are more likely to depend on their wives for social support, whereas women tend to be more integrated into socially supportive networks of friends and family. Thus, in addition to having someone to monitor their health behaviors, men also gain a health benefit by being married to more socially integrated wives. Being integrated into social networks is also a factor that predicts better health.

For men, marital status seems to bestow health benefits upon the married man regardless of how satisfying the marriage is. On the other hand, married women are healthier than single women only when the marriage is satisfying. In other words, unhappy marriages are a greater risk factor for wives than for husbands. There are two

plausible, but not yet empirically established, explanations for the close tie between women's health and the quality of their marriages. Women's self-concept is intertwined with her relationships, so a poor-quality marriage may reflect poorly on the women themselves. Second, because women are also more likely to monitor others' health behaviors in addition to their relationships, they may ignore their own psychological and physiological signs of stress. Thus, women in unhappy marriages are at the same risk of ill health as single women are, and at greater risk of health problems than married men.

In response to acute stressors in laboratory settings (for example, being harassed, public speaking), however, men generally show greater increases in physiological indicators of stress than women do. Although men are affected more acutely by general stressors, research indicates that men's physiological responses to acute stressors tend to be short-lived and dissipate quickly. Conversely, physiological indicators of stress show that women, compared with men, react more strongly to discussions of marital problems. For women, the physiological reactions to the stress of marital conflict appear to last longer and have a longer-term effect than men's reactions do.

As implied earlier, ignoring their own physiological reactions to stress can lead to long-term health problems for women. If women are unaware of their physiological stress, they are unable to reduce it. This phenomenon underscores the point that health benefits of marriage accrue to women only when the marriage is satisfying. Such benefits are more likely to accrue to men regardless of the quality of their marriages.

Psychological Health

Compared with people who are unmarried, married people are also better off in their psychological well-being. That is, married individuals are happier and less depressed. On the one hand, some evidence indicates that happier and less depressed people may be more likely than are unhappy and depressed people to get married. On the other hand, some studies suggest that this greater psychological well-being is the result of the marital relationship rather than the fact that happier people are more likely to marry. It is likely that both

selection and protection play a part in spouses' psychological well-being.

These psychological benefits of marriage have been identified from large research studies comparing survey data from unmarried and married individuals who answered survey questions about life in general. The findings, as such, did not include married participants' own assessment of the benefits of marriage. However, some researchers, in turn, wanted to know whether the individuals themselves were aware of the benefits of being married. To understand whether individuals are aware of the beneficial nature of marriage, Denise Previti and Paul Amato asked a representative sample of married people in the United States open-ended questions about what keeps their marriage together. The most popular answers by far concerned the beneficial or rewarding aspects of marriages (e.g., love) rather than the costs of leaving (e.g., financial interdependence). The next most frequent rewarding aspect of marriage was friendship or companionship. Thus, the rewards most often mentioned (love and friendship) were those that emphasize feelings of connectedness and sharing life with another person.

In a sense, this research indicates that spouses know what their marriage provides for them. They see what marital support can do. Perceiving that such support is available has been shown to benefit individual's mental health in addition to their marital satisfaction. As such, trusting that someone will "be there" in times of trouble fosters a sense of personal security and well-being. People who were insecure in relationships can become more secure over time when they are in a trusting committed relationship. When marital support is consistent, insecure wives, especially during the transition to parenthood, become more secure.

Marriage provides people with someone to count on during times of trouble and provides someone to listen and understand when things go well. Researchers have found that spouses who share day-to-day positive events with each other feel positive emotions and are more satisfied with their relationships. Again, these benefits accrue only to marriages that are satisfying. Dissatisfied spouses do not enjoy these benefits and are likely to suffer significant costs.

MARRIAGE, EXPECTATIONS ABOUT

Although most adults in the United States will marry at some point in their lives, people's expectations about marriage may influence their decisions about when to marry their partners and whether marriage is an appropriate choice for them as individuals. In scholarly research, expectations about marriage have been defined in two primary ways. First, marriage expectations have referred to unmarried people's perceptions of whether they will marry their current partner or anyone else in the future. Second, marriage expectations have referred to unmarried people's perceptions of what marriage will or should be like.

Scholars have been interested in studying expectations in both of these ways to better understand dramatic changes in contemporary marital behavior such as delays in marriage (waiting until later ages to marry), increases in cohabitation (living with a partner outside of marriage), and high rates of divorce. This entry examines what existing research tells us about the expectations people hold about marriage—both whether they think they will marry and what they think marriage will or should be like—and the implications of these expectations for their marital behavior.

Do Unmarried People Think They Will Get Married?

A growing number of adults in the United States are waiting until later ages to marry, consistent with recent trends in Canada and Europe. For example, U.S. Census data from 2006 show the median age of first marriage was 27.5 years for men and 25.5 years for women, representing a 5-year rise for both groups since 1959. At the same time, many adults are choosing to live with a partner before marriage, and a minority will not marry at all. As people spend a larger proportion of their adult lives as single individuals rather than in marital relationships, the chance that they will have a child outside of marriage during this time also increases. Because there are more alternatives to marriage today than in the past, researchers have been particularly interested in examining the marriage expectations of people who have chosen to live with their partners and who have had a child outside of marriage. Much of this research has examined how unmarried people who are already in relationships assess the likelihood of marrying their current partner to understand why delays in marriage are occurring. When people are not in relationships or do not expect to marry their partners, studies have also asked whether they expect to marry anyone else. This question is designed to assess whether people are rejecting marriage altogether rather than simply delaying it.

In general, existing research shows that most unmarried adults expect to marry, even when they have chosen to cohabit or have a nonmarital birth. Studies also suggest that many people who live with their partner view cohabitation as a step

toward marriage. Almost 9 of 10 single women without children expect to marry their partner or someone else in the future, compared with about 7 of 10 single women with children. About three-quarters of cohabitators (or people living with someone) say they expect to marry their current partner. Similarly, most unmarried people who have had a child outside of marriage indicate a “pretty good” or “almost certain” chance of marrying the other parent at the time of their child’s birth. Research suggests that most cohabiting partners and unmarried parents also agree with each other about their chances of marriage, with the majority sharing the view that marriage is likely. When partners disagree, men are more likely to expect to marry than are women.

Some people’s expectations may be lower than others if they do not want to marry, if they do not perceive themselves to be desirable partners, or if they do not think they have many opportunities to marry. For example, women’s opportunities to marry may be lower in low-income, African-American communities, because of high rates of incarceration and mortality among men. Studies suggest that unmarried women are less likely to expect to marry their partner or someone else if they are older, have less education, come from disadvantaged background, or if their partner is of low socioeconomic status. The quality of unmarried couples’ relationships, personal problems experienced by either partner, and each partner’s beliefs about gender may influence their marriage expectations. In particular, unmarried mothers are more pessimistic about the likelihood they will marry their child’s father if there is a high level of conflict in their relationships, if they do not trust members of the opposite sex, or if their partner has drug or alcohol problems or has been violent toward them.

Do unmarried adults’ expectations about whether they will marry predict whether they will actually get married? Research shows that people who report high expectations about marriage are much more likely to make this transition than are people who do not think marriage is likely. Although marriage occurs more often when either partner expects to marry, couples are much more likely to formalize their unions when both partners hold similar expectations. When partners disagree, men’s expectations about marriage seem to be

more important for making this transition than are women’s expectations. At the same time, many unmarried people who say they expect to marry their partner do not follow through on their plans, particularly if they are members of disadvantaged groups. Therefore, policymakers have been interested in understanding how issues disproportionately affecting low-income and minority communities, such as male unemployment and incarceration, may also represent important barriers to marriage.

What Do Unmarried People Think Marriage Will or Should Be Like?

Another way unmarried people’s expectations about marriage have been examined is by investigating what they think marriage will or should be like. Sociologist Andrew Cherlin has argued that marriage went through two major transitions in the 20th century that had important implications for what people expected from marriage. In the first half of the century, he suggests that the companionate marriage, in which marriage was based on the emotional satisfaction of spouses who performed certain marital roles, replaced the institutional marriage, in which marriage held a more important place in the extended family and community. In the latter half of the century, the companionate marriage was replaced by a more individualized view of marriage, in which self-development, flexible marital roles, and communication were increasingly expected in marriage. In addition to desiring emotional fulfillment and equality in marriage, Cherlin argues that more unmarried adults are delaying marriage until they have attained particular economic goals or have achieved a certain level of economic stability.

Empirical studies of unmarried adults support this argument. For example, nationally representative surveys have documented greater acceptance of equalitarian attitudes in regard to gender roles between the 1960s and 1990s among both men and women. In studies of college students, also conducted during the 1960s and 1990s, love and affection were emphasized as the most important components of marriage, whereas expectations for moral and religious unity, the maintenance of a home, and achieving a respected

place in the community were considered the least important. During this time, students' expectations that marriage would offer companionship and emotional security also grew while their expectations that marriage should involve children declined.

Other research has focused on how adults perceive the anticipated benefits and costs of marriage. Studies of unmarried adults who do not live with their partners find that most thought their lives would be better or much better if they were married. In particular, they expected their sex lives, overall happiness, standard of living, and emotional security would improve. In contrast, those who did live with their partners usually did not expect their lives to change much. Those who did expect changes, however, also thought marriage would improve their lives, especially their happiness and emotional and economic security. The one area that was not expected to improve—particularly among male respondents—was their freedom to do what they want. Couples who think their lives would be worse by making this transition have also been found to assess their own likelihood of marriage as lower, indicating there is a link between what unmarried people think marriage will be like and whether they think they will marry.

If unmarried adults generally expect their lives to be better if they married, why are they delaying marriage much longer than in previous decades and a small minority are not marrying at all? Historians such as Stephanie Coontz have argued that some of the same factors that have made marriages more satisfying in contemporary society have also made marriage less stable. Although marriages today have a higher risk of dissolution than in the past, most people still expect marriage to be a lifelong commitment. Therefore, they may be thinking more carefully about choosing a partner or a relationship that will not end in divorce. At a time when alternatives to marriage, such as cohabitation and single parenthood, have become more acceptable, interviews with couples in diverse socioeconomic conditions suggest that unmarried partners are waiting until their emotional and economic expectations for marriage are already met before taking this step.

MARRIAGE, HISTORICAL AND CROSS-CULTURAL TRENDS

Marriage is defined by the *Oxford English Dictionary* as “the formal union of a man and a woman, typically as recognized by law, by which they become husband and wife.” Marriage as an institution has existed across the millennia,

although it has often taken different forms. Marriage is usually highly valued by both the couple and the wider society, which tends to see it as an important means of regulating sexual expression within permitted limits. Marriage has also been seen as a “social glue,” binding individuals, kin networks, and wider society within a series of prescribed commitments. This entry gives a brief historical perspective on marriage, considers gender roles within marriage, then turns to some notable cross-cultural variations in marriage and patterns of change in different cultures.

Brief Overview of Marriage

For thousands of years, marriage was seen by society as primarily functional, serving political, economic, and social ends, as well as guaranteeing procreation with “approved” partners. For the rich, marriage was important for inheritance and the keeping and consolidating wealth. As a result, strategic alliances were arranged, often with minimal reference to the individuals concerned. For the poor, marriage was a means of bringing in new resources or skills, although a lack of resources meant that social mobility through marriage was relatively rare. Although individuals often fell in love with “inappropriate” others (as in the story of Romeo and Juliet), love was generally seen by families and the wider society as a poor reason for marriage. Instead, the family and wider social network was key in bringing suitable partners together.

The idea that individuals could marry for love, and that there might be a “one and only” irrespective of resources, became more prevalent in Western societies during the 18th and 19th centuries. Industrialization prompted a loosening of social ties, as individuals moved away from their families to the cities and enjoyed liberation from traditional role constraints, more financial independence, and greater opportunities to choose their own partners. At the same time, the economic challenges of these changing societies led individuals to retreat into their partnerships as an escape from a harsh world. This idealization of marriage was propagated through romantic novels of the time, and later through cinema and other media. The “golden age” of Western marriage was arguably in the

years immediately after World War II. At this time, marriage rates were higher in the United States than earlier in the century, and the age at which individuals married dropped. This was accompanied by a notable baby boom.

It has been suggested that marriage in Western societies decreased in importance in the 1960s. Increasing individualism in society led people to demand more from their relationships, with growing tensions between the fulfillment of personal desires and the commitments required for a successful marital relationship. Both actual and ideal age at marriage increased, and fertility rates decreased. There was also a decrease in numbers of those marrying. Women’s increased participation in the workplace in particular gave them new opportunities to meet potential partners, and their increased economic independence provided them with the means to “go it alone” if their marital relationship was unsatisfactory. New and more liberal divorce laws allowed for no-fault divorces that eased the divorce process and was associated with the marked rise in divorce rates in the 1970s and 1980s in the United States and Western Europe. In the United States and Canada, divorce rates quadrupled during the last three decades of the 20th century. As individuals lived longer, they were spending a smaller proportion of their lives married, or at least married to their first spouse.

Marriages have become deinstitutionalized with many of the social norms that governed behavior in marriage weakened. Recent decades have also seen a marked growth in cohabitation in Western societies, beginning in most industrialized societies in the 1970s and accelerating in the 1980s and 1990s. In both the United States and Britain, cohabitation was at first more common among divorcees, but later became more popular among those who had yet to marry. Nearly half of U.S. children now expect to spend some time in a non-traditional family, as a result of being born outside marriage, or as a result of divorce.

Although some changes in marriage patterns are indisputable, some scholars have argued that these changes in marriage patterns have been exaggerated. In the United States, the proportion of non-married women older than age 18 was actually similar at the beginning and end of the 20th century. The divorce rate was higher in Malaysia in the 1940s than it is in contemporary North

America; cohabitation was relatively common in early 20th century England. Furthermore, despite the changes noted previously, it is not clear whether that there has been any real decline in the esteem in which marriage is held. The percentage of unhappy marriages has not necessarily increased, although leaving such marriages has become more likely. U.S. research shows that mean levels of marital happiness were nearly identical in 1980 and 2000. In the United States, evidence shows strong commitment to the idea of marriage, even among those least likely to marry (for example, African Americans). Most North Americans believe that marriage is for one's lifetime and should only be ended under extreme conditions. Most continue to believe that parenthood is fulfilling and maintain a commitment to the marital ideals of a family with children. Some evidence also indicates a decline of divorce rates in both the United States and the United Kingdom (in England, the divorce rate in 2006 was at its lowest for more than 20 years).

Rates of polygamy worldwide are largely on the decrease, with monogamy increasingly the favored form of marital relationship. This is often as the result of direct governmental intervention (such as the introduction of new marriage laws in the 1950s in Vietnam and Yemen). A decline in polygamy is also associated with increased literacy and educational rates among women. Particular economic stresses, however, can lead to some unofficial polygamous behaviors, such as when migrant workers living away from home for extended periods form second families.

Gender Roles in Marriage

According to prevailing theories, modernization brings predictable changes to gender roles in marriage. In preindustrial marital relationships, couples performed mainly material tasks as part of shared common economic activities. High levels of economic uncertainty tended to reinforce traditional authority patterns, with a strong division in gender roles. Childbearing and childrearing were seen as the major female role. During a later bourgeois family period—when middle-class women stayed at home—couples carried out a mixture of material and socioemotional tasks, with the man having the principal financial responsibility and

the woman attending more to childrearing and the socioemotional needs of the family. In a postmodern world, there has been movement toward greater egalitarianism in gender roles in affluent Western societies. Roles have been reevaluated as women work outside the house: Whereas 30 percent of U.S. women worked in 1950, 55 percent did so in 1986. Egalitarian and liberal values are particularly strong among young, women, the well educated, and those who are less religious. Decision making has become more egalitarian between the sexes. However, although women may have become less defined by their family roles, no clear model defines women's life prospects. Indeed, the conflict between work and family remains a significant one for Western women. Although men have changed many of their views on gender roles, they have been slower to change than women in actual practices.

Cross-Cultural Variations

Most of the previous discussion has been framed in the context of Western marriage (primarily U.S. or Western European patterns). Although the patterns of modernization described can be seen as broadly representative of changes across the globe, there are important variations in these configurations and significant resistance to change in some cultures.

Religion

Religion is an important socializer of moral values and normative behaviors within marriage. Postindustrial societies are generally only moderately religious, with the comparatively religious United States a notable exception. In Islam, marriage is often between paternal cousins. Permitted marital age is often younger, as early as 9 in some cultures. Husbands in Islamic societies are more likely to retain authority over their wives and are less likely to encourage equality in decision-making. Unlike elsewhere, young people in Islamic cultures are no less traditional in their attitude toward marriage than do their elder counterparts. Islamic cultures are generally less likely to permit divorce, particularly if the woman wishes to initiate the break. Divorce can also be difficult to

obtain in some traditional Catholic societies, such as Chile.

Migration and Marriage

Around 2 percent of the world's population lives in countries other than those in which they were born. Marriage is now a major basis for migration into Western countries. Migration can both accelerate social factors related to modernization (by, for example, necessitating the employment of women who previously stayed at home). It can also reinforce other aspects of traditional authority (for example, when families encourage individuals to marry kin to allow those kin to migrate). Rather ironically, given that migration is usually aimed at helping the family, migration often exaggerates existing strains and provides new marital problems. For example, migrant workers in Africa are often absent during the critical early years of marriage and childrearing, frequently leading to a decline in marital quality. Life in migrant hostels can often mean the exclusion of spouses, which can create opportunities for infidelity. Unemployment and hunger has led many married women to establish economically supportive "Nyatsi" relationships, in which a married woman takes a male "friend." High levels of out-migration in Botswana have also substantially changed marriage timing, with marriages now delayed until the man is in his 30s and has the financial resources to establish a family home. Studies of male Indian migrants to the Middle East have found that women back home take on new responsibilities, leading to many new adaptations and changes for these women. This may often increase the self-confidence and self-esteem of these women, but lead to potential tensions with the husband on his return.

Marriage in Fast-Changing Societies

Rapid social changes provide new challenges for marital relationships, but can also help cement relationships. The economic pressures that followed the end of Communism in Eastern Europe caused emotional stress between partners, and have been associated with an increase in problems such as drinking and depression. Widespread unemployment in Russia led to government

directives that discouraged women from working outside the home. This loss of employment has been related to a decrease in egalitarianism in marriage. However, in the case of some more traditional cultures, such as the Georgian Republic, women were seen as more adaptable to changing market demands, and economic changes provided them new opportunities. Furthermore, although marriage rates decreased in Eastern Europe during this time of transition, numbers of divorces also decreased sharply as couples maintained their relationships to help deal with the difficulties of this time.

In China, the introduction of the one-child policy in 1979 may have had an important impact on family size. This policy also appears to underlie the large sex ratio (1.17:1 male live births to female live births), with some evidence of sex-selective abortion. This has led to concern over a lack of future female partners and national campaigns aimed at increasing the value of women. As family size in general declines, evidence indicates that the intimacy between the couple increased, alongside a strong emotional attachment to the single child. Greater freedom in partner choice and increased education has meant that couples are less keen to live with their parents, but a chronic lack of housing, particularly in large cities, has meant that coresidence patterns have persisted. Often, however, this means residence with the woman's parents, rather than the husband's, as in previous times.

As in the West, divorce rates in Asia have been growing. A failure of partners to "deliver" in the more materialistic 1980s has been seen as a major contributor to the increase, as have the temptations offered by large-scale internal migration (such as among the so-called astronauts who left mainland China to work in Hong Kong in the 1990s). Remarriage rates are high, however: in China 96 percent of divorcees remarry, 83 percent within 5 years. Furthermore, some of those who declared themselves to be single did so to obtain enhanced rations following changes in household registration procedures.

Looking Forward

In the future, marriage is likely to remain of great significance—to both individuals and societies.

Cohabitation rates may continue to increase, although most will still cohabit as a trial period before marriage, and will want to have their children within marriage. Furthermore, although modernization forces may encourage individuals to seek greater independence from their families, and greater equality between the sexes, significant religious and cultural forces will continue to play an important role in influencing marriage patterns and behaviors.

MARRIAGE, TRANSITION TO

One of the most significant psychosocial adjustments in adulthood is the transition to marriage. Although most men and women in the United States will marry at some point in their lives and

most look forward to this event with anticipation and excitement, the transition to marriage also involves adaptation to a variety of tasks that may fundamentally alter spouses' view of themselves and their alliances. During the first few years of marriage, spouses typically define new roles, which may be less individualistic and more interdependent; alter their social networks; and establish a core alliance with each other rather than with their families of origin. Additionally, more than 33 percent of divorces occur within the first 5 years of marriage. This entry presents theories about why couples succeed or fail in making the transition to a stable, satisfying marriage, identifies behaviors that put couples at risk for marital problems and behaviors that protect them from marital distress and divorce, discusses the impact of external stressors, and identifies the changes that individuals may experience in making the transition to marriage.

Theoretical Models

Several models have been developed to explain distress and divorce during the early years of marriage. The disillusionment model contends that as new marriages progress, spouses become disillusioned by the discontinuity between their idealized expectations before marriage and the actuality of their marital experiences. Before marriage, individuals may actively avoid conflict with their partners, manage impressions of themselves, and view their partners in the best possible light. During the early years of marriage, partners typically perceive a loss of love and affection, experience increased ambivalence about their relationships, and begin to view their partners and relationships in less positive lights. Some empirical evidence supports the disillusionment model because couples who divorce early in their marriage are more ambivalent about their marriages, report falling out of love at higher rates, and perceive their partners as less responsive to their needs.

Most researchers find that in happily married couples, a general decline in marital satisfaction occurs naturally. Therefore, some researchers have argued that disillusionment is an inevitable process as couples begin the transition from dating to newlywed marriage to early marriage, and therefore

cannot be a useful explanatory model because it occurs for distressed as well as happily married couples. The enduring dynamics model, in contrast, postulates that couples enter into marriage with at least some knowledge of the shortcomings of the relationship and their partner. Relationship distress, therefore, arises from interpersonal processes that are already present during courtship and that endure into marriage. This model suggests that differences between partners that are present while the couple is dating erode marital satisfaction over time and may contribute to eventual divorce. Some data support this model because the intensity of newlywed romance and negativity assessed at marriage predicts marital satisfaction 13 years later as well as, for couples who divorced, the length of time married before divorce.

Finally, the Vulnerability-Stress-Adaptation Model is an integrated model of marital processes that contends that marital quality is a function of enduring vulnerabilities that the partners bring to the marriage (e.g., attachment style, personality traits, etc.), stressful events experienced by the couple (e.g., relocation, starting a new job, having children, etc.), and the adaptive processes (e.g., social support, positive affective expressions, problem solving, etc.) couples use to contend with vulnerabilities and stressors. Considerable research has supported this model as a useful one in examining marital qualities, particularly marital problem solving, that likely moderate the effect of life events on spousal functioning. A strength of this more comprehensive model is that it reflects the diverse individual, relational, and external variables that contribute to marital quality and stability.

High-Risk Behavior

Research, guided by the theories presented, has identified behaviors in newlywed spouses that predict success in the transition to stable and satisfying marriages. Perhaps the most extensively studied area of marital relationships is communication behavior. Research on the verbal content of communication during problem-solving tasks suggests that negative behaviors distinguish satisfied from dissatisfied couples, especially hostility, stonewalling, and contempt. Rates of negative verbal communication during conflict discussions

have been shown to predict declines in satisfaction over time, particularly in the absence of positive affect and when the ratio of negative to positive behaviors is high (stable marriages typically evidence a 5-to-1 ratio of positive to negative exchanges). Growing evidence indicates that the specific emotions displayed in conflict discussions are even more powerful in differentiating distressed from nondistressed couples than is the verbal content of their discussions. For example, negative affect, particularly when it is reciprocated by the partner, appears to be a particularly powerful predictor of marital distress across many studies and has been shown to distinguish happily married from unhappily married couples after 4 years of marriage. Another important maladaptive pattern of communication is the demand-withdraw pattern, in which one member criticizes, nags, and makes demands of the partner (the demander), and the other partner withdraws and attempts to avoid conflict (the withdrawer). This pattern has been well established cross-culturally and is consistently associated with relationship dissatisfaction.

In addition to communication behavior, several studies of newly married couples indicate that the prevalence of intimate partner violence is substantially higher in young, recently married couples. If violence occurs early in the relationship, it is likely to continue, although its frequency may decrease overall. One third of engaged couples and approximately half of recently married couples report physical aggression in their relationship. The presence of physical aggression in a relationship is concurrently and prospectively associated with greater marital dissatisfaction and increases the likelihood of marital dissolution, even after controlling for psychological aggression, relationship length, and prior marital satisfaction. Aggression in newlywed couples reliably distinguishes between couples who remain married and those who become separated or divorced.

Protective Behavior

Supportive behaviors (i.e., empathic responding, constructive interactions, social support) have been associated with higher marital satisfaction, lower stress experience, and better psychological

and physical well-being. Longitudinal research suggests that newlyweds with poor social support skills are at increased risk of distress and divorce 2 years after marriage. Other researchers have expanded the concept of social support to include dyadic coping, which involves both ensuring the partner's well-being and enhancing the marital relationship. Research in this area suggests that more positive and less negative dyadic coping is significantly associated with longitudinal relationship satisfaction.

Positive affect, including expressing positive emotions, constructive engagement in the marriage, and empathic listening, is concurrently and prospectively associated with marital satisfaction. Some data suggest that positive affect can neutralize the effects of detrimental behaviors. That is, for some couples who display low levels of positive communication skills or high negative skills in problem-solving discussions, positive emotions such as humor, affection, and interest seem to diminish the negative effects, to the point where they have little bearing on declines in marital satisfaction. Conversely, the absence of positive affect appears to amplify the effects of unskilled communication patterns. This does not imply that *only* being positive is beneficial; some data suggest that exclusive positivity and excessive repression of negativity by wives is detrimental to marital relationships.

Cross-sectional research also suggests that acknowledgment of a partner's admirable qualities, pleasure derived from the relationship, and time spent with one's spouse are positively related to marital quality. For newlyweds, the relative novelty of the relationship and the excitement in forming a marital bond may also enhance marital quality. Data suggest that couples who maintain a high level of joint novel activities throughout early marriage may maintain higher relationship quality. Finally, relationship self-regulation, or the degree to which partners work at their marital relationship, predicts concurrent and longitudinal marital satisfaction for newlywed couples.

External Stressors

The stressful life events that couples experience in the early years of marriage have been linked to marital quality, in both cross-sectional and

longitudinal studies. When couples experience acute stress, they tend to report higher levels of problems in the marriage, communication difficulties, and a tendency to blame their partner for negative events. Research has also suggested that marital quality is lower among couples experiencing high levels of chronic stress and that chronic stress predicts more rapid declines in marital satisfaction. However, marital satisfaction is linked most strongly to stress when couples experience *both* chronic and acute stress; that is, negative life events are particularly detrimental when the external context places additional demands on an already strained system. Some evidence also indicates that physical violence is more likely to occur under conditions of high chronic stress combined with acute stress.

The effects of external stress on relationships may be attenuated by appropriate supportive coping responses in spouses. In general, positive responses, such as providing support and making allowances for the partner's aversive behavior, function to reduce the negative impact of stress on the relationship. For example, marital support has been shown to reduce the association between emotional distress and stressful economic events. Further, spouses who make relationship-enhancing attributions about their partner's behavior when under stress tend to fare better than do spouses who make distress-maintaining attributions about their partner's behavior.

Impact on Individuals

In addition to changes in the relationship, the transition to marriage involves changes in a variety of psychological and behavioral patterns for the individual members of the couple. One potential area of change for an individual is attachment style. John Bowlby originally speculated that infants develop working models of themselves (e.g., as lovable) and of others (e.g., as dependable) based on early interactions with caregivers, resulting in attachment styles that are presumed to be fairly stable across time. However, recent research has suggested that these spouses may transfer attachment functions (safe haven, secure base, etc.) from their family of origin to their spouse. The marital relationship, because it creates

a new caregiving environment and provides some psychological and physical distance from the family of origin, may be an opportunity for individuals to transfer their attachment functions to their spouses. Research examining attachment stability during the transition to marriage has confirmed that attachment representations are largely stable for most individuals, particularly for those who were securely attached before marriage. However, newlywed individuals with insecure attachment styles do tend to experience more security (i.e., feel less anxious about abandonment and more comfortable depending on their spouse) than they did before marriage.

A second potential area of change is in social networks. Newlyweds tend to go through a beneficial process of integrating social networks during the early years of marriage, reinforcing the couple identity and providing support for the new relationship. In contrast, newlyweds who continue to maintain predominately separate social networks may undermine the marital relationship and reinforce individuation and personal goals. Indeed, research has demonstrated that higher interdependence of family and friend networks predicts higher marital quality after one year of marriage, particularly for wives. However, these effects are not always positive. Some evidence indicates that maladaptive behaviors, such as drinking, may be fostered by integration of social networks.

Conclusion

Taken together, these data suggest that the transition to marriage is a complex one that involves many systematic and predictable changes at the individual, dyadic, and environmental level. The research has identified several robust correlates and predictors of marital *dissatisfaction*, but has been less systematic in the identification of those variables that contribute to marital *satisfaction*. If one assumes that marital satisfaction is more than just the absence of marital dissatisfaction, as considerable research and theory suggests, the research has less to offer for those facets that contribute to a lasting, fulfilling relationship. Future research is necessary to better elucidate those positive elements that can facilitate the transition in newlyweds and beyond.

MARRIAGE AND HEALTH

A key human relationship for most adults is marriage, which confers economic, social, and psychological benefits such as increased earning potential, resources for raising a family, and fulfilling needs for security and belonging. Across a number of surveys, married individuals report greater happiness and life satisfaction and have a lower risk of clinical depression than do their unmarried counterparts. In addition to these benefits, marriage confers benefits for physical health. At the same time, marriages characterized by low marital satisfaction and high conflict have damaging effects on physical health. This entry reviews evidence for

the physical health benefits of marriage, the link between marital quality and health, mechanisms that explain how marriage affects physical health, and the implications of marriage and health for interventions.

Marital Status and Health

Across a number of large-scale epidemiological studies, nonmarried individuals have higher rates of mortality compared with their married counterparts from all causes. In addition, morbidity among married persons is lower compared with unmarried persons across a variety of health conditions, including cancer, heart attacks, and surgery. Across several studies, the health benefits of marriage are also greater for men compared with women, such that the additional risk for mortality in comparing nonmarried men to married men is much larger than in comparing nonmarried to married women.

The two primary explanations for why marital status is related to morbidity and mortality are *selection* and *protection*. According to selection, marriage itself does not cause decreased morbidity and mortality; instead, a selection bias exists such that individuals who are healthier and engage in less health-destructive and more health-protective behaviors are more likely to get married. The protection explanation suggests that regardless of an individual's premarital health or functioning, marriage confers specific economic and psychological benefits, such as increased household income and social support, which contributes to better health. The selection and protection explanations are not mutually exclusive, and epidemiological findings support both explanations. Unfortunately, because relationship scientists cannot experimentally manipulate marital status, definitive resolution of these explanations is unlikely.

Marital Quality and Health

Although marriage on average is related to better overall physical health, people in troubled marriages have worse mental and physical well-being compared with people in satisfactory and happy marriages and, in some studies, nonmarried people. The most dramatic examples of the relationship

between marital *quality* and health come from studies of patients with existing chronic medical conditions. Low marital quality, typically measured through self-report, predicted earlier mortality over long-term follow-up in end-stage renal disease (46 percent increase in risk for mortality over 3-year follow-up) and congestive heart failure patients (65 percent increase in risk for mortality over 4-year follow-up). Beyond mortality, low marital quality is also related to increased risk of coronary events (including cardiac death, acute myocardial infarction, and revascularization procedures) in patients with cardiovascular disease and in a large 9,000-person cohort of British civil servants, increased illness symptoms over longitudinal follow-up (4 years) in healthy married couples, and increased pain flares in patients with rheumatoid arthritis.

In contrast to research on gender differences in marital status on health, where men derive greater health benefits from marriage compared with women, research on marital quality and health shows an opposite pattern. Specifically, the effects of marital quality on health are generally stronger for women compared with men. For instance, in a longitudinal study of participants in the Alameda County Study, increased marital strain was related to increased self-reported ulcer symptoms at 8- to 9-year follow-up in women, but not men. In addition, large, prospective longitudinal studies also show that lower marital quality is related to increased risk of disability and mortality over long-term follow-up (6–15 years), again in women, but not men.

How Does Marital Quality Affect Health?

The prevailing framework that explains the health benefits of healthy marriages and the detrimental health consequences of unhealthy marriages is the *stress/social support hypothesis*, originally put forth by Bonnie Burman and Gayla Margolin. The stress/social support hypothesis suggests that stress and support in marriages influences health through a number of pathways, including influences on the individual's cognitions, emotions, health behaviors, coping behaviors, and biological systems. The model was further elaborated on by Janice Kiecolt-Glaser and Tamara Newton, who suggested additional pathways, including mental

health and psychopathology, and individual differences in personality such as hostility. In addition, the pathways that explain relationships between marital quality and health are influenced by gender-related traits, cognitive schemas, and social roles that explain why marital quality has stronger effects on health for women compared with men. A number of entries discuss these mediating pathways and gender-related constructs; this entry focuses on how marriage influences health behaviors and biological systems.

Health Behaviors

Married partners influence each other's behavior across many contexts, including health-promoting behaviors (physical activity, diet, compliance with physician recommendations) and health-compromising behaviors (alcohol use, tobacco use, problematic eating). Indeed, large-scale studies indicate that health behaviors such as diet, physical activity, and smoking are highly correlated between spouses. However, studies that focus on couple-based interventions to increase health-promoting behaviors (notably physical activity and diet) and decrease health-compromising behaviors such as smoking have not shown significant success. In addition, attempts by spouses to control their partners' health behaviors are often ineffective in increasing health-promoting behavior, and may be met with resistance resulting in decreased health-promoting behavior and increased health-compromising behaviors. Thus, although married partners influence each other's health behaviors, the direction of influence may not always be in the direction of promoting healthy behaviors.

Biological Systems

Marital quality can also directly affect biological systems that are involved in psychological responses to stress and physical health. The three biological systems that have received the most attention in studies of marriage and health are the *cardiovascular system*, which is responsible for circulating oxygen, nutrients, and numerous cells throughout the body; the *neuroendocrine system*, which helps the brain regulate such important functions as energy balance and reproduction via

chemical messengers called hormones; and the *immune system*, which defends the body against threats such as bacteria, viruses, and parasites. Beyond serving a wide range of life-sustaining functions for the body, malfunctions or deficiencies in these systems are involved in most major chronic diseases.

Most studies in this area involve healthy samples that are disease-free and show low incidence of health-compromising behaviors, or samples where health behaviors are statistically controlled. These studies typically involve studying married couples while they interact with each other, usually involving a discussion (e.g., talking about specific problems in the relationship), coupled with measuring activity in one or more of the biological systems. Marital quality is typically operationalized as levels of hostile behavior, such as put-downs and criticism, during marital discussions. Thus, studies of marriage and biological systems have been mostly restricted to interpersonal interactions in laboratory settings.

The main finding across studies in this area is that hostile behaviors during discussions are accompanied by cardiovascular, neuroendocrine, and immune changes. Couples who show greater hostile behavior during marital discussions have more elevated blood pressure and heart rate compared with less hostile couples. Similarly, greater hostile behavior during marital discussions is related to elevated hormones that are involved in regulating energy balance and that mediate the body's response to psychological stress (including catecholamines such as norepinephrine, and hormones of the hypothalamic-pituitary-adrenal axis such as cortisol). Greater hostile behavior during marital discussions is related to suppression of the immune system's ability to fight off infectious disease and aid wound healing, and exacerbation of the immune system's systemic inflammatory response.

Although couples' behaviors toward each other affect biological systems that affect health, an empirical question is whether behavior in the laboratory actually affects disease-relevant outcomes. Any number of psychological or physical stimuli can cause changes in heart rate, blood pressure, stress hormones, or immune function, without any measurable impact on health or disease. Recent studies have begun to address whether links

between marital functioning and biological systems are relevant for actual disease. For example, coronary artery disease results from the buildup of plaques within the walls of arteries that supply the heart, a process that takes place over several decades before an individual actually experiences a heart attack. A number of studies now suggest that low marital quality and increased hostility within marriages are related to changes in biological measures that reflect the plaque accumulation process (e.g., ultrasound measures of carotid artery thickness, computerized tomography scans of the heart). These studies suggest that being in an unhappy marriage is related to greater accumulation of artery blockage over several years.

Current research has yet to demonstrate whether the link between low marital quality and disease-relevant outcomes is explained by changes in the biological systems described in this entry. For example, one important indicator of hypothalamic-pituitary-adrenal axis function is the slope of change in cortisol secretion from its normal peak in the morning to its low point in the evening. Several studies in independent research groups show that low marital quality is related to flatter slopes (that is, lesser decreases), with levels elevated in the evening hours. Additional studies have linked flat cortisol slopes to disease outcomes including increased coronary artery calcification and fatigue. Thus, although separate lines of evidence suggest that the link between marital quality and coronary artery calcification may be explained by flat cortisol slopes, no studies to date have explicitly tested these links in a single study. Studies of marriage and health are increasingly incorporating assessments of both biological systems and disease-relevant outcomes, and will be able to test links between marital quality, biological systems, and health outcomes in the future.

Clinical Implications of the Links Between Marriage and Health

The importance of marital quality for health suggests that one avenue for improving health outcomes in patients with chronic illnesses such as cardiovascular disease or cancer is improving relationship functioning. Psychosocial interventions that focus on intimate partners or other family

members of chronic illness patients are effective in improving mental health outcomes and, in some limited cases, patient survival. In addition, these interventions also improve the mental health of the partner, particularly interventions that focus on the relationship between the partner and the patient.

Moreover, in some disease contexts, partner and spouse behaviors may play an important role in exacerbating disease symptoms; the most notable context for this is chronic pain. A number of studies show that spouses who respond to their partner's pain behaviors (expressions of pain or limited functioning resulting from pain) with negative or punishing behaviors, or solicitous behaviors (providing assistance, expressing concern) can actually increase their partner's pain severity, limitations resulting from pain, and psychological distress. Thus, interventions that target both relationships between patient and spouse, and the spouse's role in reinforcing their partner's maladaptive pain behaviors would be particularly effective in this context. Overall, links between marriage and health provide additional avenues for psychosocial interventions that may improve mental and physical well-being, primarily by focusing on improving relationships and effective coping with chronic disease.

MARRIAGE AND SEX

Marriage is defined as a legal union that typically occurs between a man and a woman. This interpersonal union is usually of an intimate and sexual nature that carries along with it governmental, social, and religious recognition. *Sex* is most frequently thought of as coitus, or vaginal intercourse (penetration of the vagina by the penis). Although coitus is the most common form of sexual expression, the term *sex* can also include many other types of sexual interaction such as anal intercourse (inserting the penis into the anus), oral-genital stimulation (mouth-to-genital contact), and masturbation (self-stimulation of the genitals for sexual pleasure), to name a few.

What is the relationship between *marriage* and *sex*? Why do people marry and what do they expect from their sexual relationship after marriage? This entry examines the relationship between *marriage* and *sex* with a specific focus on expectations of marital sexuality.

When asked about reasons for marriage, U.S. residents most often cite that they marry for love, emotional and economic security, companionship, and their desire to be a parent. Although sexual involvement is commonly experienced in dating relationships, marriage is the most socially accepted context for sexual expression to date. Marriage is the only condition under which the major religions positively sanction sexual interaction between couples. Additionally, marriage remains the primary context for which society approves of the entrance of children into a relationship. The link

between *sex* and *marriage* is particularly important because sex is considered an integral part of a marital relationship. Many believe that sex is the glue that holds a relationship together.

What are common expectations for sex after marriage? After reviewing the literature on marital sexuality, a number of expectations come to light. First, it is expected that to have a satisfying marriage, sex with one's spouse should be both pleasurable and sexually satisfying. A second expectation is that in a healthy marriage, sexual interaction will be desired by both partners and should occur on a regular basis. A third expectation is that a marriage shall remain sexually exclusive, meaning that individuals within a marriage are to remain sexually monogamous and refrain from engaging in extramarital sexual involvement. Fourth, a common expectation in marriage is that marital partners should have the ability for successful and problem-free sexual encounters. And a final expectation is that marital partners should be able to have children if desired.

Marital and Sexual Satisfaction

A common expectation of a satisfying marriage is that one's sexual relationship will be both pleasurable and gratifying. In effect, it is expected that marital satisfaction and sexual satisfaction share a common bond and that both will be present in a healthy marriage. The association between sexual and marital satisfaction has been a well-studied area of investigation. In fact, a large body of literature documents that satisfaction with one's sex life is tied to the overall satisfaction of the relationship in general, thus supporting the idea that marital and sexual satisfaction are interrelated. The interrelationship of sexual and marital satisfaction has led to much speculation about which comes first. Does a satisfying sexual relationship lead to a satisfying marriage? Or does a satisfying marriage lead to a satisfying sexual relationship? These questions have been long debated in the literature.

Although the interrelationship of sexual and marital satisfaction is supported, the direction of this association is not yet clear. For example, some scholars report that individuals' sexual satisfaction predicts their overall marital satisfaction, whereas

others posit that the opposite is true. For example, following this assumption, as one experiences a decrease in marital satisfaction, one's sexual satisfaction will decline as well. Still other researchers claim that the relationship between sexual and marital satisfaction is reciprocal, meaning the levels of sexual and marital satisfaction jointly affect each other. Collectively, these findings suggest that the association between sexual and marital satisfaction warrant further exploration to better highlight the process in which they occur and contribute to each other. Although the relationship between sexual and marital satisfaction has been well documented, much of the literature on the link between *marriage* and *sex* has focused on coital frequency (how often a couple engages in sexual intercourse).

Sexual Frequency and Marriage

Another common expectation within marriage is that in a healthy marriage, sex will occur on a regular basis and will lead to a more satisfying sexual relationship. Although the data show that married couples have sex one to two times per week on average, it is assumed that the higher the coital frequency, the more satisfying the sex life and marriage will be, and several studies have supported the link between sexual frequency and sexual satisfaction. Specifically, studies have documented that how often a couple engages in sexual activity can be a measure of the level of satisfaction in the sexual relationship. In effect, these findings support the premise that couples who have the most frequent sex are the most sexually satisfied.

Sexual frequency also relates to overall marital satisfaction. For example, findings document that partners who have frequent sex, and are satisfied with their sex life, are more satisfied with their overall marital relationship compared with partners who have less frequent sex and who are less satisfied with their sex life.

Given that data support the notion that sexual frequency can be an indicator of marital satisfaction as well as sexual satisfaction, many investigators use sexual frequency as a barometer of the health of the sexual and marital relationship. However, although sexual frequency can be an indicator of higher satisfaction, many individuals

remain satisfied even after experiencing a decrease in sexual encounters. During the first few years of marriage there is a significant drop in sexual frequency. This drop in frequency tends to slow and level off in the years thereafter. In addition, the presence of children is strongly related to changes in marital and sexual satisfaction over time. In particular, marital satisfaction and sexual frequency tend to decrease after the birth of a child. Moreover, the preferred amount of sexual frequency also undergoes a decline following the transition to parenthood. Furthermore, marital satisfaction is lowest among parents of infants. Although sexual frequency declines after the birth of a child, it appears that couples may begin to experience changes in sexual frequency even before their first child is born. However, even after the decline in sexual frequency, most married couples report being generally satisfied with both their sexual and marital relationship.

In addition to the entry of children, employment demands also have a notable influence on marital sexuality. Specifically, pressure from work can result in a decrease in sexual frequency. For example, in a national survey of U.S. residents, the number of hours worked per week was related to one's sexual relationship. In particular, those individuals who worked 40 hours a week or more had more sexual problems and lower levels of satisfaction than did individuals who worked less than 40 hours per week. Moreover, working different shifts also led to lower sexual frequency, lower sexual satisfaction, and an increase in sexual problems. Thus, it appears that many contextual issues such as the transition to new roles (i.e., parenthood), the presence of and age of children, number of hours worked per week, and work shifts all may influence one's sexual and marital relationship. Considering these findings as a whole, even when coital frequency and marital satisfaction decrease, couples report being largely satisfied with their sexual interactions. Therefore, coital frequency may not be the best indicator of how satisfied couples are with their sexual relationship or marital relationship.

Finally, the quality or satisfaction of a sexual episode may have nothing to do with how frequently a couple engages in sexual activity. For example, partners may have differences in opinion as to how often to engage in sexual relations as well

as differences in which types of interactions are satisfying. Moreover, research documents that couples often have discrepant reports of sexual frequency and different interpretations of what constitutes a satisfying level of frequency in their relationships. Even though a couple may report the same level of sexual frequency, a different interpretation of that frequency may emerge, one believing the frequency is high, and the other believing it is low, thus again highlighting that sexual frequency alone may not be the best indicator of satisfaction.

Extramarital Sexual Involvement

Remaining sexually faithful (monogamous) is commonly held as one of the core assumptions of marital relationships. Moreover, many couples feel that failure to remain sexually faithful is a violation of their marital agreement and can be considered as grounds for marital dissolution. U.S. residents disapprove of extramarital sexual involvement (also known as infidelity), and those in many other cultures disapprove of sexual behavior outside of one's marriage. Although some marriages are open marriages (nonmonogamous), the frequency of this type of marriage is small.

Extramarital involvement, or infidelity, typically includes behaviors ranging from emotional involvement to sexual intercourse. Three classifications of infidelity have emerged in the literature. The categorizations are as follows: primarily sexual (involvement in any sexual intimacy from kissing to sexual intercourse that occurs without a meaningful emotional involvement), primarily emotional (involvement in a moderate-to-deep emotional attachment with negligible physical intimacy), and combined-type (involvement includes sexual intercourse accompanied by a deep emotional attachment). Typically, the data show that women more often report being involved in the combined-type of infidelity, one that involves both a sexual and emotional attachment, whereas men are more likely than women to be involved in a sexual relationship void of meaningful emotional connection.

Rates of extramarital sex vary. Although some studies report rates of infidelity to be as high as 25 percent of wives and 50 percent of husbands, these best estimates to date come from a large scale

national survey that reports that approximately 15 percent of wives and 25 percent of husbands had been involved in extramarital sexual involvement including intercourse. Rates of extramarital sexual involvement are much higher when they include emotional affairs and sexual encounters not involving intercourse. The workplace is the most common place to meet extramarital partners. However, with the increase in technology and the popularity of the Internet, online infidelity is becoming a new phenomenon.

Recovering from infidelity can be a difficult task. Results from a large scale survey of marriage and family therapists identified infidelity as the second most damaging problem couples encounter following physical abuse. Moreover, therapists report that infidelity is one of the most difficult problems to treat. Although treating and overcoming the effects of infidelity can be challenging, research reports that most marriages survive infidelity. Additionally, some evidence indicates that couples who weather the impact of the infidelity emerge stronger after working through the trauma in therapy. Although many factors have been linked to infidelity (e.g., fear of intimacy, relationship conflict, life-cycle transitions), the causes are still not clear, for infidelity may be present in both happy and unhappy marriages.

So, does extramarital sexual involvement lead to the end of a marriage? Some research reports that infidelity is involved in 90 percent of first-time divorces. However, decades of research by John Gottman, a marriage researcher at the University of Washington, finds that only 20 percent of divorces are caused by affairs. Though infidelity may be linked with marital dissolution, it is not clear whether infidelity leads to a decline in one's marital quality or whether it is a consequence of a low-quality marriage. Nonetheless, these data highlight the significant impact extramarital involvement can have on a marriage.

Sexual Problems and Marriage

Although most couples expect that they should have a healthy and problem-free sex life once they are married, many couples experience difficulties with sexual functioning, and many couples will seek marital therapy because of problems with

their sex life. Moreover, not all couples with sexual issues enter therapy with sexual problems; many couples present with general relationship issues but have underlying sexual problems present.

Sexual problems typically consist of sexual dysfunctions, or disorders that interfere with a full sexual response cycle, making it difficult for a person to enjoy or to have sexual intercourse. Common sexual problems include premature ejaculation (inability to reasonably control ejaculatory reflex on a regular basis), erectile dysfunction (failure to achieve or maintain an erection), sexual desire disorder (low or high levels of sexual desire), female arousal disorder (inability to attain or maintain typical responses to sexual arousal), orgasmic disorder (inability to reach orgasm), and sexual pain problems (dyspareunia [painful or difficulty during sexual intercourse], vaginismus [involuntary spasms of the muscles surrounding the lower third of the vagina]). National survey estimates indicate that 43 percent of U.S. women and 31 percent U.S. men have experienced problems with sexual functioning.

Research documents that sexual functioning is important to the development of intimate relationships for both men and women. Specifically, poor marital quality is related to the presence of sexual problems for both men and women. Moreover, sexual problems can affect a person's ability to form and sustain romantic relations, including marriage, and difficulties with sexual relations are linked with an increased risk of marital dissolution.

Many psychological factors have been linked with sexual functioning. Included in this class of influential factors is the state of one's mental health. Emotional problems such as depression or anxiety or drug and alcohol use or abuse are also often associated with impaired sexual functioning. Many social and relational factors have also been found to influence sexual functioning. For example, relational dynamics, such as relationship quality and work status variables including number of hours worked a week and education are associated with sexual functioning.

Sexual Reproduction and Marriage

A final assumption of marriage is that many couples expect that they will be able to have children if they so choose. Reproductive difficulty

(infertility) is typically defined as the failure to conceive after one year of regular sexual intercourse without contraception, or an inability to carry a pregnancy to live birth. Infertility affects approximately 10 percent of people of reproductive age and approximately 15 percent of married couples.

Infertility is typically equally contributed to problems of the male (40 percent) or female (40 percent). The remaining 20 percent is typically attributed to problems of the couple that can include factors such as not enough sex, too much sex, sex at the wrong times of the month, fatigue, and emotional stress. Individual factors such as the effects of sexually transmitted diseases, poor nutrition, or poor general health may also play a role in difficulty conceiving. For males, the problem is most often linked with low-quality sperm, a blockage somewhere between the testicle and the tip of the penis, or erection and ejaculation problems. For the female, infertility is most often linked with age, and the failure to ovulate. Similar to males, at times there may be a blockage (of the fallopian tube) that leads to the inability to conceive. Another common cause of reproductive difficulties for women is endometriosis, a condition in which some cells of the inner lining of the uterus grow in the pelvic and abdominal cavities. Finally, some women experience an inhospitable environment for sperm, which is an immune response or acidic chemical climate in the vagina that can immobilize sperm. In about 15 percent of cases of infertility, there are no identifiable contributions present.

Infertility may have profound psychological effects. Partners may become more anxious to conceive, which consequently can lead to further problems with sexual functioning. Marital discord often develops in infertile couples. Many couples suffer from high levels of anxiety and disappointment. Moreover, it is not uncommon for women struggling to conceive to experience clinical depression. What's more, the inability to conceive bears a stigma in many cultures. Research documents that even couples who chose to bear no children by choice are viewed negatively, thus highlighting societal values about the expectation that couples reproduce and the stigma and pressure that exists if they do not.

MARRIAGE MARKETS

Marriage markets refer to the characteristics, composition, and geographic location of dating pools within which people search for intimate partners. Broadly speaking, marriage market research posits that individuals make decisions regarding the formation and dissolution of intimate relationships, as well as decisions about when and where to have children, according to

the availability of desirable partners who reside in their marriage market.

Marriage market studies examine both the *quality* and *quantity* of potential partners. Measuring partner *quantity* is straightforward. *Quantity* refers to the numerical availability of potential partners who are of a given age. This is usually measured in terms of the sex ratio, which is the number of males divided by the number of females.

Partner *quality* is not as straightforward. It has been measured in numerous ways by numerous researchers. Perhaps the most common quality measures are socioeconomic attributes such as earned income, labor force participation, and educational attainment, although physical attractiveness is also emphasized by some researchers. Socioeconomic attributes have been particularly useful when examining the quality of males in women's marriage markets. Research demonstrates that men's traditional role as financial provider makes males with high socioeconomic status more desirable marriage and dating partners. These men may provide greater financial security and are able to sustain a household once married.

By focusing on the quality and quantity of potential partners, marriage market research examines how individuals attempt to exchange their own personal assets for a partner with the greatest number of desirable traits. While attempting to maximize one's own personal gains from establishing an intimate relationship, individuals must also compete with others in the marriage market who may possess more desirable traits than one's self. This process produces a counterbalancing mechanism inherent in marriage markets that helps ensure that assortative mating is achieved—meaning that people with similar levels of desirable traits marry one another. However, when the numerical availability of persons with desirable characteristics is low, individuals are forced to settle for a partner with a lower level (or different set) of qualities than they would prefer, delay forming a partnership until a more advantageous match can be formed, or forgo a relationship altogether. In this way, marriage market composition is hypothesized to determine the ease or difficulty of various familial processes. In the remainder of this entry, major theories of marriage markets are presented and selected research findings are discussed.

Leading Marriage Market Theories

Prominent theories of mate selection explicitly emphasize the importance of marriage markets in determining men's and women's dating, marital, divorce, and childbearing behavior. The fundamental tenets of the three leading theories are described.

Specialization and Trading Model

Gary Becker's specialization and trading model adopts a rational-choice perspective that views men and women as attempting to maximize personal gains through marriage. People search for a spouse in the marriage market. Once in the market, individuals exchange their personal assets—be it income, wealth, home production, childrearing skills, or physical attractiveness—for a partner with the highest overall value on a related set of assets. Historically, men have specialized in and traded on their economic production, whereas women have specialized in and traded on their domestic production. This mutual dependence is thought to increase each gender's gains from marriage. Becker argues that women's increasing labor force participation, as well as the separation of sexual expression from marriage, has weakened marriage as an institution by reducing men's and women's gains from marriage.

Career-Entry Theory

Valerie Oppenheimer's Career Entry Theory applies Job Search Theory to the marriage market and the process of partner selection. Job search theory asserts that potential workers look for employment in the labor market until they find a job that satisfies the minimum qualifications necessary for acceptable employment. From the perspective of the worker, the sorting of individuals into jobs is maximized when the number of jobs available in the market increases. According to Oppenheimer, an analogous situation occurs during the process of selecting a partner in the marriage market. A person wishing to establish a relationship searches for a partner in the marriage market. Similar to employment, individuals usually have a predetermined idea of the minimum characteristics necessary before a potential partner is deemed acceptable (parallel to a minimally

acceptable hourly wage). Once in the marriage market individuals compete with others who also wish to find a partner.

Oppenheimer argues that high levels of female human capital delays women's transition to marriage by extending their marital search process and simultaneously raising the minimum characteristics they deem as necessary in a husband. Perhaps more importantly, men's economic volatility also decreases the incidence of marriage by creating long-term financial uncertainty for both partners.

Though Becker and Oppenheimer approach the role of the marriage market from a different perspective, each theory asserts that the probability of finding a desirable partner is the highest when the number of opposite sex persons with desirable characteristics is at its highest. Therefore, an increase in the supply of desirable partners available in the local marriage market is hypothesized to facilitate union formation.

Imbalanced Sex Ratio Theory

Marcia Guttentag and Paul Secord's imbalanced Sex Ratio Theory rests on two important premises: (1) men and women have divergent familial goals, and (2) an imbalance in the marriage market will produce a shift in *dyadic power*. All else being equal, the theory asserts that females prefer to form stable, long-term, secure, monogamous relationships through marriage, whereas males seek more sexually permissive relationships and wish to avert or delay intimate long-term commitments. Furthermore, the gender that is in short supply is assumed to have greater dyadic power within the marriage market because of supply and demand. When the sex ratio is low—a greater supply of females relative to males—*men* enjoy more dyadic power within relationships because they are in high demand. Conversely, when the sex ratio is high—a greater supply of males relative to females—*women* benefit from greater dyadic power because they are in higher demand. Greater male dyadic power is hypothesized to lead to lower levels of legal union formation, and women's greater dyadic power is predicted to result in widespread adoption of traditional family patterns including a relatively early age at first marriage, high rates of marriage, low rates of divorce, and low rates of children born outside of marriage.

Research Findings

Interestingly, divergent marriage market theories predict identical behavior (albeit for different reasons) by women—that is, women will be more likely to form partnerships and less likely to have children outside of marriage when they reside in marriage markets characterized by numerous eligible men with desirable socioeconomic characteristics. This is in fact what studies have shown.

Studies of men's familial behavior, though not as prevalent as studies of women, are conflicting. Some suggest that men display a greater propensity to marry when they reside in marriage markets characterized by numerous potential female partners, but others do not. Research also reveals that both men and women are more likely to divorce when they reside in marriage markets that are characterized by a gender imbalance—specifically, women are more likely to divorce in marriage markets that contain a large proportion of single men, and men are more likely to divorce in marriage markets that contain a large proportion of single women.

variety of cultures tend to pair up with those who are similar in physical attractiveness. The handsome man and the gorgeous woman date and marry each other, and their more homely counterparts pair up with their plainer counterparts. Similarity in physical attractiveness also occurs in gay and lesbian couples. In everyday language, this is referred to as dating in “one's league”; a person assumed to be unattainable because of being much more physically attractive than oneself is described as “out of one's league.” Occasionally, however, one will see a couple that seems mismatched. He may be older and unattractive. She's young and beautiful. What attracted them to each other? This entry discusses the *matching hypothesis*, first introduced in the 1960s, to refer to the tendency for people to pair up with others who are equally physically attractive (unattractive). We also discuss *complex matching*, which occurs when people are able to attract partners far more physically attractive than themselves by offering compensatory assets—say, status, power, or financial standing.

Original Matching Hypothesis and Classic Dance Study

Elaine Hatfield (Walster) and her colleagues proposed the original version of the matching hypothesis. Based on Kurt Lewin's Level of Aspiration Theory, they proposed that in making dating and mating choices, people will tend to choose someone of their own level of social desirability. Theoretically, people should be influenced by both the desirability of the potential match (what they want) and their perception of the probability of obtaining that date (what they think they can get). Social psychologists referred to such mating choices as *realistic choices*, because they are influenced by the chances of having one's affection reciprocated.

The researchers tested the matching hypothesis in a classic dance study. In this study, 752 freshmen at the University of Minnesota were invited to attend a get-acquainted dance. When the participants picked up their free tickets, a panel of judges surreptitiously rated the students' physical attractiveness. Also available from either university records or additional measures completed by the

MATCHING HYPOTHESIS

A quick glance at couples in public settings will likely lead to the observation that people in a

participants was information on personality, grade point average, and social skills. The freshmen students were randomly matched with partners. The success of these matches was assessed via a survey distributed during the dance's intermission and in a 4- to 6-month follow-up. Before the dance, the more attractive the student, the more attractive they assumed their date would be. Nonetheless, once participants had met their matches, *regardless of their own physical attractiveness*, participants reacted more positively to physically attractive dates and were more likely to try to arrange subsequent dates with the physically attractive. Self-esteem, intelligence, and personality did not affect participants' liking for the dates or subsequent attempts to date them. This study, then, did *not* find any support for the matching hypothesis.

Evidence for the Matching Hypothesis: Follow-Up Experimental Studies

The dance study was criticized as not reflecting the reality of the dating marketplace because in the computer dance setting, there was no or little chance of rejection, at least for the evening of the dance. Follow-up experimental studies were conducted in which college students, in laboratory settings, were asked to react to profile information about "potential dates." The researchers manipulated the dates' physical attractiveness and sometimes presented bogus information about how likely the date would be to enter a relationship with the respondent. Similar to the findings from the classic dance study, most people—regardless of how attractive they were—reacted more positively to profiles of attractive dates than of unattractive dates. Although learning one could be rejected by a potential date had a dampening effect on reactions to the other, overall the physical attractiveness effect (physical attractiveness of the other highly associated with attraction for him or her) predominated over a matching effect or a concern about rejection.

Observations of Actual Couples

Data collected in the real world, however, told another story. In a number of studies, social psychologists measured the attractiveness level of each partner of actual couples. They did this in

various ways but tried to be objective as possible, often asking more than one "judge" to provide the ratings and having the ratings of one member of the couple done independently of the ratings of the other member (often through photographs). Here, there was strong evidence found for the matching hypothesis. Similarity has been found between the partners' levels of physical attractiveness in real couples.

Preferences, Realistic Choices, and What Actually Occurs

One explanation for the diverse findings across contexts is that in these disparate studies, scholars are studying different phenomena. Although the *matching hypothesis* is most often referred to as a single hypothesis, there may be at least three separate subhypotheses included within. As noted by S. Michael Kalick, there are distinctions among *preferences*, *realistic choices*, and what *actually occurs* (i.e., what people will settle for).

1. *Preferences*: In the strongest form of the matching hypothesis, it would be proposed that people prefer to match with partners of their own level of attractiveness. No evidence has been found for this, however. What do people prefer, if issues of possible rejection or competition are not salient? Most people prefer someone who is physically attractive. For those who are physically attractive, what they want and what they can get are identical. For those who are unattractive, however, desire conflicts with reality. In making their choices, they must balance the two.
2. *Realistic choices*: What do people choose under more realistic social situations, where they must approach someone (or wait to be approached), and social rejection is a very real possibility? Under these conditions, Hatfield and her colleagues proposed that—although all prefer an ideal partner—they would be likely to choose to approach someone of approximately their own level of attractiveness. This form of the hypothesis distinguishes between preferences and choices.
3. *Reality*: The reality considers everything—what a person desires, whether the other wants him or her in return, and market considerations (including whether other desirable alternatives come along for one or both of them). In real life, people typically settle for mating within "their league," whether they want to or not.

Of these three forms of the matching hypothesis, the least amount of support has been found for the first version (people yearn for the ideal, regardless of the possibility of attaining it), the most support has been found for the third version.

More Complex Matching

Although the original matching hypothesis proposed that people would pair up with someone as “socially desirable” as themselves—choosing people who are equal in a panoply of assets—over time, the matching hypothesis has come to be associated specifically with matching on *physical attractiveness*. However, people come to a relationship offering many desirable characteristics. A person may compensate for a lack of physical attractiveness with a charming personality, kindness, status, money, and so forth. The notion that individuals can sometimes compensate for their lack of attractiveness by offering other desirable traits has been termed “complex matching.” As social psychologists point out, a traditional type of pairing is gender-linked: An older, wealthy, successful man pairs with a younger, attractive woman—known in popular culture as the “trophy wife”—a testament to a businessman’s success.

Third-Party Assistance and the Matching Principle

Today, most people make their own dating and mating choices. The original matching hypothesis was proposed as an explanation for individuals’ decisions about their own mating and dating choices. Nonetheless, matching is sometimes assisted by third parties—friends, families, and by Internet dating sites. It is likely that friends, families, and matching services also consider physical attractiveness and other desirable traits as they determine who will make suitable matches.

Conclusions

Many years ago, sociologist Erving Goffman observed that in the United States, a proposal of marriage occurred when a man calculated his own social worth and suggested to a woman that her

assets weren’t so much better as to “preclude a merger.” Goffman and social psychologists who proposed and tested the matching hypothesis were keen observers of the dating and mating marketplace. Today, compelling evidence indicates that although men and women may yearn for the ideal mate, when the time comes to make a choice they generally settle for the “art of the possible.”

MATE GUARDING AND POACHING

Like most birds and many other species, most people employ a socially monogamous mating strategy. At any given time, a person maintains a romantic relationship with only one other person in which both members of the relationship cooperate to maintain the relationship. This social relationship, however, does not guarantee sexual exclusivity. Although it may be socially undesirable, men and women sometimes engage in sexual behavior with people other than their partners. Keeping one’s long-term mate from being sexually unfaithful is as much of a problem for people today as it was for our ancestors hundreds of thousands of years ago. Because this has been such a costly problem throughout human evolutionary

history, people today have evolved a series of cognitive and affective mechanisms that motivate behaviors intended to guard against such infidelities, as well as behaviors intended to circumvent the mate guarding behaviors of a potential mate's current partner. This entry discusses findings from recent research in the area of human romantic relationships suggesting how and why people keep their own mates from being sexually unfaithful and how and why other people evade those attempts.

Having one's mate be unfaithful can be costly for both men and women. Men whose partners are sexually unfaithful run the risk of being cuckolded—unwittingly investing time, energy, and material resources in genetically unrelated offspring. In addition, a man whose partner has been unfaithful also risks permanently losing his partner to another man, effectively losing all previous investment in his partner and in the relationship, as well as all possibility of future reproduction with her. He must then expend effort finding another mate and developing a new relationship. Women, on the other hand, are never at risk for cuckoldry. When a woman has a child, she knows that the child is hers. However, women still are subject to negative consequences of their partner's infidelity. A woman whose partner defects the relationship, even temporarily, risks losing her partner's investment in herself and her offspring. If she is interested in establishing a new romantic relationship, she must expend effort finding another mate who is willing to invest in her and any children she may have. Given the reproductively costly consequences of a partner's infidelity, then, people in romantic relationships perform a variety of behaviors intended to discourage their mates from defecting from the relationship in the form of an infidelity.

Mate Guarding

People use a variety of behaviors to guard their mates and attempt to keep them from being unfaithful. Studies have reported dozens of different behaviors that people use as part of their mate guarding efforts. These behaviors have been categorized into five general tactics: direct guarding, intersexual negative inducements, intrasexual

negative inducements, positive inducements, and public signals of possession.

Direct Guarding tactics include some of the more overt forms of mate guarding behaviors—for example, snooping through a partner's personal belongings, insisting that a partner does not go out without oneself, and monopolizing a partner's time to keep him or her from interacting with potential affair partners. Intersexual Negative Inducement tactics focus on the manipulation of one's partner. For instance, a woman may flirt with another man in front of her partner to make him jealous, or a man may yell at or be physically violent toward his partner when he catches her flirting with someone else. Intrasexual Negative Inducements are similar to Intersexual Negative Inducements except that they include behaviors aimed at same-sex rivals rather than one's partner. Instead of hitting one's partner for flirting with another man, for example, a man may hit the man who flirted with his partner. He may also tell other men negative things about his partner to keep them from being interested in her.

Not all mate retention behaviors are negative, however. Some behaviors, such as those tactics categorized within Positive Inducements, are aimed at enticing one's partner to stay in the relationship rather than punishing a partner's defection. These tactics include behaviors such as presenting a partner with gifts, enhancing one's own appearance to look nice for a partner, and offering a partner help, support, and affection. The fifth category of mate retention tactics, Public Signals of Possession, also includes behaviors that amount to bestowing benefits on a partner rather than inflicting costs on a partner. These tactics can include being physically affectionate in public and bragging about one's partner to others. Regardless of which category of tactics is used, and whether or not they are consciously associated with the goal of guarding one's partner, all mate retention behaviors are ostensibly aimed at keeping one's partner invested in the current relationship.

Just as mate guarding tactics differ, people differ in their use of these tactics. For instance, men are more likely than women to attempt to retain partners by displaying their resources, such as by spending a lot of money on their partners. This is not surprising given that women are particularly attracted to men who have resources and are

willing to offer access to those resources. Men are also more likely than women to threaten other men who show interest in their partners. Women, on the other hand, are more likely than men to keep their partners invested in the relationship by enhancing their own appearance, telling other people that their partner is taken, and punishing men's threats to be unfaithful.

In addition to differences between men and women in the use of mate retention behaviors, there are also individual differences that vary from one relationship to another. For example, men perform more mate retention behaviors with younger partners. This is because younger women are perceived to be "higher quality" mates than older women, although there is as yet no research investigating mate guarding by male partners of postmenopausal women. Men's perceptions of their partner's physical attractiveness also influences mate retention behaviors. Men who believe that their partners are more attractive perform more mate retention behaviors than do men who believe their partners are less attractive. Age discrepancy in a relationship is also associated with mate retention behaviors, with men who are significantly older than their partners performing more mate retention behaviors. Mate retention behaviors also increase with the perceived risk of partner infidelity. The more likely a man thinks that his partner will be sexually unfaithful, the more mate retention behaviors he uses, suggesting that mate retention behaviors are indeed enacted to thwart anticipated infidelities.

Not all women perform mate retention behaviors to the same degree either. Younger and more attractive women are more likely than are older and less attractive women to enact mate retention behaviors. Women in general perform more mate retention behaviors with husbands who have higher incomes and who display greater status striving. In contrast to men, women who believe that their partners are more attractive perform fewer mate retention behaviors.

Mate Poaching

Mate guarding behaviors function to keep one's partner from deserting the current relationship. Mate poaching, one reason for leaving an existing

relationship, occurs when a person attempts to attract someone who is already involved in a committed relationship with another person. Although the percentages vary across cultures, about 50 percent of men and women report having made at least one attempt at poaching someone from a relationship at some point in their lives. Roughly 70 to 85 percent of men and women report that someone else has tried to poach either themselves or their partner out of a relationship.

The particular tactics that people use to poach potential mates are not unlike the tactics people use to attract and then to guard their own mates against poaching. Women enhance their own physical appearance to attract the attention of an already-mated man and then provide him with easy sexual access. Men, on the other hand, are more likely to display resources and generosity (i.e., a willingness to invest in a woman and any possible offspring) and by making a woman question her current partner's fidelity and commitment to the relationship.

As with mate guarding, all poaching behaviors are not equal. Not all people are poachers, and some people are more likely to receive poaching attention than others. Agreeable and conscientious people are less likely to be poachers than are unreliable and self-described erotophilic people (i.e., people who have positive feelings and responses to sex and sex-related stimuli). Extraverts and those open to new experiences are more likely to receive poaching attempts, whereas neurotic, unloving, and masculine people are more likely to be successfully poached away from an existing relationship. Characteristics of the existing relationship are also important to consider in the use of poaching tactics. Poaching tactics are perceived to be less effective when used on men and women in established, long-term, committed relationships, compared with people who are just starting or just ending a relationship.

The benefits of mate poaching mirror the benefits of nonpoaching relationships: Men gain access to physically and sexually attractive women and women gain access to men who have resources and who display a willingness to invest those resources in her and possibly her children. The potential costs of mate poaching, however, are substantial. A poacher must be concerned with competing against a current partner and with retribution by the

current partner, should he or she discover the poaching. In addition, most relationships include some amount of fidelity uncertainty. In a relationship in which one of the members has been poached from a previously existing relationship, the risk of infidelity is exacerbated. That person might still be sexually involved with the partner from the earlier relationship, and he or she might be susceptible to further poaching from other sources.

Being poached is not a passive process, and some relationships are subject to poaching enticement. Poaching enticement occurs when a person in a relationship encourages poaching by a partner's rivals. Women who desire to be attracted away from their current partners are more likely to display physical beauty and offer sexual access to desirable men other than her current partner. Men who want to be poached are more likely to display resources and dominance behaviors to potential poachers.

Poaching enticement is not without costs, however. A person whose poaching enticement efforts have been detected by his or her current partner may be at risk for more severe and most likely unwanted mate guarding behaviors. Consequently, people who engage in poaching enticement also engage in behaviors intended to disguise such enticement, often by overtly giving their current partners what they want most. For example, women may increase the frequency of sexual activity with their current partners in addition to maintaining their daily routines and keeping atypical behaviors to a minimum. Men, on the other hand, are more likely to display overly pronounced commitment to their current partner.

MATE PREFERENCES

Romantic relationships are everywhere—people in all cultures engage in various forms of mating, including short-term, casual sexual relationships on the one hand and committed partnerships and marriage on the other. This entry looks at people's mate preferences, including the characteristics that people desire in long- and short-term relationships, how selective people are in choosing a mate, and trade-offs individuals make. Some important ways in which men and women are alike and differ are described; these mate preference phenomena are explained from two major theoretical perspectives.

Short-term relationships, including one-night stands, casual sex, and sexual affairs, tend to lack commitment and revolve around sexual or physical relations. Conversely, long-term relationships, including marriage and exclusive, steady relationships, tend to involve commitment and investment between partners, and endure for a while. Although people may sometimes find themselves in relationships that have characteristics of both types, a general division of relationships as either committed, long-term, or casual, short-term is nonetheless useful in characterizing the various nuances of mate preferences, and is used in this entry.

Valued Characteristics In Mates

Mate preference researchers have found distinct patterns in the characteristics that people desire for short- and long-term relationships. To begin with, many characteristics are important to both men and women for both types of relationships, including kindness, intelligence, physical attractiveness, creativity, an exciting personality, sense of humor, and social status. For short-term mates such as one-night stands, casual sex partners, and affair partners, both sexes place particularly high value on physical attractiveness. Specifically, both men and women consider it necessary for short-term partners to have a minimum level of physical attractiveness. Indeed, when given the opportunity to obtain information on a potential short-term partner, people inquire first about the potential mate's physical attractiveness.

For long-term mates such as marriage partners, mutual attraction and love, dependable character, emotional stability and maturity, pleasing disposition, and education and intelligence were identified as the top five most desired characteristics across three major regions in the United States. Many traits, such as those related to kindness and intelligence, tend to be equally valued by men and women and may be important in demonstrating parenting skills, fidelity, trustworthiness, generosity, and ability to maintain a relationship. Such characteristics tend to be equally valued across cultures and generations. However, some preferences are more prevalent in certain cultures. For instance, when David Buss and colleagues compared 29 cultures from different parts of the world, they found that physical attractiveness was more highly valued in cultures with higher levels of parasites. In addition, some characteristics change over time. For example, in an analysis of more than 50 years of studies on mate preferences in the United States, researchers observed an increase in the importance of love and mutual attraction.

The sexes tend to differ on their preferences for physical attractiveness and social status in a long-term mate. Specifically, men value physical attractiveness more than women do and women value social status (and earning potential) more than men do. These sex differences in preference for social status and physical attractiveness have been studied extensively and have been found across age

groups and ethnicities in the United States, across several decades, and across numerous countries around the world.

In particular, men prioritize finding a minimum level of physical attractiveness in long-term mates, whereas women prioritize obtaining a minimum level of social status in their partners. That is, although people would ideally like to have well-rounded mates who are great looking, smart, successful, funny, talented, kind, and virtuous, men want someone who is at least minimally physically attractive and women want a partner who has at least a minimal level of social status.

Explaining Sex Differences in Valued Characteristics

The priorities that men and women place on physical attractiveness and women place on social status can be explained by two major perspectives: sociocultural and evolutionary. Sociocultural theories look to social norms (what is appropriate for people to do in social situations) and the influence of larger groups, including family, religion, and society. From a sociocultural perspective, women in most societies have less access to status, power, and economic resources than men do. To gain stable access to economic resources and achieve upward mobility, women need to select marriage partners who have status and income potential. Men, on the other hand, are in the economic power seat, and thus are free to pursue what society deems as pleasurable, such as a long-term mate's physical attributes. However, if the intended mating duration is short-term, then economic constraints should be less relevant and both sexes should be free to value their mates' physical attractiveness.

Whereas sociocultural theories revolve around societal constraints, evolutionary theories rely on more distal explanations and consider biological constraints and heredity. Evolutionary theorists maintain that preferences and behaviors may be heritable, and that the psychologies we have today may have been naturally selected during millions of years. Specifically, psychologies that aided ancestral humans in reproducing more successfully are likely to have been passed down over evolutionary history. Because men and women have

different reproductive capacities and constraints, the sexes may have evolved different psychologies relating to mating and reproduction.

Evolutionary theorists note that men vary in their ability to provide resources for offspring. Ancestral men with high social status had good access to resources, whereas ancestral men with low status may have had little or no access to resources. Thus, ancestral women who prioritized having some status in their long-term mates likely secured essential resources for their offspring and outreproduced those who did not and passed this proclivity down through the generations. For short-term mates, resources are less relevant, but a man's heritable traits, including his physical appearance and qualities implied by his appearance, may be passed on to any resultant offspring. Thus, evolutionary psychological theories suggest that women may value physical attractiveness in short-term mates for heritable benefits. This point is elaborated further later.

Men's preference for physical attractiveness may be related to an important constraint in female reproductive capacity. Whereas men's fertility tends to decline slowly over their life spans, women are most fertile in their 20s and decrease in their ability to have children after age 30, until hitting menopause by age 50. Because of this reproductive constraint, ancestral men who were attracted to the most fertile women—more specifically, physical features belonging to the most fertile women—would have outreproduced men who were not. Consequently, attraction toward fertility-related features would have become more prevalent over generations.

Physical Attraction: A Closer Look

The qualities that people list as important in choosing a mate can be further studied to uncover the detailed nature of preferences. Research on what people find physically attractive illuminates the specificity of preferences. Both men and women find physical characteristics that signal good health to be attractive in a mate. Traits such as smooth skin, strong hair, good teeth and gums, and normal gait and movement can provide evidence of good nutrition and healthy development.

Men are additionally attracted to those features in women's physical appearance that indicate fertility. In particular, men tend to be drawn to secondary sexual characteristics and signals of youth, because female fertility varies with age. These characteristics include full lips, soft and lustrous hair, smooth skin, colorful cheeks, good muscle tone, breasts, buttocks, and a low waist-to-hip ratio (the circumference around the thinnest part of the waist divided by the circumference around the thickest part of the hips).

Among the various features, the waist-to-hip ratio is one that has been studied extensively in recent years. Waist-to-hip ratio is a visual cue that is noticeable from a distance and from behind as well as from the front. Although preferred overall female body size tends to vary over time and by culture, male preferences for a low female waist-to-hip ratio (around 0.7) has been found to be stable across time and across various cultures. Research in this area has found that lower waist-to-hip-ratios are associated with both increased fertility and lower health risks in women. A study done at a fertility clinic found that every 0.1 increase in waist-to-hip ratio is associated with a 30 percent decrease in conception probability.

Conversely, women are physically attracted to male features such as facial masculinity, muscularity, and symmetry that may be indicative of good genes. According to proponents of the good genes theory, a healthy set of genes and immune system allow a person to resist pathogens that can adversely affect developmental stability. In addition to having negative health consequences, individuals who are not able to fend off pathogens during development tend to possess a greater degree of bilateral asymmetry (left-side development deviates from being symmetrical to right-side development). Because testosterone suppresses the immune system, only men who have good immunity are able to maintain high levels of testosterone and remain healthy. Thus, testosterone-related physical features, when present with symmetry, advertise that a man's genes are resistant to pathogens.

Indeed, research shows that men who are symmetrical tend also to possess testosterone-mediated secondary sexual characteristics such as muscularity, broad shoulders, and facial masculinity, and they are the men that women tend to consider

sexually attractive. Compared with asymmetrical men, symmetrical and masculine-looking men start having sex at an earlier age, are more desirable as sexual partners, have more sexual partners, and are more likely to bring their partners to orgasm. In ancestral environments, women who were more physically attracted to symmetrical than to asymmetrical men may have passed on good genes to offspring, who then were more likely to be healthy and survive to reproductive age, and, in the case of male offspring, more likely to be attractive to potential mates.

Mate Selectivity

Which mate preferences a person expresses is influenced by a person's inclination to seek and accept mates for particular relationships. For instance, men and women tend to be equally careful and selective when entering a potential long-term relationship. Studies have found that when considering minimum requirements for a marriage partner, both sexes have equally high standards. For example, both men and women indicate that they require above-average intelligence in a marriage partner. Where the sexes differ are short-term relationships: men tend to be much more eager than women for sexual opportunities. In a study done on Florida State University's campus, men and women were approached by an attractive, opposite-sex stranger (actually, a student who was helping to carry out the experiment) who immediately makes an invitation for casual sex. A majority of men—75 percent—said yes, whereas 100 percent of the women said no. Several of the women threatened to call the campus police. In contrast, of the 25 percent of men who declined, many were apologetic and asked to reschedule.

Men are much more willing than women to engage in sexual relations after any length of acquaintance from 1 minute to 5 years. To facilitate sexual relations, men require much less commitment and investment before consenting to sex. Indeed, men report significantly lower standards for short-term relationships, especially for one-night stands. For instance, whereas women's minimum acceptable intelligence for one-night stands is at the same high level that they require for long-term partners, men indicate that they are willing to

accept a one-night stand whose intelligence is far below average (around the 25th percentile).

Explaining Sex Differences in Mate Selectivity

Men's lower short-term mating thresholds and mate preferences in general can be explained by the two major perspectives. According to a socio-cultural view, societal norms tend to influence men to be more proactive and women to be more passive across many endeavors, including sexual behaviors. Thus, the difference in whether to enter short-term relationships may be the result of gender role differences, whereby men are socialized to be sexually autonomous and women are socialized to be sexually restrained.

An evolutionary perspective suggests an alternative explanation for this sex difference. A key to understanding this perspective is to consider that in an ancestral environment, long before birth control, pregnancy was always a possible outcome of sex. However, women, not men, are physiologically required to provide substantial resources during and after pregnancy for offspring to survive. Thus, uncommitted, casual sexual encounters present much higher potential reproductive costs to women than to men. As such, short-term sexual relationships are reproductively less favorable to women. On average, those ancestral women with a choosier mating psychology that favored long-term relationships, where partners are more likely to stick around and invest in offspring, likely outreproduced those who were less selective and favored having casual sex, where partners are likely to be absent if offspring show up.

Men, on the other hand, are not physiologically constrained by pregnancy and nursing, and can contribute as little as a few sex cells to a casual sex encounter, even if offspring result. As such, male reproductive success can be more readily increased through openness to casual sex than female reproductive success can. Thus, because of the asymmetry in reproductive costs between men and women, men may have evolved to be more open to casual sex and have lower requirements for potential sex partners than women do.

Whereas only women make a potentially substantial reproductive investment in short-term

relationships, both sexes tend to invest significantly in the relationship and in raising children in long-term relationships. Thus, according to an evolutionary perspective, both sexes may have evolved to be selective about taking on a long-term partner.

An evolutionary perspective further suggests that in addition to selectivity, men and women may also desire characteristics in mates that indicate a willingness to engage in the preferred relationship type. For instance, when men look for short-term mates they may look for a willingness to engage in casual sex. When men and women look for long-term mates, they look for a willingness to commit.

Tradeoffs in Individuals' Mate Preferences

Aside from general sex differences, individuals' own traits affect the type of relationships they pursue and, consequently, the preferences they have in mates. Although women tend to prioritize physical attractiveness in short-term mates and social status in long-term mates, it would be reproductively ideal for women to find mates who can provide both genetic and material benefits to offspring. However, obtaining both sets of features in one male partner is difficult. Such men tend to be in high demand and are targeted by women who are willing to have casual sexual relationships; thus, these men tend to be less committed to any one partner. As such, research suggests that most women may need to make a strategic tradeoff by selecting long-term partners who are higher in investment potential than sexual attractiveness. However, evolutionary-minded researchers also suggest that it may be adaptive for women to seek primary partners who provide investment while obtaining better genes through extra-pair mating (sex with individuals other than one's primary partner).

Evidence for this dual-mating hypothesis comes from studies that examine mate preferences throughout a woman's menstrual cycle. Around the time of ovulation, when pregnancy is most likely, female sexual desire becomes stronger and the frequency of sexual fantasies increases. However, these fantasies are directed not toward primary partners, but toward potential affair

partners. This is particularly true if a woman's primary partner is not physically attractive and lacks indicators of genetic fitness, including strength, symmetry, and social dominance. When women are ovulating, they also more strongly prefer masculine faces and symmetrical features in men, and the scent of symmetrical men, compared with when they are not ovulating. Indeed, men who report being chosen for sexual affairs tend also to have symmetrical measurements. Furthermore, self-report research conducted in the United Kingdom indicates that women who are in a steady relationship tend to have sex with their primary partner evenly across the ovulatory cycle. However, if partnered women have sexual affairs, they are more likely to do so around the time of ovulation.

A strategic trade-off that men face involves the allocation of effort to mating versus parenting. The resolution of these trade-offs depends on cues from the environment. When men possess indicators of good genes and are sexually attractive to women, they tend to allocate more effort to mating. When men do not have the attributes that make them sexually attractive or otherwise face limited sexual opportunities, they tend to invest more heavily in a single mate's children. For example, African tribal evidence shows that men of high status have more wives and spend less time on parenting than do men of low status. Thus, men's access to short-term mates is a primary factor in determining the type of relationship that men prefer, which in turn influences what characteristics they value in a mate.

MATERIALISM AND RELATIONSHIPS

Human relationships take place in broader cultural contexts that provide the settings and norms governing how people relate to each other. Many contemporary humans live in cultural contexts characterized by capitalism and consumerism, both of which encourage individuals to pursue their own self-interest, to obtain financial wealth, and to acquire many possessions signifying high status and the “right” image. When people believe that money, possessions, image, and status are important goals to strive for in life, they have internalized materialistic values. Although most research on materialism has investigated its negative correlations with indices of personal well-being, a growing number of studies also report that problematic interpersonal relationships are associated with strongly valuing materialism. This

entry briefly reviews that literature and describes three possible explanations for these findings.

Materialism and Relationship Quality

Studies with adults and adolescents have shown that the more people endorse materialistic values, the lower the quality of their interpersonal relationships. For example, materialistic values are associated with having relationships characterized by lower trust and acceptance, and by more jealousy and emotional volatility; these findings occur with both self- and peer-reports of relationship quality. Materialism is also associated with lower marital satisfaction among couples and higher conflict among parents and their children. People who strongly value money, image, and status also tend to feel more alienated, detached, and separate from those around them. It may not be surprising, then, that adolescents who put a high priority on “being rich” are more likely to be diagnosed with personality disorders indicative of problematic interpersonal relationships and with disorders involving antisocial activities.

Three Explanations

One explanation for these findings is that when people care a great deal about materialistic pursuits, they tend to care less about close interpersonal relationships and other people in general. Cross-cultural research on values and goals consistently demonstrates that self-interested, materialistic aims typically stand in opposition to the kinds of values that promote good interpersonal relationships. For example, materialistic values tend to oppose benevolence and affiliation values, which concern being “helpful” and “loyal,” obtaining “true friendship” and “mature love,” and having close, committed relationships. Across various cultures, materialistic values and goals also typically oppose universalism and community feeling aims such as working for “social justice” and “equality,” and trying to make the world a better place. Experimental results in the United States even suggest that activating materialistic values by making people think about money and possessions may cause them to orient away from friendly, helpful, cooperative acts.

For example, in one study with 4- and 5-year-olds, children randomly assigned to watch a commercial promoting a fun toy were more likely to decline the opportunity to play with their friends so they could instead play with the toy. These subjects were also more likely to choose to play with a “not so nice” boy who had the toy than with a “nice boy” who did not. In a different series of studies, U.S. college students randomly assigned to create sentences out of money-related words (as opposed to neutral words) later spent less time helping an experimenter pick up pencils that had been dropped and less time helping a confused confederate. They also donated smaller portions of their honorarium to charity. Such results suggest that it is quite difficult for individuals to simultaneously strive for materialistic and relationship goals and that relationships tend to lose out when materialistic goals are activated in people’s minds (as happens so often in capitalistic, consumer culture).

A second explanation for the interpersonal problems associated with materialism is that individuals who endorse such values, beliefs, and goals tend to be highly focused on how others view them. Indeed, the materialistic aims of money, image, and status are typically referred to as “extrinsic” because they reflect strong concern with external rewards and the opinions of others. Supporting this label, studies show that materialistic values are associated with thinking more about the impression one is making on others, with fearing the negative evaluations of others, and with feeling pressure to conform to one’s peers. Other research suggests that materialism is typically motivated by concerns about looking cool, seeming to be of high status, and demonstrating one’s competence to other people. Such concerns and motives are likely to interfere with high-quality relationships, as worries about evaluation or desires to appear certain ways typically are inimical to feeling close and connected to others.

Finally, a strong focus on money and possessions is associated with a tendency to “objectify” other people. That is, materialism apparently increases the likelihood that other people are treated as objects to be manipulated in the pursuit of one’s goals, rather than as unique, subjective individuals with their own desires,

experiences, and needs. This tendency toward objectification can be seen in some of the attitudes empirically associated with strong materialistic values, including lower empathy, more manipulative tendencies, and a stronger likelihood of being socially dominant and prejudicial. Materialistic individuals also report engaging in fewer prosocial and more antisocial activities, including questionable ethical behaviors in business settings. Finally, a few studies suggest that when placed in resource dilemma games, materialistic values are associated with being less generous and with acting in more competitive and less cooperative ways. None of these qualities are likely to promote healthy, mutually satisfying human interactions.

Conclusion

Although a populace focused on materialistic aims may be beneficial for economic growth, corporate profits and retail sales, existing research suggests that materialism is consistently associated with poorer interpersonal relationships. More studies are necessary to test these associations in a wider array of cultures and with other types of relational outcomes.

MATE SELECTION

Mate selection refers to the process by which an individual chooses, or is chosen by, a potential partner from the pool of eligibles and the factors that predict the formation, maintenance, escalation, or dissolution of a long-term, romantic relationship over time. As part of the process, each individual is thought to consciously or unconsciously evaluate one's fit with a partner on a wide variety of social, personal, and relationship characteristics. These evaluations of the partner and relationship are thought to be an ongoing process in which an individual considers an array of factors at different stages of the relationship and as new information about the partner is discovered. The importance of a particular characteristic, however, is likely to vary as the stage of involvement in the relationship changes. A woman, for example, may place more importance on physical appearance in her decision about whether to accept a date or give someone her phone number, but may place much less importance on appearance when deciding whether or not to marry a long-term boyfriend who may have other redeeming qualities. When individuals feel their partner and their relationship are a good match for them, they are likely to increase their involvement in the relationship. The process and meaning of mate selection, however, has continued to evolve as demographic trends have influenced the social practices associated with the choosing of a mate. This entry discusses several factors about mate selection, including a historical perspective to mate selection, social and contextual influences on partner selection, an evolutionary perspective to mate selection, and formal intermediaries in mate selection.

Evolution of Mate Selection and Demographic Trends

The evolution of mate selection can be seen throughout the history of the United States. In colonial times, a man who wished to court a woman had to ask for her father's permission, be introduced to the family, and had to have a chaperone for all interactions. In the late 19th and early 20th centuries, the industrial revolution and

changes in the social position of women led to the emergence of dating, as individuals arranged times and places to meet outside of the home. In the middle of the 20th century, dating became formalized with role-based scripts, and relationships generally followed an orderly progression toward marriage.

In early studies on mate selection conducted during the middle of the 20th century, the term *mate selection* was used to describe an individual's selection of the initial marital partner and the progress of a romantic relationship toward marriage. Most of these studies were based on the idea of a courtship continuum that began with the first meeting and advanced through dating, going steady, courtship, and engagement, progressing to marriage.

More recently, however, the term *mate selection* has been broadened in the research to include non-marital, romantic relationships, such as cohabiting relationships. The focus of research on mate selection has subsequently moved from relationship formation and progress toward marriage to the study of relational characteristics and phenomena in various close and romantic relationships. Although there may be many potential reasons for this shift in the focus of the research, some possibilities include a change in the meaning of marriage and three demographic trends, the delay in marital timing, the growing prevalence of cohabitation, and the increase in nonmarital fertility.

The mate selection process may have evolved because of a change in the societal meaning of marriage. In the past, marriage has been described by some as a social compromise in which men and women exchanged different resources for their mutual benefit. Men provided economic support and protection, whereas women provided child-rearing and homemaking. Although this view likely oversimplified and excluded key components of marriage (e.g., love, commitment, attraction), it was believed people primarily chose partners to fulfill socially defined roles. As society has continued to change, however, individuals are thought to see marriage as more of a personal choice with more emphasis on other relational qualities, such as love, rather than as an exchange of resources. Individuals are thought to be seeking their *soul mate* with whom they may have a physical, emotional, and spiritual connection. Finding such a

partner likely requires greater selectivity, self-awareness, and more time, perhaps altering the mate selection process, especially marital timing.

During the last 50 years, there has been a substantial increase in the median age of first marriage, meaning the age at which half of all people born within a 5-year period have entered into their first marriage. In the past, many young adults chose to marry in their early 20s after they finished high school and entered the workforce or college. According to the most recent U.S. Census report, the median age at first marriage has been steadily rising to historically high levels, to 27.1 for men and 25.3 for women, with the greatest increases occurring for women. This rise means more and more individuals are delaying marriage until their later 20s and 30s, perhaps offering opportunities for greater diversity in mate selection activities, including dating, hanging out, hooking up, or sexual encounters. Researchers estimate that more than 90 percent of individuals will eventually marry at some point of their lifetime. Additionally, this marital delay has influenced some individuals' mate selection because they may be choosing marital partners in different social environments because they are older (e.g., workplace or social club rather than college/high school environment), and some may be engaging in mating behaviors before marriage (e.g., cohabitation or nonmarital fertility).

The second demographic trend that may alter mate selection is the increasing prevalence of cohabitation, or individuals living together before marriage. About 50 percent of all individuals who marry have cohabited at some time with a partner before marriage. Researchers have discovered that not all individuals who cohabit do it for the same reasons and have subsequently identified three groups of cohabitators: those who see cohabitation as a stage in their relationship, those who already have plans to marry, and those who use cohabitation as a replacement for marriage. Cohabitation is likely to alter the mate selection process and social practices for some people because researchers have found that cohabitation may serve as initial screening or trial marriage in which partners test their compatibility and gather more information and determine whether their relationship should progress. Once a couple cohabits, they likely have greater barriers to seeking new

partners and often begin an inertial movement toward marriage. Research on cohabiting couples, however, has suggested cohabitation may have some negative influence on future marital success (e.g., higher divorce rates and lower levels of marital satisfaction for those who have cohabited). The trend of cohabitation is continuing and will influence mate selection.

The mate selection process may have also evolved because of the increase in nonmarital fertility, or the birth of children to unmarried individuals. Recent estimates suggest as many as 33 percent of all births in the United States are to unwed mothers and as high as 66 percent of all births are to unwed African-American women. The separation of fertility from marriage may further influence the mate selection process because social expectations or scripts may be modified, leaving individuals without a socially defined, delineated path for their relationship.

Research on Mate Selection

Although many disciplines have explored mate selection (e.g., anthropology, communication studies, family science, psychology, sociology), this entry concentrates on three prominent approaches in the research on mate selection: (1) the sociological perspective of mate selection, focused on the choosing of and match between partners; (2) an evolutionary psychology viewpoint, concentrated on the genetic and biological influences of attraction and sexual selection; and (3) the interdisciplinary study of close relationships, concerned with the formation, maintenance, and characteristics of romantic and marital relationships.

Sociological Research on Mate Selection

The first approach to mate selection in the research largely focuses on macrocharacteristics from a sociological perspective. Most of this research investigated the social and contextual influences in partner selection. This perspective also examined the social exchange of resources between partners in their attempts to maximize their resources.

A number of important concepts, themes, and theories were formed from this literature. One

central theme regarding mate selection was the ideal of propinquity, or the necessity for potential partners to be close in time and space. This concept simply meant individuals who were not close in age or geographical space likely would not have the opportunity to meet or develop a relationship.

A second major theme in the research was the presence of homogamy, or the tendency for similarity between coupled partners on various characteristics. This research often investigated the similarity of various social characteristics (e.g., age, education, intelligence, occupation, race, religion, and social status) between existing coupled partners compared with random pairings of individuals and demonstrated that individuals were more likely to choose someone similar to them than a random pairing of partners. A related term was developed, *endogamy*, meaning the tendency for a person to select a partner within a particular group (e.g., same race or religious denomination). Later research on similarity suggested similarity of attitudes, values, and behavior was perhaps more important than were social characteristics as the relationship progressed. The explanation for the importance of similarity was called *consensual validation*, or that one's own values, attitudes, and behavior are reinforced when one's partner has similar values, attitudes, and behavior.

Another concurrent theme in the mate selection literature, opposites attract, suggested complementarity of some characteristics would be desirable in potential partners. Although the ideas of similarity and complementarity appear to be contrary and more empirical support existed for similarity, researchers eventually concluded both ideas had merit. A group of theories, called filter theories, suggested that a combination of similarity and complementarity was most ideal. These theories suggested as coupled partners fit well with each other at various levels, they would pass through these filters and progress in their relationship. Researchers found similarity of attraction and social characteristics are important initially in relationships, similarity of values and attitudes become more important when individuals begin dating more seriously, and complementarity of needs and roles become important when individuals are considering a marital relationship.

Sociologists also developed the concept of marriage markets, or local communities defined by

geography and other social characteristics. Individuals are often limited in their choices of potential partners to those within their marriage market. Ideally, a marriage market would contain an equal ratio of men and women. The calculation of the number of men divided by women is referred to as the sex ratio. In a well-functioning marriage market, the matching hypothesis suggests those who are most desirable pair off with partners who are equally desirable; those who are less desirable pair off with partners who are also less desirable, and so forth. However, an imbalanced sex ratio places individuals in the larger group in a marriage squeeze because not enough partners exist for them. The most often cited example of a marriage squeeze occurs for African-American women, who have fewer numbers of African-American men from which to select because of their higher rates of unemployment, homicide, incarceration, and participation in interracial relationships.

Although some research continues in this discipline, the focus of mate selection research has shifted more to changes in the courtship continuum and other forms of relationships outside of marriage. New research is needed as the process of mate selection continues to evolve and social practices continue to change.

Evolutionary Psychological Research on Mate Selection

Darwin's theory of evolution posited the survival of the fittest, but did not explain why some species possessed heritable traits that would not necessarily promote their survival (e.g., a male peacock's tail is likely to attract the attention of its predators or the nutrition and effort to grow large antlers each year for deer could reduce its ability to survive the winter). As a result, Darwin developed sexual selection theory to explain the heritable traits and innate preferences possessed by species to help promote their ability to attract a mate, and compete against and fend off potential rivals.

Sexual selection theory was originally rejected by those who studied humans, but during the last 30 years, evolutionary psychology researchers have taken great interest in mate selection. The increase in interest is largely based on Robert Trivers's explanation of sexual selectivity in humans using the idea of parental investment. Because of

the disparity in the level of parental investment and reproductive roles, men and women tend to prefer different characteristics in their mates. Because women have a greater investment in child-bearing, they are thought to be more selective in their sexual partners. Men's selectivity, however, tends to increase as the level of involvement increases toward marriage, when their selectivity is similar to that of women.

As predicted by the theory, researchers have found some differences in preferences men and women have for characteristics in their partners. Men are more likely than women to state a preference for characteristics that suggest women are fertile and healthy. Examples of these characteristics include measures of attractiveness, including large eyes, prominent cheekbones, facial symmetry, and a small waist-to-hip ratio, as well as indicators of their ability to care for children. Women tend to report greater preferences for evidence of economic resources to provide for their children (e.g., income), and the ability to provide and protect (e.g., height, strength). The value of these resources, however, may not increase linearly, but may be just to avoid poverty or a short spouse. David Buss and colleagues, as well as others, have shown that these preferences are likely to change as they are a combination of innate mechanisms and societal values. They may also vary as a function of the seriousness of a relationship or when considered simultaneously in a cost-benefit analysis, when actually choosing a partner.

Some researchers have called for the combination of the sociological and evolutionary psychological approaches because they are not inherently incompatible, but may work simultaneously. Social influences, such as the sex ratio, mate value, and cultural norms are likely to influence mate selection and moderate the influence of evolutionary mechanisms involved in sexual selection. Results from several studies appear to indicate that both of these approaches are needed to explain mate selection.

Interdisciplinary Research on Mate Selection

During the last 30 years, researchers from many disciplines have come together in the study of various types of intimate relationships. Rather than a focus on the progress of romantic relationships toward marriage, this interdisciplinary

approach has emphasized universal properties across various types of relationships. Topics in this body of research include topics such as relationship satisfaction and stability, commitment, trust, and interdependence. Emphasis has been placed on various levels of influence, for example, contextual and social network influences (e.g., macrolevel) as well as dyadic and intrapersonal phenomena (e.g., microlevel). Although this approach is interdisciplinary, some have suggested the need for more integration among disciplines to combine the strengths of many approaches.

Formal Intermediaries in Mate Selection

From the ancient use of matchmakers to more modern intermediaries—such as personal ads and dating services—formal intermediaries, or alternative ways of meeting and selecting mates, have influenced the mate selection process. Because the selection process continues to evolve and because of the delay in marital timing, the use of formal intermediaries likely will continue to rise. Additional intermediaries have been created with the proliferation of the Internet, including chat rooms, online dating services (e.g., match.com or eharmony.com), and online communities (e.g., Facebook.com or Myspace.com).

The use of formal intermediaries and technology may help some to overcome issues of propinquity, imbalanced sex ratios, and difficult marriage markets. These intermediaries may first help individuals overcome geographical separation, by letting people meet and interact with potential partners they likely never would have met and allow individuals to find others who have similar interests to their own (e.g., religious beliefs, leisure activities or hobbies, or political orientations). Although these intermediaries may help individuals find potential partners, many feel that they will not fully replace face-to-face interaction in the selection of a marital partner.

Conclusion

Mate selection is a complex and evolving process that will continue to require study by researchers from many disciplines to fully understand it. Although the focus of research on this topic may

have changed over the years, the investigation of how individuals select, form, and maintain marital or long-term, nonmarital unions, should continue to be an important emphasis in the study of close relationships.

MEDIA DEPICTIONS OF RELATIONSHIPS

Different relational roles such as strangers, acquaintances, coworkers, friends, family members, and romantic partners are depicted through different media channels including television, movies, print, video games, and music. These depictions are presented with regularity to media consumers. In 2006, Americans watched an average of 4 hours 35 minutes of television everyday. The mass media are social agents that shape viewers' attitudes and behaviors such as gender role-related behavior; sexual behavior; conflict; aggression; and privacy, disclosure, and betrayal. This entry discusses how gender roles, sexual attitudes and behaviors, conflict, aggression, and privacy and disclosure are viewed or presented in the media.

Gender Role-Related Behaviors

Television often portrays males and females in stereotyped traditional gender roles. Females are portrayed as youthful and constitute more than half of 18- to 34-year-old prime-time characters, whereas the reverse is true for 35- to 49-year-olds. Marital and parental status is more easily identifiable for female characters. When parental status is known, females are twice as likely to be caregivers. Females are more likely than males to be unemployed. For those who are employed, males have more occupational power and higher salaries. Children's programming often portrays males and females in even more stereotyped roles than prime-time programming does.

Romantic relationships in romance novels generally depict two strong-willed people who initially do not like each other but are nonetheless attracted to

each other. The couples eventually realize their passion for each other (sometimes violently), and the novels often result in a happily-ever-after ending.

In films intended for children, familial relationships are portrayed as a strong priority for their members. Families are generally diverse but the diversity is often simplified. The importance of the paternal role is elevated, whereas the maternal role is marginalized. Also, relationships are created by “love at first sight,” are easily maintained, and are often characterized by gender-based power differentials.

Sexual Attitudes and Behaviors

Within the recent phenomenon of reality dating programs, participants often espouse attitudes such as, “Dating is a game,” “Women are sex objects,” and “Men are sex driven and have trouble being faithful.” Frequent viewers of these shows endorse these attitudes personally, but they do not engage more frequently in the behaviors that are portrayed on the shows.

Sexual relationships are frequently portrayed on television, and sexual content has increased throughout the past decade, appearing in almost three-quarters of entertainment programs. The frequency of sexual relations between unmarried couples on television has increased since the late 1990s with just over half occurring between established partners who are in an ongoing relationship. A third of sexual relationships occur between people who have just met, or who have met before but are not in a committed relationship. Depictions of nontraditional sexual relationships, such as homosexual relationships, have also increased on television.

Sexual risk and responsibility messages also increased in programs that feature sexual content. About a quarter of programs depicting intercourse mention sexual risks and responsibility, with about a third of those scenes featuring risk and responsibility as the principal focus of a scene.

Across several film genres, married couples represent less than a fifth of total sexual behavior with unmarried couples composing the majority. The most common sexual behavior among husbands and wives is passionate kissing. Implied intercourse is the most common sexual behavior among unmarried partners.

Sexual content in video games is depicted with increasing frequency. One study of games found that more than a quarter of the games sampled contained sexual content.

Conflict

Very little research has examined conflict on television. The work that has been done found that opposite sex clashes appear to be most prevalent. The most frequent response to conflict is avoidance. Contrary to research with actual couples on the demand-withdraw pattern, which indicates that women are more likely to demand and men are more likely to withdraw, men on television were less likely than women to physically withdraw from an argument. A recent analysis of the top ten shows watched by adolescents, which crossed genres, showed that conflict occurred in less than half of romantic relationships, was most frequently initiated by the female partner attributing the cause to the male partner, and was characterized by distributive conflict resolution (such as patronizing comments and chastisement) by women and integrative conflict resolution (such as apologizing or changing behavior) by men.

In film, stepfamilies are typically portrayed in a negative or mixed way with almost half depicting stepchildren resenting stepparents. The most common type of stepfamily portrayed is mother-stepfather relationship. Within young adult novels, the focus is generally around conflict or dramatic events that a family experiences. Most often, the relationship between mothers and daughters is characterized by conflict or separation because of illness or death or an emotional disconnect. Fathers are generally absent, which is contrary to the finding for children’s films, which was that fathers’ importance is usually elevated.

Aggression

Much research has focused on televised violence. Overall, more than half of all shows depict violence, and most of it is sanitized, glamorized, trivialized, not chastised, and committed by adult Caucasian males. About half of all victims are acquainted with the perpetrator. Children’s shows are the genre most likely to contain violent

content with about 14 violent acts per hour of programming.

Some researchers have claimed that there is a link between violent video game play or television violence and subsequent aggression, but other researchers doubt this claim.

Privacy, Disclosure, and Betrayal

One issue that has been uniquely studied with television talk shows is privacy, disclosure, and betrayal. Television talk shows portray people in controversial and sensationalistic relationships. An analysis of them showed that self-disclosures accounted for less than half of private information revealed about guests on the shows. Hosts and trusted personal relations of the featured guests were revealing the private information most of the time. The guests were victims of public “ambush disclosures.” Although the most frequent response to an “ambush disclosure” was a face-saving attempt by the guest, a murder of an acquaintance by the featured guest occurred after one such disclosure by the acquaintance.

MEDIA INFLUENCES ON RELATIONSHIPS

Through their stories, articles, and visual images, media convey cultural messages about relationships,

including desirable relationship and relational partner qualities, relationship roles, likelihood of relationship success, and prescriptions for forming and maintaining relationships. This entry specifically addresses the effects of media on viewers' expectations for romantic relationships. Expectations for romantic relationships have implications for real life relationships. Unrealistic expectations have been associated with lower relationship satisfaction and may contribute, in part, to divorce, depression, and abuse. Although expectations for romantic relationships form in a number of ways, media content may contribute to their creation and maintenance.

Theoretical Background

Media's power to influence conceptions of romantic relationships lies firmly in people's consumption of media content and the nature of that content. Nancy Signorelli wrote that television may be the single most common and pervasive influence on perceptions and behaviors related to marriage and romantic relationships. According to Cultivation Theory, television shapes viewers' beliefs about reality. Early cultivation researchers argued that frequency of viewing was more important than the viewing of specific program content because television programs present a uniform message. Though a substantial amount of research has documented the association between heavy viewers' beliefs and predominant television messages, this frequency orientation has been largely replaced by a content-specific approach (i.e., analyzing the frequency of viewing specific genres). Researchers have also investigated media beyond television, such as films, novels, music, and magazines, for their effects on romantic relationships.

Romantic Relationship Expectations

A growing body of work examines how media affect viewers' ideas about romantic relationships. A recent study found that as television viewing increased, never-married viewers' idealistic notions about marriage decreased. Idealistic beliefs included such ideas as expecting one's partner to read one's mind, seeing disagreement as destructive to the relationship, and perceiving

destiny to be a major causal force in relationship development or deterioration. Perhaps television content directly contradicts such idealistic beliefs, but it is more likely the case that messages about marriage and romantic relationships vary by genre. For instance, watching a great deal of romantic movies and television programs, reading appearance-focused magazines, and consuming gender-stereotypic and reality-dating television programming have all been associated with viewers' greater support of idealistic relationship beliefs. Other media-related behaviors that extend beyond viewing frequency may matter as well. The degree of dependency on television for information about relationships, the presence of alternative sources of information, and the belief that television presents accurate information have been important factors identified in past media effects studies. For example, late adolescents who rated themselves as highly influenced by media in early adolescence reported more unrealistic beliefs about romantic relationships.

Another argument is that these associations arise because people with idealistic notions of romance select more idealistic romantic programming. In partial support of that argument, participants who used more romantic media also reported ruminating and fantasizing more about romance. When asked to view a romantic comedy in an experiment, the attitudes of these already romantically minded individuals did not become more accessible (i.e., easily recalled and retrieved). However, another experimental study concluded that viewing a film that emphasized relational destiny (e.g., "fate brought the couple together") strengthened participants' beliefs in relational destiny. Hence, evidence indicates that viewers who take in a great deal of romantic media have more idealistic expectations for romantic relationships. This outcome is attributable partly to media influence and partly to viewer selectivity.

Other viewer characteristics may influence relational expectations. For instance, people may become more realistic as they age or life experiences may counteract media models. Despite higher portrayals of divorce, single parenthood, and pre- and extramarital sex in today's programs, heavy-viewing Generation Xers (children of the 1980s) hold more unrealistic relationship expectations (e.g., believing that partners who care about

each other should be able to sense each other's needs and preferences and that one must be a perfect sexual partner) than heavy-viewing Boomers (children of the 1950s). Heavy-viewing Generation Xers also prescribe to gender stereotypic relationship roles. Similarly, heavy-viewing adolescents were found to support traditional gender roles and scored higher on the sexism scale than did light viewers. They endorsed such statements as, "Women are happiest at home raising children" and "Men are born with more ambition than women."

Content analytic studies have indicated that media portrayals are mixed in that spousal relationships are presented as more equal and expressive but men and women are still shown in traditional ways. Men are more likely than women to be shown "on the job," and female characters are more likely to be seen dating, seen talking about romance, or presented as rewards for men who choose the right product. A recent study found that viewing prime-time comedies and dramas is positively correlated with believing that men are sex driven, women are sexual objects, and dating is a game.

Romantic Relationship Success

Media content also sends mixed messages about the likelihood for relationship success. Romantic relationships are highly valued on television and in movies but are often presented as fragile and difficult to maintain. Viewers report corresponding perceptions. Heavy-viewing adolescents saw singlehood more negatively than did light viewers. Heavy-viewing young women in the study conveyed the strongest desire to get married and have many children, and they wanted to engage in these activities at a younger age. Heavy-viewing college students of soap operas more strongly endorsed the belief that marriage is fragile than did their light-viewing counterparts.

Some experimental studies have attempted to clarify the causal relationship between media content and relationship success beliefs. In one study, elementary schoolers who were exposed to heavy doses of soap operas decreased their estimates of the number of happy marriages and increased their estimates of the number of divorces and

extramarital affairs. Similarly, in an experiment with college students, extensive exposure to sexually explicit films led to greater acceptance of sexual infidelity and sexual promiscuity. Being exposed to highly attractive women in magazines may also alter relational outcomes. Males who viewed highly attractive women in magazines lowered their partner's attractiveness ratings and rated themselves as less committed, satisfied, serious, and close to their actual partners.

In sum, research supports that media content can alter people's beliefs about and expectations for relationships. Yet, people may also gravitate toward media presentations that coincide with their belief systems. Ultimately, researchers need to account for these prior belief systems, as well as for the nature of the media content, frequency of viewing, and other viewer characteristics, when studying the influence of media on relationship expectations.

MEDIATION, MARRIAGE DISSOLUTION

Because divorce is both a legal and an emotional process, these processes interact in ways that create problems for both. This entry briefly explains the legal processes used to divorce and present an

influential theoretical model explaining emotional processes of divorcing parents. The goal is to provide a brief review of legal divorce methods while highlighting potential unintended consequences of those processes for couples locked in negative emotional cycles.

Legal Process

The legal process is defined as the entire process and procedures used to obtain a legal divorce. It is a linear process with a set of complicated, rigid rules and procedures that unfolds over months to years. To begin, one spouse must file with the court a set of specific documents detailing how the financial and child-related issues should be settled. There are sets of rigid rules for what documents that must be filed, the wording, and providing the documents to the other spouse. The second spouse then has a particular period to submit his or her own set of documents to be allowed to question any of the positions in the beginning set of documents. From this point forward, the legal process varies widely depending on whether the spouses agree, or can negotiate an agreement over time, or whether additional or alternative procedures need to be used to help the spouses agree.

Litigation

Traditional litigation is not a unitary phenomenon. In its simplest form, using attorneys, or through negotiations on their own, a couple can create an agreement that addresses financial and child-related issues and file it with the court. If the court approves, the agreement will become an order of the court. This process can be lengthy or swift depending on the level of cooperation between the couple (and the attorneys, if any).

If an agreement cannot be worked out in this manner, the couple can make proposals until an agreement is negotiated. This process can require hours of attorney time, multiple documents filed with the court, and multiple court appearances. At the extreme, couples can be so hostile and polarized as to require significant hours of attorney and several additional professionals' time (e.g., accountants, appraisers, psychologists or psychiatrists, attorneys for the children) to resolve disputed

issues. This extreme type of litigation is seen as formalized competition in which there is a “winner” and a “loser” for each issue, and has been criticized for being inherently competitive, adversarial, and expensive—which it is.

Although three decades of research have addressed divorce mediation, there has been little on this litigation process. The popular perception is that divorce lawyers are obnoxious, argumentative, and refuse to settle for what is fair thus increasing acrimony between the spouses. Unfortunately, no empirical studies confirm the number and percentage of lawyers who behave in this manner and no studies that focus on what lawyers see as their goal. Interview research indicates just the opposite: Argumentative and unreasonable lawyers are in the minority. The overriding desire among divorce attorneys interviewed is for a “reasonable divorce.” The major role of attorneys is to limit client expectations and overcome the resistance of angry clients who do not want to settle but instead want to use the legal system to play out emotional rather than legal issues. This process is often called *cooling out* the client. An interesting twist is that more clients are choosing to negotiate on their own and not involve attorneys or mediators. There is no empirical research on how the negotiation process works when clients negotiate in this manner.

Divorce Mediation

Mediation differs from litigation in several important ways. Most divorce mediation in the United States is through court-connected programs or court-appointed mediation providers. The issues to be settled are nearly always restricted to child-related issues (e.g., custody; parenting time; holiday and vacation schedules; education, religion and medical decision-making). Thus, while in litigation, spouses can resolve all issues; in divorce mediation couples must return to litigation to resolve any financial disputes. Thus, mediation is most often an *adjunct* to litigation rather than an *alternative* to litigation.

The divorcing partners are the negotiators in mediation. They are encouraged to consider options and alternatives, make proposals, consider what is best for their particular family, and to formalize an agreement. By contrast, attorneys assist

the clients in formulating proposals and are the negotiators for that proposal. Troubles often arise because clients in emotional crisis do not understand (or remember) what the attorney is negotiating or the attorney is not in agreement on the client’s position. Often forgotten is that divorcing clients (in addition to attorneys) have tremendous influence in choosing the level of hostility of any given divorce.

Another feature of mediation is that the couple meets with a neutral third party to express their concerns and tell their side of the story. Some argue that this may be *the* most important feature of mediation. Clients are further able to refine the narrative of their divorce in a cooperative, rather than adversarial, process. And, the cooperative nature of mediation has lasting effects on the clients’ postdivorce parenting (e.g., noncustodial parents see their children more).

The manner in which the features of mediation are then put into practice vary greatly. The process varies state-to-state, and even county-by-county within a state. At one end of the spectrum, clients participate voluntarily and pay hourly fees for mediation provided by private mediators. Private mediators can have a range of prior training (e.g., social worker, lawyer, psychologist, business, or no professional training). If the mediator is trained in a mental health discipline and offers a therapeutically oriented model of mediation, a significant number of sessions can focus on resolving emotional issues (e.g., focus on separating parenting and marital roles, defining boundaries of closeness and intimacy, frequency of contact, letting go of past conflicts, building conflict resolution skills). These private mediators can use as many sessions as necessary (and the clients can pay for) to resolve some or all divorce-related issues for a family, including financial and child-related issues.

At the other end of the spectrum are court-connected mediation programs that offer services for free (or a sliding fee) and are generally time-limited (1 to 10 sessions). Mediators in these programs are generally trained in mental health disciplines but, because of time constraints, the focus of this type of divorce mediation is on obtaining an agreement regarding child-related issues, rather than on resolving all issues in dispute (e.g., financial or emotional distress).

Emotional Processes

An influential, normative theoretical model for understanding the emotional process of divorce posits that whether people make the choice to divorce (the “leaver”) or are pushed into one by their spouses (the “left”), the process is filled with grief associated with many losses (e.g., friends, the social role of husband/wife, a daily routine, financial security, social status). As the grieving process proceeds, three competing emotions (*love*, *anger*, and *sadness*) vary in intensity and longevity. Spouses do not cycle through the emotions at the same time but they nevertheless are locked in the cycles with the other. Regardless of the other spouse’s emotions, one spouse can become “stuck” in one of the three emotions and not cycle back into the others. This “stuckness” can affect the legal process in several ways.

A person stuck in *anger*, for example, can express this anger by making outrageous accusations against the other parent in court, delaying the legal process, and refusing to follow court orders, which requires a spouse to go back to court again and again. In divorce mediation, this angry spouse can reschedule sessions, show up late, agree, then change his or her mind at the last minute and renege on these prior agreements. Recent research has found a significant predictor of making an agreement in mediation is the level of disparity in attachment between the spouses. If, for example, one spouse is attached and does not want the marriage to end, and the other spouse is not attached, the chances of reaching an agreement in mediation significantly decrease.

One or both spouses can reexperience the grief associated with the divorce and often it occurs during life events and life changes (e.g., holidays, graduations, when one spouse remarries or has a child with a new partner). Ex-spouses may suddenly, on the remarriage of one spouse, begin filing documents in court about parenting time, custody or both. Careful assessment of this situation is important. It may well be that the new spouse or siblings are negatively influencing the existing relationships within the first family; however, it may also be essentially grief and resentment manifesting through the legal process.

Intimate Partner Violence

Intimate partner violence (IPV) has become a growing concern among professionals working with divorcing couples. Within the mediation context, the number of mediation cases reported as having some type of IPV ranges between 40 and 80 percent. This range is significantly higher than that found in the general population, which is between 5 and 25 percent. In addition, few couples referred to mediation are screened out because of IPV (6–7 percent).

A particular type of IPV, *culture of violence* or *coercive control*, may be of particular concern. Critical elements include an ongoing strategy of isolating victims from friends, family, and children; controlling access to resources such as transportation, money, and housing; and controlling access to employment and education. Control is subsequently maintained through the use of (or threats of) physical and sexual violence to the victim or the victim’s family and friends. Thus, when coercive control is successful, the physical violence necessary to maintain control may be sporadic and in less severe forms. Critical for screening for IPV in divorce cases is to focus on coercive control. Recent research indicates that mediators focus on physical violence, injury, and outside involvement with the family (calls to police, arrests, hospital visits) to make determinations of IPV and may miss victims of coercive control.

Noncoercive negotiations, with a neutral third party, to consensually develop agreements reflecting the needs of all family members are the central elements of a fair mediation process. If one party is being coercively controlled, this is impossible. Within the litigation process, provided attorneys have a sophisticated knowledge of IPV and are aware of the coercive control, they may be able to better shield the client from direct negotiations. Unfortunately, no published empirical research indicates the level of knowledge of most attorneys regarding IPV, if attorneys screen clients for IPV, and if they do shield victims from their abusers.

Concluding Remarks and Future Directions

The manner spouses process their emotions can have tremendous impact on the legal process of

divorce for the family and vice versa. While families are in the midst of a psychological and sometimes financial crisis, they must also participate in a complicated, rigid, linear legal process that focuses “winners” and “losers” of particular positions presented to the court. Research indicates that people need to develop a coherent, organized, and meaningful personal narrative about stressful events (in this case divorce). To do so, spouses need to tell and retell their stories. The litigation process, however, does not allow spouses to tell the story of their relationship and what led to the divorce, nor does it allow the parties to express to the judge moral outrage, anger, or fear. Spouses may recite their stories to an attorney, but attorneys generally do not know what to do with the emotionally laced stories. The attorney’s job is to elicit what the client wants in a financial and parenting settlement and argue for it, not to assist a client develop a meaningful and organized narrative of their divorce. Spouses raw with the emotions or stuck in one emotion can use the legal system as an emotional weapon to harass, punish, and drain financial resources from their spouse, without any significant consequences.

For victims of IPV, accurate assessment of and responses to IPV by lawyers, mediators, and judges is essential to protect the victims yet we have little research that addresses whether it is done or if it is done accurately. Continued research addressing the interactions between the emotional and legal process of divorce are essential to design a more fluid system to better address the needs of divorcing families.

MEMORIES AND RELATIONSHIPS

People tend to have detailed and vivid memories of their relationships, outlining how their relationships have changed and developed over time. These memories form the basis for the relationship stories people present to others, and they provide the framework people use to reflect upon their relationships. This entry discusses how memories influence current feelings, accuracy in relationship memory, how current feelings influence recollections, how memories can predict future outcomes, and how people recall their relationships changing over time.

Accuracy in Relationship Memory

Research on relationship memory demonstrates that like memories in general, memories for relationships are not fully accurate records of past events. Although relationship memories have some degree of accuracy, these memories become degraded over time, essentially missing some of the specific details. Consequently, people use information that is accessible in the present when trying to fill in the gaps in their memory. This is shown in existing research in at least three ways. First, to the extent that people are currently committed to their relationships, they are motivated to preserve their sense of relational security and consequently fill in the gaps in their memory with details that maintain their faith in their relationship. Second, people use their current sentiments and knowledge about the relationship to help them interpret their pasts. Third, people use their current beliefs about how relationships change to help them understand how their own relationship

has changed over time. Although these processes tend to bias relationship memories, these biases, are informative, illuminating how people feel about their relationship at the present time and the likely future of that relationship.

These biasing effects have led some researchers to argue that researchers should be cautious in how they interpret self-reports of change or reports of past relationship events. However, people can enhance the accuracy of relationship memories by asking partners to recall past events together. *Collaborative memories*, memories constructed when two people work together to recall past information, tend to contain more accurate details and fewer errors than the memories recalled by individuals. When working together on recalling a past event, partners can cue each other's recall and even correct one another's errors in recalled details. For example, imagine a couple telling the story about their first date. One partner's recollection that they met at the roller coaster might remind the other partner to add the detail about how long the line was. Alternatively, one partner might recall they met at the roller coaster while the other partner is convinced they met at the water slide. In such instances, partners might be able to correct each other's recollections. Importantly, the process of working together to recall past events can reveal certain relationship dynamics such as respect, shared emotions, and dominance. For example, unequal levels of dominance among partners would be revealed if one partner always conceded when the partners disagreed on the details of a past event.

Memories Influence Today

Relationship memories surface frequently. Relationship researchers aren't the only ones who ask people about their relationship memories. Friends and family members routinely seek information about the course and development of relationships (e.g., "How did you two meet?"). Relationship memories can even be elicited by a partner's current behavior.

In addition to influencing the behavior partners engage in today, recollections of past relationship events shape the partners' current feelings about their relationship. For example, when people recall a time when their partner surprised them with a

kind and selfless act, they are reminded of a variety of past (or perhaps present) positive feelings about that partner. Such momentary recollections may lead individuals to feel a boost in their good feelings about the relationship. Conversely, present relationship evaluations might be far more negative if one had instead been reminded of a serious past conflict or partner transgression.

Today Influences Memories

Research on relationship memories, like much of the research on memories in general, demonstrates that present knowledge and sentiments play an important role in recollection. Current feelings influence which events are recalled, and as people piece together recalled information, they may interpret, embellish, and revise information to be consistent with their current understanding of their relationship. This process is likely not deliberate or intentional; people merely use their current knowledge to "fill in the blanks" in their memories.

Cathy McFarland and Michael Ross conducted a pioneering study investigating how present feelings can influence the recollection of a relationship. They used what has now become one common method for studying bias relationship memories: Participants were asked to indicate their current feelings about their relationships (Time 1), and 2 months later, they indicated their current feelings (Time 2) and recalled their initial reports (Time 2 Recollection). In this particular study, participants' feelings about their relationships at the present moment (Time 2) biased their recollections of their initial reports. People believed that their current feelings toward a partner were reflections of how they had always felt toward that partner: Those whose affections toward their partners increased retrospectively exaggerated the intensity of earlier reports whereas those whose feelings became more negative underestimated their original positivity toward their partner.

Research on memories for specific events, and not just overall evaluations of the relationship, has demonstrated similar patterns of bias. More satisfied couples fail to recall negative statements from previous conversations, and their relationship memories contain less negative affect and

ambivalence than do those of less satisfied couples. Similar effects have also been reported in nonromantic relationships: Happy friends recall a previous laboratory interaction with a friend as more enjoyable than they had indicated at the time of the initial interaction.

Relying on Scripts

People use their current feelings to infer their recollection and rely on their *scripts*, or general theories of how relationships progress and change, to help fill in the blanks in their memories. Scripts are highly influenced by cultural and social stereotypes. For instance, when people are asked to provide the script for how heterosexual relationships begin, they typically place the male in the initiator role (e.g., asking her for a date) and the female in the gatekeeping role (e.g., accepting or declining his advances). As relationships progress and time passes, people are more likely to use their scripts to fill in the gaps in their memories. For example, people are more likely to downplay the wife's role in initiating a relationship or proposing marriage when recalling the beginnings of a relationship at a later time than soon after the wedding.

Sometimes people rely on their unique, individualized theories of how relationships should progress to help them complete their relationship histories. For example, husbands who consistently endorse high egalitarian beliefs recall equally sharing responsibilities with their wives. However, husbands who wane in their egalitarian beliefs over time revise their earlier memories to reflect an unequal division of responsibilities (e.g., being less involved in wedding planning).

Memories for Own and Others' Relationships

People also exhibit bias when recalling other people's relationships, although typically in the opposite direction. The *perceived superiority effect* refers to the tendency of individuals, especially those who are currently happy in their relationships, to describe their own relationships as better than those of other people. When asked to report their memories for recent events in their own relationship and in the relationships of other people they know, people are more likely to describe more positive events for their own relationship than for

others' relationships. This is true when people are describing what they know about their parents' relationship, their friends' relationships, the relationships of acquaintances, and the relationships of people in the media. Such uneven recollections could certainly fuel the perceived superiority effect and possibly heighten optimism for the future of their own relationship.

Memories Influence Tomorrow

Memories can also influence how people feel about their futures. If a relationship has been satisfying for the last several years, people are likely to feel optimistic about their future together. Conversely, if partners can only recall negative relationship events and see their relationship history as a string of misfortunes, they are likely to be pessimistic about its future. Research in this area demonstrates that when individuals who are asked to recall past events in their relationship describe those memories with greater negativity and disappointment, they are more likely to separate or divorce in the years to come. Similarly, when partners' memories are biased to perceive recent improvements, they are more likely to be happy in their marriages in future years.

Memories for Relationship Change

How do people see their relationships changing over time? The research described suggests that people are inclined to view their pasts in a manner that is consistent with their present feelings. Viewing a relationship as stable might enable individuals to feel more secure. However, Charles Carver and Michael Scheier argued that perceiving improvement was more satisfying than perceiving stability. In other words, people prefer a story that suggests that their relationship has been getting even better to a story that suggests their relationship has always been good. Michael Ross and Anne Wilson proposed the Temporal Appraisal Theory, which suggests that the most recent past has the greatest implications for the present. In a sense, what happened in the distant past is dissociated from the present self and relationship and only the recent past has direct implications for the here and now. Consequently, perceptions of

improvement in the recent history should offer more benefits than should perceptions of improvement in the distant past.

The typical methodology for studying this phenomenon includes asking individuals to report on their relationship quality at several points in time. Further, at each point in time, except for the initial assessment, participants are asked to reflect on the trajectory of change in their relationships since the last assessment(s). In some studies, participants indicate how much they have changed since a specific time point, and in other studies, participants are asked to draw the trajectory of change in their relationship quality over time. Researchers then compare participants' memories of change in quality to their contemporaneous reports. Results reveal that retrospective reports indicate improvement in the *recent* past even though contemporaneous ratings tend to show stability or declines. These effects have been found in studies that have followed spouses and dating partners from periods ranging from 2 to 40 years.

Research also reveals that relationship partners benefit from perceiving recent improvement. First, recalled improvement is strongly associated with present relationship satisfaction. Second, recalled improvement is strongly associated with optimism for the future of their relationships. Third, recalled improvement actually predicts whether a couple will remain together.

Indeed, perceptions of improvement may not simply be beneficial but may be motivated. Perceptions of improvement can also provide a mechanism that allows individuals to maintain positive views of their relationship despite specific negative events. For example, when individuals are asked to recall a time when they hurt or transgressed against their intimate partner, they are apt to report relationship improvement even when their victims do not report similar levels of improvement. In this way, the perpetrators of these transgressions can dissociate themselves from their misdeeds and maintain optimism for their future together. Indeed, these perpetrators were more likely than were their victims to be optimistic about the future of their relationships. As such, perceptions of improvement allowed these perpetrators to feel secure in their relationships and to be optimistic for the future. This suggests that perceptions of improvement might boost cognitive

coping strategies. Importantly, recent evidence in a study conducted by Nancy Frye suggests that perceptions of improvement might also reduce negative conflict in relationships. When individuals do not see improvement in their relationships, they have fewer psychological resources available to pursue effective dyadic coping strategies, resulting in a higher rate of verbal and physical aggression. Presumably, perceiving improvement provides hope for the future and ultimately encourages positive relationship behaviors in the present.

MENTAL HEALTH AND RELATIONSHIPS

The relationships people have with their romantic partners and other family members are likely to be the most intimate and long-standing relationships they have in their lives. For example, relationships with romantic partners and family members provide the most frequent opportunity for social support. Because they assume such a prominent role in people's social environment, family and relationship functioning is likely to influence and be influenced by the mental health and well-being of the members of these relationships. Evaluating the importance of family and relationship functioning with respect to mental health is consistent with modern biopsychosocial models of well-being and psychiatric disorders. This entry describes the role of family and relationship functioning on the onset, course, and treatment of mental health problems.

Family Functioning

There is growing awareness that family dysfunction and mental health problems such as psychiatric disorders are often associated with one another. On one hand, the need for emotional and instrumental support that accompanies mental health problems, as well as the symptoms of mental health problems (e.g., negative mood), may be taxing and burdensome for family members. On the other hand, family members may influence the course of mental health problems through such means as treatment adherence and promotion of behaviors that facilitate recovery. Indeed, poor family functioning is associated with a variety of psychiatric disorders, including mood disorders, anxiety disorders, substance use disorders, eating disorders, and schizophrenia spectrum disorders.

Furthermore, the level of family dysfunction observed in the families of psychiatric patients is higher than in families with a medically ill member; however, there is little difference between families with different specific psychiatric diagnoses in their level of family dysfunction. Compared with nonclinical families, families in which one member has a psychiatric diagnosis appear to be particularly impaired in communication and in resolving problems.

Although the research design for much of the research on family functioning and mental health is cross-sectional (i.e., measures of family functioning and mental health are collected at the same point in time), some research shows that family functioning assessed at one point in time is associated with changes in measures of mental health collected at a later time. For example, results from longitudinal or prospective studies indicate that family functioning is associated with the course of mood disorders. Specifically, compared with people with better family functioning, those with poorer family functioning report higher levels of depression, lower recovery, and lower levels of overall adjustment over time. Furthermore, families with a depressed member report worse family functioning than do control families, both during an episode and at remission, suggesting that family problems are not just a consequence of depression.

To the extent that poor family functioning is associated with the onset and course of mental health problems, improving family functioning through interventions such as family-based therapy should result in improvements in psychiatric functioning. In support of this perspective, family-based treatment approaches have been shown to be effective for a variety of mental health problems, including schizophrenia, bipolar disorder, conduct disorder, eating disorders, alcoholism, and adolescent substance abuse. Studies comparing family-based treatments with other types of intervention generally suggest that family-based treatment is as effective as other approaches to treatment. Furthermore, family-based interventions affect not only the person with the mental health problem, but also have the added benefit of improving functioning in other family members. For example, family-based interventions have positive effects on relatives' caregiver burden, psychological distress, and overall family functioning.

Thus, it appears that family therapy, singly or in combination with other psychiatric interventions such as medication or individual psychotherapy, may be an important part of a comprehensive approach to the treatment of mental health problems.

Marriage and Relationship Functioning

Relationship Quality and Psychopathology

The most commonly studied measure of relationship functioning that has been studied with respect to mental health is partners' self-report ratings of the overall quality of the relationship, as described by terms such as *satisfaction*, *discord*, or *distress*. Furthermore, most of the research on relationship functioning and mental health has focused on married individuals. Studies have found a negative association between marital satisfaction and symptoms of psychopathology. For example, many studies have found that increasingly lower levels of marital satisfaction are associated with increasingly higher levels of symptoms of depression. To provide an overall estimate of the strength of association between marital satisfaction and personal well-being (e.g., depression, anxiety, psychiatric symptoms), a meta-analysis was conducted of existing research; a meta-analysis is a summary of previous research that uses quantitative methods to compare outcomes across studies and provide a measure of the magnitude or degree of the association (i.e., an effect size). A meta-analysis of the association between marital quality and well-being using different measures of well-being across 93 different research studies yielded a mean effect size (r) of .37. The square of the effect size r (i.e., r^2) can be interpreted as the proportion of variance in either of the two variables that may be accounted for by the variance of the other variable. Squaring the effect size of .37, therefore, suggests that 14 percent in the variability in either marital quality or personal well-being can be accounted for by the other variable.

In addition to symptoms of mental health problems, researchers have studied the association between relationship quality and diagnosable mental health problems (i.e., psychiatric disorders). Results from these studies have consistently shown that marital satisfaction is lower among people with psychiatric disorders. In studying this

association, researchers have generally adopted one of two strategies. First, researchers have examined the marital satisfaction of people seeking treatment for a psychiatric disorder compared with people not in treatment. Compared with those without a psychiatric disorder, marital satisfaction is lower among people with mood, anxiety, substance use, and eating disorders. However, because only a subset of people with mental health problems seek treatment for their psychiatric disorder, these studies may be limited in their generalizability insofar as they do not include people with mental health problems that do not seek treatment. Therefore, a second strategy used by researchers studying the association between marital quality and diagnosable psychopathology has been to examine this association in representative, population-based community samples. Results from large epidemiological surveys have found that lower marital satisfaction is associated with sexual functioning and a variety of mood, anxiety, and substance use disorders. For example, in a population-based sample of more than 2,000 people, marital distress was associated with (a) broad-band classifications of anxiety, mood, and substance use disorders; and (b) narrow-band classifications of seven specific disorders, with the strongest associations obtained between marital distress and bipolar disorder, alcohol use disorders, and generalized anxiety disorder. In an earlier population-based study involving more than 2,500 married individuals, maritally distressed individuals were two to three times more likely than were nondistressed individuals to experience mood, anxiety, or substance use disorders. In addition, lower marital quality is associated with higher psychological distress, poorer perceived health, and greater functional impairment (i.e., social impairment in relationships with relatives and friends, work impairment); these associations remain significant when controlling for current mood, anxiety, and substance use disorders, suggesting that relationship discord is incrementally related to distress and impairment, over and above the effects of psychiatric disorders.

Although cross-sectional studies such as these are important for establishing an association between marital quality and psychopathology, the design of these studies does not address the causal direction of this association. Is lower marital

satisfaction for people with mental health problems a cause or a consequence of their emotional and behavior problems? On the one hand, mental health problems can adversely affect relationship outcomes. For example, being married or involved in a committed relationship with a person with mental health problems can result in stress and burden on the spouse or partner, which may contribute to relationship problems and increase the likelihood of relationship dissolution. In support of this perspective, studies have shown that people with early-onset psychiatric disorders are more likely to marry early and are more likely to experience marital separation or divorce.

On the other hand, lower marital satisfaction can adversely affect people's mental health. For example, decreases in support from the partner or increases in relationship stressors or strains can affect the psychological and biological functioning of the person, increasing the risk of mental health problems. In support of this perspective, marital dissatisfaction has been shown to predict increases in symptoms of depression over time. Furthermore, marital dissatisfaction has been shown to predict the onset of psychiatric disorders. In a population-based sample in the United States, low marital satisfaction at baseline predicted increased risk for the onset of major depression and alcohol use disorders among people that did not meet criteria for the corresponding disorder at baseline. Furthermore, marital quality predicts first onset (i.e., incidence) of psychiatric disorders among people who do not have a history of mental health problems. In a longitudinal population-based study of more than 4,500 people in the Netherlands, lower marital quality at baseline was associated with an increased risk for the onset of psychopathology assessed during a subsequent 2-year period. Specifically, lower marital quality at baseline was associated with an increased risk for first incidence of broad-band factors of mood and anxiety disorders, as well as for the separate diagnoses of major depressive disorder, dysthymia, social phobia, and alcohol abuse. Thus, it appears that marital functioning and mental health mutually influence one another over time in a bidirectional, recursive fashion.

Whereas much of the research on couple functioning and mental health has focused on global relationship quality, research is beginning to

identify some of the specific relationship components that are associated with mental health outcomes. For example, studies have evaluated communication behaviors and patterns that are associated with mental health problems such as depression, anxiety disorders, and substance use disorders. Furthermore, studies have found that physical abuse occurring in the context of marriage and romantic relationships demonstrates a cross-sectional and longitudinal association with increased risk for psychiatric symptoms and onset of psychiatric disorders.

Finally, marital and relationship functioning is also associated with the mental health of the partners involved in the relationship, as well as with the mental health of their offspring. Specifically, parental marital discord and violence between parents is associated with elevated rates of psychiatric symptoms and diagnosed psychiatric disorders in children and adolescents. For example, parental marital discord and aggression are associated with the presence of anxiety, depression, oppositional defiance, conduct problems, and substance abuse in children and adolescents. Given this association, researchers have sought to identify moderating variables that affect the magnitude of the association between parental relationship functioning and mental health outcomes in children. Researchers have also sought to identify the mediators or mechanisms by which parental relationship functioning may increase risk for mental health problems in children. For example, parental conflict and aggression may create vulnerabilities that, by themselves or in interaction with genetically based vulnerabilities, produce disruptions in psychosocial functioning, disruptions in stress-responsive biological regulatory system, and poor health behaviors. Thus, poor marital functioning affects the mental health of other family members, including children, as well as that of partners. Furthermore, as with partners' mental health and well-being, marital problems and child mental health problems appear to influence one another in a reciprocal, bidirectional fashion.

Relationship Quality and Treatment of Psychopathology

To the extent that marital discord is associated with the onset and course of mental health

problems, then it may be expected that the higher rates of marital discord will be associated with poorer outcomes to treatments for mental health problems that do not specifically address relationship problems. For example, marital discord might be expected to be associated with poorer outcome for people on medication or who receive psychotherapy that includes only the person with the mental health problem. Indeed, poor functioning in marriage or other intimate relationships is associated with poorer outcome to individual-based treatments (e.g., medication, individually oriented psychotherapy) for mood, anxiety, and substance use disorders. Compared with people who report greater levels of relationship satisfaction, people with lower levels of satisfaction have higher levels of symptoms at the end of treatment and during follow-up and are more likely to relapse or experience a recurrence of the mental health problem following treatment.

To the extent that marital discord is associated with the onset and course of mental health problems, then treatments such as marital or couple therapy that specifically target relationship problems should be effective in improving mental health outcomes. Support for this perspective comes from studies showing that couple therapy is effective in treating major depression and alcohol and drug use disorders; partner-assisted exposure (in which the partner is included in the treatment as a cotherapist, assisting the patient in practice sessions at home) has been shown to be effective in treating obsessive-compulsive disorder, and partner-assisted exposure and partner-assisted cognitive behavioral treatment have been shown to be effective in treating agoraphobia. When the efficacy of couple therapy or other couple-based interventions are compared with the efficacy of medication or individually oriented psychotherapies, couple therapy and couple-based interventions have generally been found to be as effective as these other approaches in the treatment of these disorders. Furthermore, whereas individually oriented treatments for mental health problems do not appear to alleviate marital discord, couple therapy has been shown to improve marital or relationship functioning, as well as reduce psychiatric symptoms. Finally, some evidence indicates that changes in marital quality are responsible for (i.e., mediate) the effects of couple therapy on changes in

psychopathology, at least in treatment effects of couple therapy on depression. Taken together, existing studies suggest that couple therapy and other couple-based interventions may be effective for a variety of mental health problems, particularly those that co-occur with marital or relationship discord.

Expressed Emotion and Perceived Criticism

In addition to global measures of family and relationship and functioning, researchers have sought to identify specific aspects of the couple and family environment that predict mental health outcomes. One such component of a person's interpersonal environment that has been identified as important in this respect is the degree of *expressed emotion* (EE). EE refers to how the partner or other relative of a person with a mental health (i.e., psychiatric) problem talk about the person in a private interview with a researcher. Partners or other relatives are classified as high in EE if they make more than a specified threshold number of critical comments about the person with the mental health problem, or show signs of hostility or marked emotional overinvolvement. Initially, EE was developed to understand relapse rates for people with schizophrenia. More recently, it has been more extensively studied as a predictor of relapse for other mental health problems, including depression, bipolar disorder, and eating disorders. A meta-analysis of existing studies indicates that EE predicts relapse in people with schizophrenia (mean $r = .30$), mood disorders (mean $r = .39$), and eating disorders (mean $r = .51$). Furthermore, relatives who are classified as high in EE behave in a more negative fashion when interacting with patients than do relatives who are classified as low in EE. Finally, results from several family-based treatments indicate that decreases in EE following treatment are associated with decreases in relapse rates. In summary, it appears that differences among partners and relatives in their level of EE reflect characteristics of the patient-relative relationship that are important for understanding relapse rates across a range of mental health problems.

Whereas the EE construct is based on observations of a partner or other relative's behavior when talking

to a researcher about the person with mental health problems (or, in some cases, based on self-report questionnaires completed by the partner or relative regarding their relationship with the person), researchers have also evaluated the perceptions of people with mental health problems regarding how critical they think their partner or relative is of them. This subjective measure of *perceived criticism* completed by the person with the mental health problem has been shown to predict relapse for people with mood, anxiety, and substance use disorders. Furthermore, perceived criticism ratings are stable over time and are not related to concurrently assessed symptom severity, suggesting that the association between perceived criticism and relapse is not an artifact of symptoms. Thus, it appears that the degree of criticism in the marital or family environment, whether measured by outsiders' coding of spontaneous comments about the person or by insiders' ratings of their perceptions of criticism, is important for understanding the course of mental health problems.

MENTORING PROGRAMS

Mentoring programs pair youth who are perceived to be at risk for poor outcomes with volunteers who are trained to provide mentoring. Such programs have experienced tremendous growth in recent years. An estimated 3 million young people are in formal one-to-one mentoring relationships in the United States. This represents a sixfold increase from just a decade ago, and funding and growth imperatives continue to fuel growth. As mentoring programs have expanded, so too have the ways in which the services are delivered. Among the most popular alternative to the traditional one-on-one pairings of adults and youth are group, peer, and e-mail mentoring. Strategies tied to particular settings—such as school-, workplace-, and faith-based mentoring—also are exhibiting rapid growth. Indeed, although mentoring programs have traditionally been community-based, nearly half of mentoring relationships now meet through schools. Big Brothers Big Sisters of America (BBBSA), the nation's largest and oldest mentoring program, has seen a fourfold increase in school-based matches since 1996.

The enthusiasm for and growth in initiatives to support mentoring speaks volumes about the faith society places in one-to-one relationships between vulnerable young people and unrelated but caring adults. And with good cause. The success of human services initiatives often rests on the quality of relationships that are forged among participants. By putting relationships at center stage, mentoring programs can deliver this healing in full

potency. This entry reviews evidence for the effectiveness of mentoring programs and discusses the elements of mentoring programs that appear to be central to this effectiveness.

Effectiveness of Youth Mentoring Programs

Program evaluations suggest that high-quality youth mentoring relationships can effectively reduce social, academic, and behavioral problems. Nonetheless, there appears to be considerable variability in program impact. In some instances, negative or no effects have been found, or effects have eroded to nonsignificance within only a few months of program participation. Only one mentoring program, "Across Ages," has achieved the status of "model program" on the Substance Abuse and Mental Health Services Administration (SAMHSA) Registry of Evidence-based Programs and Practices (NREPP), an online registry of independently reviewed and rated interventions.

BBBSA was listed on this registry as an "effective program," a designation that stemmed, in part, from the landmark study of their community-based mentoring (CBM) programs. The evaluators traced the experiences of youth given access to the programs, as well as a control group, over time. Although the standardized effect sizes across all outcomes in the study were relatively small, several widely cited, statistically significant differences in behavior and academic functioning between the mentored youth and the control group were uncovered.

More recently, a large randomized evaluation of BBBSA school-based mentoring (SBM) program was conducted by Carla Herrera and her colleagues. Overall findings were mixed. At the end of the first school year, youth assigned to receive mentoring showed significant improvements in their academic performance, perceived scholastic efficacy, school misconduct, and attendance relative to a control group of nonmentored youth. These effects were generally small in magnitude and, when youth were reassessed a few months into the following school year, most differences were no longer statistically significant.

Despite these somewhat discouraging trends, the group differences that have been uncovered in these evaluations do give grounds for cautious optimism

about the potential viability of mentoring interventions. Given the vast continuum in the quality and duration that exists in the mentoring relationships, however, it is unrealistic to expect dramatic, across-the-board reversals of the negative trajectories that are typical of adolescence. Indeed, matches and programs can vary considerably in their effectiveness, depending on the characteristics of the individuals involved and the quality, intensity, and duration of the relationships they form. Secondary analyses of the SBM data revealed that mentees who experienced longer, closer relationships received bigger benefits than do those in shorter or weaker relationships. And, in Year 2, those involved in weaker, shorter relationships actually showed declines relative to their nonmentored peers. The same patterns have been found in CBM. When all relationships are combined, positive outcomes are easily masked by the neutral and even negative outcomes associated with less effective mentoring relationships. The challenge is to identify those program inputs and factors that can facilitate the formation of close, enduring, and, ultimately, effective mentor-youth ties.

Research has been conducted in this regard. Close, enduring connections between youth and mentors appear to be fostered by factors resembling those identified as important in effective therapeutic relationships, such as empathy and authenticity, and a basic compatibility in youth and mentors' personalities, interests, and expectations for the relationship. The formation of a close, effective relationship is also conditioned by the background characteristics of the mentor, the effectiveness of the mentor in addressing the developmental needs of the child, the consistency and duration of the tie, and the quality of broader program and community context in which the relationship unfolds.

A series of meta-analyses also shed light onto the issue of effectiveness. David DuBois and his colleagues revealed favorable effects of mentoring programs across relatively diverse types of program samples, including programs in which mentoring was provided alone or in conjunction with other services. Positive effects were found both in programs that had general goals and in those with more focused goals, and held up for youth of varying backgrounds and demographic characteristics. Among the small number of studies that included

follow-up assessments, the benefits of mentoring appeared to extend a year or more beyond the end of a youth's participation in the program. Although there was considerable variation across studies, the average effect size across the samples was relatively small, particularly in comparison with the effect sizes that have been found in meta-analyses of other prevention programs for children and adolescents. More recent meta-analyses have found similarly modest effects.

Conclusions

In some cases, youth mentoring interventions can have extraordinarily influential effects; in others, they can do more harm than good. The balance can, and should, be tipped toward the former. A deeper understanding of mentoring relationships, combined with high quality programs, enriched settings, and a better integration of research, practice, and policy will better position programs to harness the full potential of youth mentoring programs.

MENTORING RELATIONSHIPS

Association with guiding patrons and more knowledgeable others is featured in stories and biographies of successful men and women in the past and present. Finding and building a relationship with a mentor has been described as facilitating success in business, education, and other life pursuits. Likewise, identifying a talented and promising protégé has been linked to building support and one's life work living on in others.

These relational partners could be college professor and student, business executive and junior partner, volunteer and special-needs child, grandparent and grandchild, neighbor and newcomer, spiritual leader and neophyte, or sports coach and athlete—to name only a few possible mentors and protégés. The knowledge learned and tasks accomplished are as varied as mentors and protégés.

A *mentor* is a person with more knowledge and sophistication in a particular area of expertise who shares this knowledge with someone less knowledgeable through a relationship. The person who learns from the mentor is a *protégé*. Together, the mentor and the protégé form a mentoring relationship.

Mentoring relationships are personal relationships in which neither partner can be substituted without significantly altering the relationship. Mentoring relationships can develop through mentoring programs or they can develop informally. Many long-term mentoring relationships are the result of informal mentoring relationships that develop into high-quality mentoring relationships. This entry discusses the development, maintenance, and repair of mentoring relationships and the overall benefit of these relationships.

Development of Mentoring Relationships

Mentoring relationships are unique from other relationships in that there is no assumption of equality in the relationship. There are fewer mentors available than there are potential protégés. Mentors have knowledge, skills, and connections that are desired by protégés. This gives mentors more relational power and influences the dynamics of the development, maintenance, and repair of mentoring relationships.

Potential mentors may perceive risk in becoming part of a mentoring relationship with a protégé. Those who perceive greater risk in being close to others will be less likely to mentor than will those who do not perceive risk in being close to another. In professional and academic environments, mentors may perceive risk in sharing their secrets and strategies for being successful with others because the protégé may one day become more proficient than the mentor, or the protégé may share the mentor's closely held secrets with others. Generally, mentors may perceive risk in investing the time in helping another person to become successful. As a person's time is typically at a premium, the time spent helping a protégé may be a cost that a potential mentor is not willing to commit. There is the risk that time will be invested in a protégé but that person will not be successful and the protégé will reflect badly on the mentor. Finally, there is the risk that the protégé will simply take the mentor's knowledge and move on to another mentoring relationship.

For the mentor, the risks of a mentoring relationship are countered by the opportunity to help another person, see one's accomplishments remembered by another, be the source of positive regard by another, have a protégé to assist with projects and activities, and receive social support from the protégé. Mentors may also participate in mentoring relationships to help members of disadvantaged groups, to help those they care about, or to help their profession, passion, or area of expertise grow with talented new members who have gained from the knowledge shared.

The limited number of potential mentors coupled with the perceived risk in becoming part of a mentoring relationship places protégés at a disadvantage in finding mentors. Protégés have much to gain from a mentoring relationship and fewer risks to consider. Protégés might perceive risk in exposing lack of knowledge or expertise to a mentor, associating with a mentor, and possible future discouragement by the mentor if one wishes to move on to other relationships or pursuits. However, for protégés, the perceived risk of being close is not as strongly associated with avoiding mentoring relationships as it is for mentors. Being a protégé with a more accomplished mentor means having someone to help one gain knowledge, to advocate on one's behalf, and to help with gaining access to

opportunities that one may not have had the opportunity to access on one's own. Those who report having a mentor also report greater success in business, education, and other pursuits. There is often competition with other potential protégés to develop a relationship with particularly successful mentors.

Mentoring relationships can be facilitated through invitation from the mentor to the protégé, through the protégé approaching a mentor, by a third-party arrangement placing the mentor and protégé together, or through routine and strategic social interaction between a potential mentor and protégé.

According to Mentoring Enactment Theory, mentoring relationships are developed, maintained, and repaired through strategic and routine communication with mentors and protégés. Just as with any relationship, mentoring relationships build slowly and communication should be appropriate for the level of the relationship. Mentoring Enactment Theory predicts a protégé approaching a potential mentor for general help and advice will be more effective at building a mentoring relationship than will a protégé who directly asks a potential mentor to be one's mentor. This is because a direct request to mentor would be the relational equivalent of asking someone in a beginning friendship to be one's best friend or asking someone in a beginning romantic relationship to marry. Although sometimes these bold questions will be met with the reward of the other's commitment, more likely the potential relational partner will be rebuffed for requesting too much commitment too soon in a relationship. This would not be the case for potential mentors who have already made the commitment through joining a formal mentoring program.

For mentors and protégés, the relationship develops in the context of the common goal or shared interest, be it work, career, education, hobby, spirituality, or whatever has drawn the mentor and protégé together. The mentor having more knowledge and experience in the area is in the position to teach and guide the protégé. The protégé is in the position to learn from the mentor and perhaps share new insights and discoveries with the mentor. Mentors may introduce the protégé to others who are accomplished in the area of interest and who can also help the protégé.

Mentors may also serve as advocates for the protégé, helping when difficult situations or competitors are encountered. Protégés help the mentor with tasks and with projects relating to the common goal or interest. A new perspective can help the mentor stay fresh. Also as protégés' skills and abilities develop, they can reciprocate with the mentor by sharing new insights, introducing the mentor to new associates with complementary interests, and advocating for their mentor as well.

Relational Maintenance and Repair

Mentors and protégés are members of a relationship and, as with other types of relationships, they can build trust and social support as well as have conflict and jealousy. Any factors or processes evident in any human relationship can be a part of a mentoring relationship. The mentoring relationship is unique in that the focus of the relationship is the goal or interest that drew the two together. This focus is elaborated in the context of a relationship.

Mentoring relationships may last only a few years or they may last a lifetime. Mentoring relationships have been studied as phase-based relationships with a specific beginning, development, and end. Mentoring relationships have also been studied as ongoing relationships that do not necessarily have a predictable trajectory. This perspective considers mentoring relationships to be developed through strategic and routine communication and these relationships may move forward or backward in development depending on the conflicts, challenges, and opportunities that occur as part of any relationship.

As in other relationships, mentors and protégés engage in relational maintenance strategies to keep their relationships viable. When conflict with their mentors occurs, protégés may employ a number of strategies to appease their mentors and to maintain their relationships. These can include pragmatic appeasement, such as pledging to work harder to accomplish expertise and complete tasks, as well as affable appeasement, such as expressing positive regard and focusing on the relationship more than on tasks.

Research has shown that mentors tend to forgive their protégés and to maintain positive regard for them after conflicts have occurred, with pragmatic

appeasement strategies being more effective than are affable appeasement strategies. In these situations, the mentor and protégé power differential is evident, with protégés in the position of communicating appeasement and mentors in the position of forgiving the protégé.

Problems can occur in mentoring relationships when protégés' interests change or develop in ways that are no longer compatible with their mentors' interests. Protégés may disagree with the mentor's advice or surpass the mentor in accomplishments. In some cases, as protégés attempt to leave mentoring relationships or redefine these relationships as friendships or other more general sources of social support, this change may not be acceptable to the mentors. Some protégés experience difficulties exiting or redefining mentoring relationships as mentors may resist losing their protégé. As with any relationship, not all mentoring relationships are positive, however the relationships may still flourish with the protégé learning desired skills and the mentor building a legacy of knowledge shared.

Some protégés have several mentors. Others have built a network or constellation of social supportive relationships with mentors and others who are interested in their success. Some mentors have several protégés at one time or have several serial protégés. These protégés may form support networks among themselves as protégés or former protégés of a mentor.

Those who have been mentored are more likely to mentor others. This means that even if a mentor has only mentored one protégé in a lifetime, generations of protégés may be influenced by this relationship. If each protégé mentors one or more other protégés as they develop expertise and knowledge in an area of interest, the number of generations could be endless.

Mentoring relationships are the relational conduit for social support and success of a protégé. They can also provide social support to a mentor. Together the mentor and protégé form a relationship of care and assistance. Mentoring relationships will not always be smooth. However, if the mentor and protégé are able to maintain their relationship and go on to mentor others, then a web of social support and expertise can result from these mentoring relationships.

METACOMMUNICATION

“The two of you might metacommunicate,” the facilitator said to the two vice presidents who were struggling with understanding each other. Their puzzled looks were punctuated by one of them asking, “What do you mean by ‘meta-communicate?’” The facilitator replied, “Meta-communication is communicating about communication. For

example, when you say, ‘John, I’m only kidding’ that tells him how to interpret what you said. The facilitator continued, “Such is the role of metacommunication—always present, not always noticed, yet an important interpersonal skill.” This entry on metacommunication describes the types and uses of metacommunication and its use by competent communicators.

Explicit Metacommunication

Metacommunication occurs explicitly and implicitly. When someone says, “This is an order,” or “I don’t mean this as a criticism,” or “I’m really upset with you,” that person is telling the other explicitly how to interpret what is said. Explicit metacommunication serves as a verbal “frame” to guide the other’s interpretation. As with any communication, explicit metacommunication may not match the receiver’s experience of the speaker. For instance, if one has a habit of “joking,” but is really saying sarcastic things, when he or she labels it as “Oh, I was just joking,” the attempt at providing a frame may not match the other’s experience. A good relationship occurs when the verbal frame provided matches with the other’s experience—saying it was meant as a joke and the other interpreting it as a joke.

One of the skills personal counselors and therapists use is providing alternative “frames” or metacommunication labels for what clients are communicating. For example, if in a marital couple, the man says, “There she goes again, criticizing me,” the counselor may say, “That is interesting—it sounded to me like she was just being descriptive and didn’t mean that as a criticism.” The counselor adds a different metacommunication label or frame, trying to help the man reinterpret the communication from his partner.

Explicit metacommunication can be seen as negative or positive. Early writers on metacommunication thought that in counseling, for example, most metacommunication was negative, such as “there he goes, trying to control me again.” However, explicit metacommunication serves positive functions as well. A competent person in the business world might say, “I need to talk about this issue with you so we can be ‘on the same page’ and you will feel more supported”—clearly, a

positive metacommunication. In personal relationships, positive metacommunication is often at the heart of good exchanges, by labeling exactly what one intended so the other will not misinterpret the verbal message.

In this example, explicit metacommunication is used in the conversation itself. One can also metacommunicate explicitly about the nature of the relationship. For instance, to say, “Julio and I are friends” is a form of relationship-level metacommunication, so if the two of them hurl insults at one another, saying they are friends cues onlookers to their relationship—and how to interpret the exchanges. Romantic partners, who begin as friends and then become romantically involved, have to change their relationship-level metacommunication, by exclaiming, for example, “Oh, yes, we were friends and now we are seriously dating.” Explicitly saying, “This is our relationship” is a form of metacommunication about how to interpret the exchanges. At times of relationship change such as this, it helps others interpret the communication by being explicit.

When you attend a party with your romantic partner, and say, “This is Carl, my boyfriend,” it cues others about the nature of your relationship. Or, the reverse, when a politician is accused of having an affair and says, “Our relationship is strictly professional,” the politician is trying to convince outsiders that the relationship is not romantic. A brother and sister, for example, may be close to each other and do lots of hugging and gentle touching. When they are with others, the brother may say, “Hi, this is my sister—I’m really lucky to have such a close relationship with her.” The participants in all these relationships are trying to cue outsiders about the nature of their relationship by being explicit. One rather fascinating example of explicit attempts comes from a parrot. When the owner comes home and opens the door, the parrot says, “I love you.” Although it warms the heart of the owner, the parrot is likely motivated more by the desire for a treat than by the desire to provide clear, explicit metacommunication!

Implicit Metacommunication

Humans also metacommunicate implicitly—without labeling their intentions. Implicit metacommunication is cueing the other nonverbally

rather than verbally. For instance, if someone says, “Close the door” with a harsh tone of voice, or alternatively, says, “Close the door” in a friendly tone of voice, different implicit signals are given for how to interpret the communication. Interestingly, these implicit forms are more common than explicitly labeling how to interpret communication. The implicit forms occur within every exchange—participants are always cueing others with tone of voice, body language, and body tension about the proper meaning for the message. For instance, if someone is angry at his or her child, using a stilted tone of voice, tense body tone, and eye gaze directed above the child’s head cues the child that the parent is upset. Or, the child, who, in response to a request from the parent to clean up her bedroom, doesn’t look up and quickly says, “Whatever,” lets the parent know the child is not really listening nor complying.

Other animals besides humans also implicitly metacommunicate. For instance, two dogs can signal each other how to interpret their intentions, with absolute accuracy. One dog, while looking aggressive, can metacommunicate to the other, “This is play—not serious dominance.” And then they play. The elaborate rituals dogs and other animals use when greeting another of their species ensures fairly accurate metacommunication. The dog in the park doesn’t walk up and say, “I’m friendly and won’t attack you” to another dog, but body posture, speed of closing in, eye gaze, tail wagging, and the degree of body tension, all signal the other that no attack is forthcoming. It is interesting watching humans who do not know a particular dog misinterpret that dog’s implicit metacommunication. Rosie, an Australian shepherd, for example, bares her teeth to humans she likes—it is a “smile,” rather than a sign of aggression. But humans who do not know her may think she is snarling at them. Another dog, meeting her, however, relies on a host of cues in addition to the smile, and there is no miscommunication—the meaning is instantly clear and accurate. Dogs also read dominance signals from other dogs they have just met. What is it about dogs (and other animals as well) that allows them to metacommunicate with another with absolute accuracy, yet humans seem to struggle over their metacommunication with someone they have lived with for years? It

may be that humans emit messages with more mixed signals than do other animals. Humans, can, however, learn what signals work to cue their animals about their intentions. Dog owners, for example, who want to play with their dogs can do so without any words. Rather than explicitly saying, "Rover, now we are going to play," the human will hunch over, move rapidly, grab the dog's toy, and instantly the dog knows that this is play behavior—good, implicit metacommunication is occurring between the two of them. An engaging television program, *The Dog Whisperer*, illustrates how interspecies' implicit metacommunication occurs. Caesar Milan, the dog whisperer, specializes in retraining dogs that have gotten out of control. Using no words, he can instantly metacommunicate with a dog. For example, to get a dog to stop jumping on humans, he simply quickly grabs the dog on the neck and lets go. The dog apparently interprets this as a "bite" and, as if an adult dog were training her, stops jumping on the human.

Metacommunication of both types, explicit and implicit, are skills that can be learned. Children learn both by observation and through explicit instruction. For example, a father may teach his son to look someone in the eye when speaking, rather than looking sideways, to signal sincerity and respect. For children, and all of us, once someone learns some metacommunication repertoires, he or she can implicitly show their intentions for a conversation or explicitly say what those intentions are. This allows the receiver into the world of the sender, and opens dialogue about what the receiver interpreted. For instance, if one metacommunicates and describes what is going on in a conversation ("I note that every time I say something about your team, you interrupt me"), it can serve as a springboard to clarify communication patterns.

There may be important cultural differences in the recognition and use of metacommunication because humans learn how to use or not use metacommunication. Some cultures teach and practice it on levels not seen in Eurocentric cultures. For instance, the Maori indigenous culture in New Zealand has the *Haka*—a dramatic approach to strangers that entails a threatening posture and loud vocal sounds. More research could uncover forms of metacommunication used across the world. It would be useful to find examples of when

metacommunication enhances communication exchanges and relationships. Learning the skills of both explicit and implicit forms of metacommunication helps individuals expand their communication repertoires. It may be, as trained mediators and counselors know, improving both explicit metacommunication ("talk about talk") and being more sensitive to the implicit cues are both important and useful skills. Such skill improvements are useful in many contexts, from personal relationships to situations where persuasion is the key to success, such as in a sales situation.

MILITARY AND RELATIONSHIPS

In practical terms, the military family must be divided into at least two major groups, according to the military's institutionalized pattern of stratification. There are officers; an educated, managerial class; and enlisted personnel, a class of workers whose normal duties include the performance of manual labor, or, in the case of higher-ranking enlisted soldiers, the immediate supervision of lower-ranked enlistees. By design, there is little mobility between officer and enlisted classes, but there are gradations within each. There are then at least four main categories of military family, according to the rank of the serving soldier: junior

enlisted (new recruits), senior enlisted (soldiers promoted out of the ranks to administrative and ceremonial positions), junior officers (recent college graduates now tasked with small group leadership), and senior officers (the highest ranked service members). Within each category are subdivisions by the usual demographic markers such as race, gender, sexual orientation, socioeconomic origin, marital status, and number of children (if any). This portrait is further complicated by changes to the military institution itself across time. In the 20th century alone, the U.S. military experienced periods of build-up as well as periods of personnel drawdowns, both popular and unpopular wars, segregation and subsequent desegregation (1948), periods of conscription (World War I, World War II, and 1948 to 1973), and several anomalous events, including a military participation rate of 12 percent during World War II, unmatched in U.S. history, before or since. Thus, there is no single “military family,” just as there is no monolithic “civilian family.”

Service members serve the needs of a demanding and unusual institution. On the one hand, the families of service members pass through phases familiar to any sociologist of the family: mate selection, marriage, parenting, competing career demands, divorce, internal conflict and perhaps even violence within the family, and retirement planning. On the other hand, these phases are shaped by the unique features of the military institution, among the most intrusive of which are the following: (a) Members of the military are subject to an additional set of laws known as the Uniform Code of Military Justice (UCMJ). These laws are stringent and socially conservative. For example, adultery and homosexuality are both criminal acts according to UCMJ. In practice, the laws of UCMJ pertaining to family dynamics are selectively enforced. For example, the “Don’t Ask, Don’t Tell” policy is an attempt to regularize selective enforcement of the legal prohibition on homosexuality. Although only the service member is subject to UCMJ, his or her entire family is often forced to conform to its mandates by extension. (b) Service members are required to be available to the military at all times, and for whatever duty, however inconvenient, unpleasant, or hazardous. The family must adapt to this reality, which often translates into prolonged separations, frequent relocations,

disruptions to the career of the spouse not serving in the military, school system irregularity for the children, the risk of death or disability to the main provider of the family, and general uncertainty about the future. On a more positive note, the military provides its members and their families with a social welfare net unparalleled in the civilian sector, except perhaps in some religious orders. This safety net consists of such substantial benefits as job security, housing and food subsidies, free medical care, educational benefits, low-cost life insurance, and subsidized retirement plans. Given these distinctive features of military life, it is not surprising that the demographics and trends of military families sometimes differ dramatically from those that characterize their civilian counterparts. This entry describes military families, their benefits, and the challenges they face in contemporary U.S. society.

Characteristics of the Military Family

Marriage

The military provides significant support for single-earner families. Military compensation is to some extent need-based. Although the base salary for enlisted soldiers is low, soldiers with families to support are allocated tax-free housing awards. The amount of the award is based on the zip code in which the soldier is stationed, thus reflecting the actual cost of living in a given area. Similarly, service members with families are provided with allowances for food, and are entitled to free medical care and subsidized childcare. The military also pays service members a moving allowance when relocation is ordered. Again, this amount is based entirely on need: the formula is based on the weight of the family’s possessions and the number of miles to be traveled. A by-product of this need-based system of compensation is that the married soldier receives pay in partially prebudgeted form, with money set aside for housing and groceries separately. In this same spirit, senior enlisted personnel are expected to ensure that junior enlisted soldiers provide for their families. For example, sergeants often help new recruits find affordable off-post housing. This house hunting is often carried out in uniform, during the course of a normal day of duty, and often by order of a still-higher

ranked enlisted soldier. Two qualifications should be made here: (1) This family-protective policy is a recent innovation. The military was a conscript force from 1948 to 1973, during which time the normal soldier, in demographic terms, was a young, unattached male serving only for a short time. Family-friendly policy in the military has improved continuously since the advent of the all-volunteer force in 1973, often in response to crises in housing or education. (2) The family-friendly policies of the military are based on a narrow definition of family. No material provisions are made for same-sex couples or heterosexual cohabitators. These policies are thus favorable only to heterosexual married couples and implicitly assume a traditional breadwinner-homemaker model.

The reinforcement of the traditional family model extends beyond financial compensation. Some of the hardships inherent to military life are detrimental to the career of the nonmilitary spouse. Many military posts are located in otherwise remote areas where there may be a lack of employment opportunities. Frequent relocations may prevent the spouse from cultivating the social network and institutional affiliation essential to many high-paying or prestigious jobs. Lastly, the frequent and prolonged absences of the military spouse require that the nonmilitary spouse be prepared at all times to take full responsibility for childcare, a demand incompatible with a high-pressure career. The nonmilitary spouse is effectively assigned a supporting role, an assignment that, according to the little research done in this area, some male spouses find particularly difficult. Perhaps not coincidentally, male service members are more likely to be married than are female service members. In 2002, 42 percent of enlisted women and half of all women officers were married, whereas half of all enlisted men and 71 percent of male officers were married. A contributing factor to this disparity is that men are more likely than women to serve for prolonged periods, and the likelihood of being married increases with seniority. In contrast with the dual-working civilian family norm, the gendered breadwinner-homemaker family model is more common in the military because of such institutional structures. An important exception is the joint-military family (roughly 1 in 10 military marriages), and these marriages are far less likely to have children. The

military's structural conditions and lack of support for cohabitation thus lead to high marriage rates at younger than average ages, even though mate selection is impeded (for men) because of the gender imbalance in the military and strict rules that prohibit romantic relations between service members of different ranks.

Children and Parenting

Service members tend to have children earlier in the life course in comparison with civilians. Many recruits marry and have children before the end of their first term of enlistment. Because of lack of seniority in the military, their pay is low, which is compounded by the fact that they have little experience with budgeting at this point in their lives. As a result, even though they receive some important financial subsidies from the military, they often experience financial difficulties.

Military personnel are usually required to relocate every few years, often to assignments abroad. This policy has both negative and positive consequences for the children of military families (who often refer to themselves as "military brats"). Military children benefit from well-funded Department of Defense schools and living abroad provides the opportunity for second-language acquisition. On the other hand, this distinctive lifestyle can have negative effects on a child's development. Frequent relocations, for example, interrupt the social and educational developmental process for some military children.

Domestic Problems

"The family," Richard Gelles and Murray Strauss wrote, "[is] our most violent institution with the exception of the military in time of war." As noted earlier, many institutional, legal, and economic forces in the military isolate the nonmilitary spouse and ensure her (in most cases) dependence on the service member. Further, the military is an institution where young men (in most cases) are taught to solve problems through aggression and violence. The military invests heavily in domestic violence-prevention programs. Its counterpart to the civilian Child Protective Services is particularly well funded. Families also have much less of a right to privacy than their civilian counterparts, which

facilitates aggressive intervention by social services as well as by superior officers. It is, however, unknown whether the military's additional safeguards against domestic violence compensate for the additional risk factors inherent to military life. Although some studies conclude that domestic abuse is more widespread in the military than in the civilian sector, other studies have come to the opposite conclusion.

Divorce

The divorce rate in the United States increases after war. After World War II, there was a dramatic and unprecedented surge in the divorce rate. By 1950, the rate had subsided to levels approximately equal to that of the immediate prewar period. The rate of divorce after World War II was not equaled again until the 1970s and the advent of widespread female employment and no-fault divorce. Does service in the military increase likelihood of divorce? It is difficult to compare military and civilian divorce rates for several reasons. Approximately a third of new enlistees fail to complete their first term of service, and of those who do, most do not reenlist for a second term. Thus, junior enlisted personnel may separate from the service (just) before divorcing. Nevertheless, some (inconclusive) evidence suggests that the rate of divorce might be lower in the military than in the civilian sector. After all, the military provides legal, social, and economic support for marriage in a way unmatched in the civilian sector. In addition, no conclusive evidence supports the hypothesis that frequent deployments adversely affect marital outcomes, although deployments involving combat are linked to a higher likelihood of divorce.

In sum, available evidence suggests that the experience of combat generally has a negative impact on military families; however, the military attempts to counteract this with policies that both promote and protect the family. Most military service takes place during times of peace, so families appear to benefit overall from such compensatory policies.

Fictive Kinship in the Military

There are concepts of family operative in the military that do not meet the U.S. Census criteria for

"family" (individuals related by birth, marriage, or adoption). Some family ties are illegal or unrecognized. As noted earlier, cohabitators in the military receive no support or recognition, and same-sex couples are in violation of military law. On the other hand, there exist institutionally supported family-type relationships between otherwise unrelated soldiers. Just as families are power systems with more or less clearly defined roles, so is the military, with many of the same consequences, both good and bad. Military sociologists have carefully studied the role of male bonding as it relates to combat motivation. The consensus among military sociologists after World War II was that soldiers fought not for ideology but, rather, for their buddies. Military authority, taking the lessons of sociology to heart, has now in effect mandated brotherhood among soldiers at the level of the small unit. This is particularly prevalent in combat units where female soldiers are excluded. This mandate is carried out through the creation of "buddy teams" and through sustained and intense rhetoric. Similarly, the commander of a unit often uses the language of a distant and authoritarian father. The concept of family is thus overlaid on the rigid hierarchy of military life.

MINDING THE RELATIONSHIP

Minding the relationship refers to a theory of relationship maintenance and satisfaction. The name of the theory, “minding,” emphasizes that relationship satisfaction is primarily a matter of how partners think about a relationship; happiness in a relationship is created in the minds of the partners. The theory suggests that relationship satisfaction may be sustained over long periods through positive habits of cognition and communication between partners. Minding Theory incorporates five basic recommendations: self-disclosure, respect, positive attributions, reciprocity, and continuity. This entry discusses the Minding Theory and its five basic recommendations.

Self-disclosure refers to sharing personal information about oneself with a partner. It is central to Minding Theory that satisfied partners, over time, will gradually disclose more intimate information to each other. One effect of this disclosure between partners is to promote a deeper knowledge of each other’s past experiences and current emotions. Another purpose of disclosure is to increase trust between partners, assuming that when disclosure becomes more intimate, partners treat new revelations respectfully. Finally, continuing disclosure allows partners to grow together over time through the continued sharing of new insights, desires, and experiences.

Also central to Minding Theory is the principle of respect and acceptance. In a satisfying relationship, as disclosure increases, partners will be able to respect what they learn about each other. When new information is revealed about a partner, Minding Theory recommends that even if this information is negative, a sense of respect for the other should be retained. Ideally, the information is incorporated into the partner’s existing beliefs about the relationship without damaging the overall positive nature of these beliefs. Some discoveries may be too negative for one partner to continue holding onto these positive attitudes, for example, a disclosure of long-term infidelity or dishonesty. Because Minding Theory predicts that relationships are based on how partners think about each other, information that severely damages the positive mindset about a partner should also endanger relationship satisfaction and long-term stability.

The third principle of minding is that partners in a stable and satisfying relationship will tend to make positive attributions or explanations for each other’s behaviors. The theory recommends that partners generally explain each others’ actions in a positive way. For example, if Sam is late to a dinner date, Chris may initially assume outside factors must be involved rather than immediately blaming Sam for thoughtlessness. The tendency to positive attributions may be especially important when a partner’s actions may be ambiguous or awkward, such as giving a well-meant but badly chosen gift or making a clumsy gesture of affection. A minding partner will perceive and acknowledge the good intention. A simpler way of putting this is to say that partners should give each other the benefit of the doubt. It is important in minding to respect information about a partner and to attribute positive motives to the partner’s behaviors.

The first three principles of Minding Theory, as discussed, describe ways of developing a particular way of thinking about a partner. During disclosure, partners develop a positive view of each other. Respect encourages partners to maintain this positivity when learning new information about each other. This constructive view of a partner makes it easier to create positive attributions for his or her behavior. The final two Minding Theory principles, reciprocity and continuity, are about the practical nature of maintaining a satisfying relationship.

The principle of reciprocity assumes that disclosure, respect, and positive attributions are most helpful to a relationship when both partners are practicing them. When one partner is not open to intimate sharing with the other, cannot respect what is known about the other, or cannot maintain a generally positive view of the other’s behavior, this may damage the stability of the relationship. No matter how hard one person tries to establish a positive foundation for the relationship, Minding Theory predicts that a lack of matching response from the other will ultimately undermine the overall quality of the relationship.

The final component of Minding Theory is continuity. Minding is not just essential at the beginning of a relationship or when a relationship is in danger of ending. To achieve long-lasting relationship satisfaction, the theory stipulates that the process of sharing, respect, and positive attributions

should continue throughout the life of the relationship. There will be points in any long-term relationship when partners are stressed and one or more of the minding elements suffer. The theory would suggest that during those times, the sense of togetherness and stability that minding supports will also suffer. Only when partners begin minding again with regularity will the relationship recover its previous strength. If partners have never fully engaged in the minding components, these ordinary relationship stressors may easily precipitate relationship crises or break ups.

Minding Theory is based on the assumption that relationships are most likely to last over time when they provide emotional satisfaction to the partners. Marriages or other partnerships that are based on other factors, such as social status or financial stability, may be long-lived for other reasons that have little to do with minding. Minding Theory would suggest, however, that even partnerships formed for reasons other than emotional satisfaction can still be sources of this satisfaction if partners begin to practice the components of minding. Minding Theory was also conceived primarily as a method of explaining long-term satisfaction and maintenance of romantic relationships, but can be applied to other types of interpersonal relationships.

MISATTRIBUTION OF AROUSAL

Misattribution of arousal occurs when people incorrectly identify the source of their physiological arousal. For example, one might incorrectly attribute elevated heart rate to the presence of a person sitting close by, when this physiological response may actually be caused by some recently ingested caffeine. Although many variables may influence which of several possible sources is acknowledged as the cause of arousal, in the end, two primary factors are necessary for misattribution to occur: physiological arousal and at least two possible sources of that arousal (the true cause and the misidentified cause). Given this simple recipe, the misattribution of arousal may occur during transient interactions as well as in more enduring relationships. This entry discusses the theoretical and experimental origins of the misattribution of arousal effect and how the misidentification of emotions can influence social relationships.

Emotion Misconstrued

One result of misidentifying the source of arousal may be the mislabeling of emotional arousal. In a classic study, Stanley Schachter and Jerome Singer suggested that emotion is experienced when both physiological arousal and a cognitive label for the experience co-occur. It matters not whether the arousal precedes or follows the emotional label for the experience of an emotion, just that they are jointly experienced at some point. For example, imagine that a person enters a situation expecting joy and is subsequently aroused. According to this model, this person will experience joy because that label was most available when the arousal was experienced. Although in this instance the emotion (joy) occurs with the onset of arousal, one might also imagine a situation in which arousal precedes the cognitive labeling process. For example, a person might experience an elevated heart rate while sitting in a coffee shop and not attach an emotional label to the arousal until another person sits nearby at another table. In this case, the caffeine-induced arousal might be misattributed to the more salient environmental cue of

the other person, resulting in the attachment of an emotional label (e.g., attraction, love, lust) to the experienced arousal. In this instance, the arousal precedes the emotional label and the true source of the arousal may not be prominent in the person's mind as the situation unfolds.

The impact of the salience of possible sources of arousal and the subsequent mislabeling of emotions has been examined extensively over the years. In Schachter and Singer's experiment, participants were placed in a situation where the source of their arousal could be attributed to multiple sources. Schachter and Singer reported that subjects who did not have an accurate explanation for the cause of their arousal were more likely than others were to mimic the behavior of another person (e.g., euphoric) who was present. This imitation has been interpreted as the result of the misattribution process that resulted in participants' mislabeling of emotion. That is, participants in this situation employed the most salient cue available to interpret their experience—the confederate's behavior—and thereby produced an emotional label that was consistent with the confederate's behavior. Although Schachter and Singer's model is no longer viewed as a viable explanation of emotion, their initial inquiry spawned numerous studies demonstrating that people actively interpret their social situations, consider plausible explanations to label their experiences, and at times settle on the most cognitively available explanation.

Arousal and Attraction

The suggestion that people might mislabel their emotional responses in social situations has served as fertile ground for the study of attraction. For example, why do people feel attracted to another person? Is it because of a unique constellation of traits the other possesses or might this reflect misidentification of the true source of arousal? In an early study, Donald Dutton and Arthur Aron had an experimenter (either male or female) interact with male participants after crossing a 230-foot gorge over a bridge constructed of wooden boards and rope. After a short interview, participants were given the experimenter's phone number to call for additional information about the experiment. Other participants were met after crossing a

small footbridge across a pond on campus and the same procedure was followed. Participants who crossed the rope bridge were more likely than were the footbridge participants to call the female experimenter. These results have been interpreted as the males' misattributing the source of the arousal (the scary bridge) to the female experimenter and labeling their experience as attraction rather than fear. One might argue that the source of the arousal was clearly available in this setting, but nevertheless, the men acted in a fashion suggesting they substituted one source label for another. This study has been replicated widely over the years in both laboratories as well as in field settings.

In numerous demonstrations of the misattribution effect, a common theme emerges: arousal is experienced but a likely source of the arousal is discounted or minimized. Therefore, the true impact of the earlier arousal on later behavior and emotional labeling is not accurately assessed; the emotional response to a later situation may be mislabeled entirely. Such mislabeling because of source substitution is consistent with a traditional application of Schachter and Singer's model and usually is paired with the belief that the true source must be ambiguous. However, as suggested earlier, arousal appears to influence assessments of interpersonal attraction even when the ambiguity of the true source varies widely. For example, the link between arousal and attraction has been demonstrated in a variety of settings where the arousal source is diverse and ambiguous, including movie theaters, amusement parks, zoos, and lab settings using aerobic exercise. A meta-analysis of 33 studies confirms a moderately strong relationship between arousal and attraction.

Alternative Explanations for Misattribution

Several plausible alternatives to a misattribution explanation for the link between arousal and attraction have been proposed. For example, the *response-facilitation model* suggests that arousal will enhance the dominant emotional response to a person or a situation. Therefore, if one is predisposed to be attracted to another person, the experience of arousal in the presence of this person would increase the emotional response to them.

Similarly, if the dominant response to one's roommate is disgust, then arousal following exercise would enhance those feelings when encountering him or her. Absent from this model is a need for the source of the arousal to be ambiguous. Therefore, arousal will augment the dominant emotional response regardless of how salient the true source of the arousal is.

A different explanation of the link between arousal and attraction (the Excitation Transfer Model) emphasizes that arousal does not quickly dissipate after being experienced because the sympathetic nervous system takes some time to quiet down. Therefore, arousal from one source may persist following its initial experience. This lingering arousal may enhance later emotional reactions to others but cannot be too salient for the effect to occur. For example, the residual arousal left over from a frightening encounter may augment or intensify attraction to another person if enough time has passed since the arousing event.

Lastly, Craig Foster and his colleagues offer a two-stage *judgment and adjustment model* that integrates the results from the many studies examined in their meta-analysis. The first stage of their model (judgment) allows for arousal to have an automatic effect on attraction regardless of source salience. The second stage (adjustment) represents the period that follows the initial impact of arousal. During this stage, people may alter their initial assessment of attraction (or repulsion), if aware of the arousal and if motivated to change.

Misattribution Research Applied to a Broader Context

Although feelings of attraction to another person may involve arousal, the judgment and adjustment model suggests that there are opportunities to negate (or make negligible) the impact of arousal. For example, one might resist an initial attraction if it is interpreted as coming from an external source. However, one might also ignore these cognitive brakes and accept the feelings of attraction. Perhaps this is a place where personality variables or previous learning histories influence decision-making processes. Or, possibly, this is where alcohol comes into play. Ultimately, this two-stage explanation of the misattribution effect suggests

that human cognitive processes are able to override their initial emotional reactions, if so chosen.

Emotional responses other than attraction should also be considered when applying misattribution to human relationships. For example, arousal may augment emotional responses such as anger or hate. Augmenting these emotional responses may lead to aggressive or violent acts directed against other people involved in an arousing situation as well as individuals encountered after the event. Again, using the judgment and adjustment model, it might be predicted that arousal induced by vehicle jousting in rush hour traffic would increase the likelihood of aggressiveness against other commuters, work colleagues, or loved ones after arrival at home. However, as noted earlier, the model also predicts that people can decide whether or not to act upon their emotional states.

Can the misattribution of arousal effect extend to leisure or mildly competitive activities? If one assumes that arousal is a component of these situations, then simply participating in the activity may influence emotional evaluations of others present during the activity as well as persons encountered immediately following the activity. For example, emotional responses might be enhanced toward companions in a robust tennis match or an exhilarating scuba dive.

Finally, although people may recognize that certain situations produce arousal, being overly attentive to the experience of arousal may interfere with performance on some tasks. For example, math exams can elicit high arousal for individuals who believe they lack the aptitude for quantitative reasoning. Talia Ben-Zeev and her colleagues found that female participants were able to overcome the arousal associated with stereotypes of poor female performance on math tests when they were permitted to attribute their arousal to an external source. Under certain circumstance, then, misattribution of arousal may weaken rather than calcify socially harmful stereotypes.

MONEY AND COUPLE RELATIONSHIPS

Contrary to what many people believe, romantic relationships bear the imprint of economics. *Money*, or economic resources such as earnings or income from stocks, affects whether romantic relationships are formed, how people experience those relationships, and whether they dissolve. This entry defines *couple relationships* as romantic, typically sexual relationships between two individuals. Because most research on the connection between couples and money focuses on married couples or couples who are living together, rather than dating, this entry follows suit.

Forming Couple Relationships

It is well established that married couples enjoy higher incomes than do same-sex or opposite-sex couples who are living together. However, scientists have shown that *getting married* is linked to people's monetary situations, with people who are financially well-off being more likely to marry. Conversely, those who have little money or are poor are less likely to marry, with some never marrying. These conclusions stem from scores of studies that analyze information from thousands of people representative of the U.S. population, or large subgroups of the population, as well as studies based on lengthy interviews with a small number of individuals; the former is termed *quantitative* and the latter *qualitative* research.

Why is money related to getting married? There appears to be a cultural belief that one must be financially secure to wed and that marriage signifies that one is no longer struggling economically. Specific factors include having the money for a wedding and reception, a house, being debt-free, and not living paycheck to paycheck. Scientists have also found that, despite increasing commitment to equality between men and women, some people, both men and women, pay more attention to the man's economic situation than to the woman's in deciding about marriage. In other words, men's monetary standing has a stronger positive impact on marriage than does women's, suggesting a continued cultural emphasis on men as primary breadwinners.

Now that living together, or what is also termed *cohabitation*, has become commonplace and, indeed, the typical path to marriage, many family scientists have been studying the linkage between money and cohabitation as well as money and the movement into marriage among cohabiting couples. Qualitative research shows that many opposite-sex cohabitators explicitly state that the ability to save on expenses is an important and logical reason to move in with a romantic partner, given that the couple is usually already spending so much time together. They report that moving in with a partner allows couples to save money by combining resources and splitting a variety of expenses such as groceries, gas, electricity, and rent.

At the same time, cohabiting couples hold higher economic expectations for marriage than

for cohabitation. In other words, even after moving in together, the decision to get married is connected to economic circumstances: Marriage is more likely to occur when the couple is well-off in job stability and earnings. In addition, more emphasis is again placed by both men and women on men's economic capacity to be a breadwinner than on women's, although one recent study indicates that women's earnings are becoming increasingly important in the decision to marry.

Scientists are increasingly focusing on poor women or couples who have had children outside of marriage. Having children while single or cohabiting has become increasingly common: Nearly 40 percent of children today are born in these circumstances. Policymakers are interested in what can be done to increase the chances that these children grow up in a two-parent, married family. This interest is controversial and based on some research that suggests such a circumstance may be best for children, although this is not always the case. When a marriage is marred by domestic violence or overt conflict, for example, children are better off if their parents part ways. Further, as discussed in this entry, monetary problems make relationships vulnerable to break up.

Similar to research on couples in general, low-income unmarried mothers say that money is an issue when they think about marriage. They expect their male partner to be a reliable breadwinner; inability to do so is an important basis for these mothers' hesitation to marry. Thus, couples are hesitant to marry unless economic stability has been achieved, whether they have children or not. Scientists have also shown that the partners of low-income women, not surprisingly, tend to be disadvantaged themselves. They typically have low education, making it difficult to be optimistic about their capacity to obtain well-paying jobs in the current U.S. economy.

Couple Dynamics

When two people live together in a romantic relationship, whether or not they have formally married, money influences how each experiences the relationship, including their sense of satisfaction. The issue that has received the most attention by researchers, however, is the connection between

money and the division of household labor in heterosexual marriages or cohabitations. Many scientists have focused on who does the housework, and why, based on the notion that the partner with less economic power, traditionally the female, will take on the bulk of household and childcare duties.

Although an increasing proportion of women are earning as much or more than their husbands (about one third), husbands still earn more in most marriages. Gender inequality in earnings holds among cohabiting couples, too, although the disparity is somewhat less sharp. An additional point is that earnings differences become more pronounced when a couple has children. This is because many women cut back at work or leave the workforce entirely for a time upon childbearing.

As a result, some scholars argue that women reap greater economic benefits from marriage than men; sharing economic resources increases a woman's standard of living while she is caring for young children, although she is also sacrificing the accumulation of additional employment experience. Even when she is fully employed, some income discrepancy usually remains because of women's lower earnings in the labor market compared with men in general, even when both have the same education and work experience.

Division of Housework

Scientists have drawn on Exchange Theory to understand the division of household labor. This theory posits that the individual who brings more money into the household will have more bargaining power in the relationship. Power essentially refers to who is more likely to get one's way when it comes to decision making about major purchases or the division of household labor.

Research provides general support for this idea. Among gay couples, the wealthier and more educated man enjoys greater power, although this appears less likely to hold in lesbian couple relationships. In heterosexual couples, women decrease time doing housework when they earn relatively more money, perhaps purchasing substitutes such as help with childcare and housework, but still perform the majority of the household work compared with their male partners. Yet one scholar recently demonstrated that wives' relative earnings

compared with their husbands' does not explain how much housework they do. Rather, it is women's absolute earnings that matters: The more a woman earns, the less housework she does. Research also shows that when husbands or wives perceive the division of housework to be unfair, marital satisfaction for both spouses is reduced, putting couples at greater risk of divorce.

Financial Arrangements Among Couples

An emerging focus of research is the extent to which different types of couples *pool* their incomes. That is, do they combine their incomes fully, keep some money separate, or keep all money separate? It is important to emphasize, however, that all couples living together share expenses in one way or another even if their incomes are not combined into joint checking or savings accounts. In this case, each partner pays a share, often proportionate to their earnings, for joint expenses (e.g., mortgage, utilities, children's needs) and pays for independent purchases (e.g., clothing) separately.

Married couples are most likely to fully pool, about three quarters, although cohabiting couples are not far behind at approximately 50 percent. Research also suggests that Blacks, the elderly (likely for tax purposes or to qualify for Medicaid), those who marry at older ages, and couples in which at least one partner has been divorced are less likely to pool economic resources; when partners earn a comparable amount, they are more likely to pool incomes. Some scholars have found that when married couples do pool *and* the husband earns more money, the husband tends to have more control over the couple's economic resources. Although data are lacking about historical trends, arguably pooling was much more common in the past when women were less likely to be employed.

Turning to the matter of relationship quality, pooling money can be a source of tension or conflict: One partner may not agree with the way the other is spending money he or she perceives as jointly owned. In some cases, dual-earner couples begin their marriages with pooled economic arrangements, but later decide that it is best for their marriage to establish separate accounts.

Two other areas of research are relevant to the topic of income arrangements. Recently, some

researchers are examining the linkage between debt and marital satisfaction. Taking on large amounts of consumer debt (e.g., credit cards, installment loans, or overdue bills) appears to decrease satisfaction, whereas completely paying off this type of debt increases marital satisfaction. Only large increases in consumer debt are associated with declines in marital satisfaction; this could be a result of longer work hours, and thus less time spent together, to try to pay off debt, as well as arguments about money when couples are under financial stress. Interestingly, mortgage debt does not appear to affect marital satisfaction. A likely explanation is the economic and tax advantage of home ownership. Research has shown that homes constitute the most valuable asset for most married couples.

An area about which little is known concerns dating couples. Who should pay for dates? Although many people still believe that the male is responsible for paying the bill, a 1996 study of college students suggests that women are more likely than men to believe that the person initiating the date should pay. Furthermore, younger students tend to hold less traditional views about paying for dates and do not expect it to necessarily fall to men to do so.

Ending Couple Relationships

It is well known that levels of divorce are quite high, with estimates suggesting that about 50 percent of marriages are likely to end in divorce. The incidence of relationship dissolution is even higher among cohabiting couples. What role does money play in these patterns?

Simply put, the key scientific finding is the opposite of what encourages the formation of couple relationships and particularly marriage. Whereas good economic circumstances encourage marriage, precarious ones make couples vulnerable to break up and divorce. This linkage has been replicated time and time again. For example, scientists have consistently shown that the likelihood of divorce is inversely related to measures of economic well-being such as family income and educational attainment and positively related to economic hardship.

Thus, people who are economically advantaged are more likely to marry and more likely to stay

married. Consider the following estimates, though they draw on education rather than actual income, a measure that scientists often use if necessary to indirectly tap economic standing: 60 percent of the marriages of women without high school degrees will end, compared with only one third of the marriages of women with college degrees or more.

Relationship Quality

Why do disadvantaged economic circumstances translate into higher rates of couple dissolution? Scientists have made progress in unearthing the mechanisms behind such patterns, using both qualitative interviews and analyzing large surveys. The simple answer is that economic distress affects marital quality, with money being protective of couple relationships via interactional and psychological processes. For example, perceived economic hardship is negatively related to relationship quality, with low income and employment uncertainty associated with marital conflict and psychological distress. A study focusing on Black married couples finds that perceived economic adequacy—measured by sufficient income for food, clothing, medical care, leisure, and some extra money left at the end of the month—is connected to marital satisfaction. In addition, scientists have shown that economic pressures harm marital satisfaction by promoting hostility in interactions and decreasing supportive behavior of husbands toward wives.

Cohabiting couples are subject to the same stresses engendered by lack of money. A qualitative study suggests that financial constraints are a source of relationship conflict that affects relationship quality. Couples fight about money when money is tight and not enough to pay all the bills at the end of the month, stressing the relationship. Money, or rather lack thereof, is thus problematic for their relationships and the sense of a stable future, indicating a pathway by which financial difficulties decrease the chance of marriage. In the event that financial circumstances improve, cohabiters report that their relationships improve too.

The financial consequences of divorce differ by gender. Study after study has shown that divorced women fare poorly economically compared with divorced men. Their total incomes usually decline more than men's do when a marriage ends because men typically earn more than women do, and men's

postdivorce incomes are lower than divorced men's even after accounting for child support payments.

The greater instability of cohabiting than marital relationships is a growing focus of research. Additionally, now that cohabitation is such a common family form, scientists are increasingly asking the same questions about the break ups of cohabitations as they have asked about divorce. For example, researchers have long documented the economic consequences of divorce for men and women. Recently, researchers have asked the identical question about what happens economically when cohabiting couples break up: The upshot is similar to divorce. Compared with men, women experience a steeper decline in economic well-being, and have less money, when a cohabiting relationship ends.

Conclusion

A theme throughout this entry has been gender. Despite women's massive entrance into employment during the last several decades and attitudes about gender becoming increasingly egalitarian, when it comes to couples and money, things are not equal. Couples consider the male's economic situation more than the female's when it comes to thinking about and getting married, housework and childcare responsibilities still primarily fall to women, and the economic fallout from breaking up is worse for women than for men. In same-sex couples, the partner having more wealth or a traditionally masculine job wields more power and, not surprisingly, does less work in the home.

Although these may be choices that couples make, consciously or not, it is fascinating fodder to family scientists. In the last several decades, new family forms are being constructed, with decreasing cultural pressure to conform to a traditional or single model of family life. Couples are thus freer to write their own scripts for their relationships. And yet these scripts are still marked by gender difference.

Love, passion, marriage: One might not immediately think about money when contemplating the meaning of romantic relationships. But money is part of the picture all the same. It plays an important role in the formation of couple relationships, how couples divide their time in housework

and employment, how they organize their finances, and whether and why relationships fall apart.

People who are economically well-off are more likely to marry (although they now usually cohabit first), raise children within marriage, and stay married. Those at the economic margins may remain single, cohabit and perhaps cohabit again, have children in cohabitation or dating relationships, and are more vulnerable to the break up of their marriages and live-in relationships. Money can't buy happiness, but it does help to buy marriage, reduce housework for women, and keep divorce at bay.

MOOD AND RELATIONSHIPS

Moods are affective states that can be every bit as intense as emotions, but are not directed at a target and thus are often experienced in a more prolonged fashion. Emotions, on the other hand, are of shorter duration and largely depend on the onset and offset of a specific event. In some cases, moods may be the residual of an emotion, such as the lingering anxiety that persists even after the original threat has subsided. Affective states such as serenity or irritation are examples of "pure" moods.

Our moods constitute powerful influences on how people think about themselves and the outside world. As such, moods also shape perceptions of the processes in human relationships. At the same time, various relationship processes can lead to the experience of positive and negative moods. This entry discusses the reciprocal influence moods and close relationships exert on each other.

How Moods Shape Perceptions of Relationship Processes

Moods influence perceptions and evaluations of others in such a way that good moods lead people to perceive and evaluate others more favorably, whereas bad moods lead people to perceive and evaluate others less favorably. It is thus not surprising that moods influence judgments of the physical attractiveness of potential dating partners in predictable ways: Attractive and unattractive others alike look better when perceivers are in good moods and worse when they are in bad moods. Moreover, this congruency extends to the perception of behavior: When in a good mood, perceivers interpret the behavior of others more positively than when in a bad mood. For example, the same smile that is perceived as friendly when one is in a good mood may be considered awkward when one is in a bad mood.

The effects of moods on judgments of attractiveness are not entirely the result of mood congruency because moods can also have a direct influence on the behavior of others. When people are in a good mood, they tend to smile and disclose more; when in a bad mood, people may come across as more passive, uncomfortable, unfriendly, and perhaps even disgruntled and hostile. However, whereas expressing happiness can invite positive behaviors from others, it can also be met with distrust, especially by others who feel that they are somewhat undesirable.

Moods influence perceptions and judgments, especially of others who are somewhat atypical. Making sense of atypical others requires additional time and effort and allows judgments to be infused with positive and negative affect. For example, because couples tend to be well-matched in physical attractiveness, judgments about them can be made with ease because they meet people's expectations. However, judgments about couples who are mismatched in attractiveness require additional processing time and allow affect to come into play. Specifically, happy moods lead to particularly favorable impressions of couples that are mismatched in attractiveness whereas sad moods lead to particularly unfavorable impressions of mismatched couples.

Going beyond happiness and sadness, one of the most well-established findings in the social

psychological literature is that people are most attracted to others who are similar to oneself in their attitudes and beliefs. However, romantic moods brought on by interacting with an attractive other profoundly decrease the importance of attitude similarity. When people are in a romantic mood, they feel greater attraction to others who do not share their attitudes, leading to the conclusion that these others are perhaps more similar than it appears. Love appears to be blind, indeed.

In addition to shaping perceptions of others' attractiveness, moods influence a variety of processes in ongoing relationships. These processes include how close people feel to their partners, the extent to which they provide help and support that benefit their partners, perceptions that their needs are being met, and the explanations they generate for relationship conflicts.

Happy moods promote feelings of closeness and sad moods attenuate them. For that to occur, happiness and sadness do not have to result from processes within the relationship. Feelings of closeness increase or decrease even when the respective moods are brought on by events outside the relationship. For example, simply watching a movie with a happy ending may improve feelings of closeness to one's partner whereas watching a movie with a sad ending may decrease those feelings. However, not all sad endings may lead to a decrease in feelings of closeness. A sad mood brought on by thoughts of relationship loss (for example, thinking about losing a partner to death) can lead to increased rather than decreased feelings of closeness.

Providing support and help to a close other is both expected and commonplace in close relationships. Although good moods have been shown to lead to more helping in general, whether people are willing to help their romantic partners also depends on expectations that providing help is rewarding and is likely to lead to enhanced positive mood. At the same time, helping may become less likely when there is a chance that it might interfere with a good mood. Expectations of this sort are especially important in relationships characterized by compassionate love. In these types of relationships, behaviors such as providing verbal support are considered to be especially good examples of "compassionate love acts."

People are naturally concerned that their relationships meet their needs without paying too

much attention to whether their partner treats them fairly in such matters as the division of labor. However, negative moods elicited by relationship distress often compel people to more closely scrutinize the extent to which they are getting a fair shake than they would in the absence of a negative mood. Conducting such mood-induced scrutiny can transform the relationship from one that revolves around meeting each other's needs to one in which the partners instead focus on issues of fairness and equity. If this scrutiny suggests a lack of fairness, partners will be unhappy and the relationship will be marked by conflict.

It has been said that when it comes to conflicts in a relationship, the question is not whether a relationship will experience a conflict but, rather, *when* will a conflict occur and how it will be resolved. Resolution of conflict hinges importantly on how partners explain why it arose in the first place. Sad moods may shape these explanations in pessimistic ways. Specifically, when people feel sad, they are more apt to blame themselves for the conflict and are more likely to think that it was caused by global and nonspecific causes that are difficult to change, especially when the conflict is serious. As a result, sad moods lead to the expectation that there may be little that can be done to resolve the conflict. Happy moods, on the other hand, tend to have a somewhat counterintuitive effect. Although one might suspect happiness would make people more generous and accommodating, happy people are more likely to attribute the causes of a conflict to their partners or the situation than to themselves. Expressions of anger can lower the chances that a conflict will be resolved in a constructive way. This is especially the case when a person responds to a partner's expressions of anger in a reciprocal fashion. Such negative affect reciprocity generally contributes to an exacerbation of an existing conflict.

How Relationship Processes Affect Moods

Just as moods shape perceptions of a number of relationship processes from initial attraction to conflict resolution, what goes on in relationships also influences moods. Sharing positive experiences or simply telling one's partner about positive things that happened give rise to positive affect. Feelings

of closeness and relatedness, perceptions of fairness and equity, and receiving social support have also been causally linked to the experience of positive affect in close relationships. On the other hand, depressed moods often result from attachment anxiety, a perceived lack of intimacy, and relationship breakups. Anger and, to some extent, guilt can result from perceptions of inequity as well as the experience of conflict. Although these feelings may more appropriately be considered emotions directed at another or the relationship, they may leave an affective residue akin to moods that then can shape perceptions of just about everything, including other aspects of the relationship.

A sense of relatedness tends to produce good moods, as does a sense of autonomy and a sense of competence. In addition to being the foundation for good moods, a sense of relatedness, autonomy, and competence tends to provide the basis for, among other things, more positive sexual experiences that can lead to further mood enhancement. Happiness and contentment further result from the perception that one is being treated equitably in the relationship. However, people experience negative affect in the form of emotions and moods when they feel underbenefited in their relationships—that is, when they appear to receive less than expected on the basis of contributions to the relationship, while their partners seem to receive more relative to his or her contributions. Being overbenefited also may lead to the experience of negative affect, albeit to a lesser degree. People who feel that they are receiving more than they deserve given their contributions while their partners receive less often experience feelings of guilt.

As one might expect, receiving support from close others in times of distress generally results in improved moods. Interestingly, the extent to which support is received depends on the severity of the problem. When it is particularly stressful, people are more likely to ask for support directly and thus are more likely to receive particularly helpful forms of support. Under such circumstances, people experience improved moods along with a greater sense of being cared for by partners.

The nature of affective bonds with partners also has important consequences for moods. Securely attached individuals who feel that their partners can be trusted and provide a sense of comfort experience feelings of happiness and contentment.

Anxiously attached individuals who feel that their partners do not reciprocate their romantic feelings tend to experience anxiety and worry. Moreover, anxiously attached individuals are relatively poor at providing support. Although they sometimes provide more help than securely attached individuals do, their support is often inept or self-centered. As a result, they often deprive their partners of the emotional benefits of helpful and effective caregiving, which can lessen the emotional benefits they receive in return.

Attachment security in combination with confidence that one can effectively deal with negative moods also plays a role in dealing with conflict and romantic breakups. Securely attached individuals approach conflicts in a more constructive manner to the extent that they feel confident about their ability to manage their negative moods. Generalized expectancies for the regulation of negative moods also play a role when it comes to dealing with the emotional reactions to distressing events, such as a divorce or romantic breakup. Although most people experience depressed moods as a result of a breakup, individuals with a high degree of confidence in their ability to manage a depressed mood tend to employ more effective coping strategies and consequently experience less long-term depression than do individuals with relatively low negative mood regulation expectancies.

MORALITY AND RELATIONSHIPS

The nature of personal relationships depends to a considerable extent on the moral precepts and norms accepted by members of the community in question. This entry is not concerned with the particularities of what is considered right or wrong in a particular culture, for cultures differ, but with the way in which the nature of morality impinges on that of personal relationships. In the real world, morality is different from the set of rules that it appears to be at first sight, and this affects the nature of relationships.

What Is Morality?

Moral behavior usually implies behaving positively to others. It is easy to see how selfish and self-assertive behavior arose in the course of biological and cultural evolution, for individuals who looked after their own interests would succeed in competition with their peers, but how could prosocial behavior (that is, behavior that benefits others but not necessarily the self) to potential competitors have arisen? Because early humans lived in small groups that competed with each other, it would have been to individuals' interests to behave positively and cooperatively with members of their own group because they would be promoting the success of their own group in competition with others and thus their own access to resources. Thus, conflict between competition and cooperation with ingroup members is a necessary concomitant of living in groups. Moral rules maintain a balance between cooperation and competition. But there is no cause to behave prosocially to outsiders, and moral rules may not apply to them. Early in human history the ingroup was probably defined by familiarity but the boundary can be influenced in other ways.

Certain moral rules are probably common to all cultures. Variants of the so-called Golden Rule (Do-as-you-would-be-done-by) seem to be

recognized in all cultures: If it were not so, it is difficult to see how the culture could survive. It is useful to distinguish such moral “principles,” which are common to all cultures, from “precepts,” which have some degree of cultural specificity. Most precepts are compatible with the Golden Rule but apply to a specific type of situation. For instance, “Do not steal from your neighbor” is compatible with the Golden Rule, because one does not want to have one’s own possessions stolen, and is probably accepted in all cultures. But the Judeo-Christian precept not to covet your neighbor’s wife is clearly not applicable to any culture that does not recognize the institution of marriage: In some cultures, women are inseminated by a number of partners, and in other cultures, women have only temporary sexual liaisons. Children must be looked after, and it is seen as morally right that parents should look after their children unless other practices, such as adoption or fathering by the mother’s brother, have been institutionalized.

Precepts governing conduct in relationships differ between cultures and between relationships of different types within any one culture: uncles, for example, but not cousins, may expect respect. Precepts also change over time. For instance, a few decades ago in Western cultures, it was considered grossly improper for a couple to live together if they were not married. For a variety of reasons, including the ready availability of birth control, it became more common in the decades after World War II: As it became more common, it became more respectable, and as it became more respectable, it became more common. Now premarital cohabitation is even sometimes advocated as a wise precaution before full commitment. Such a dialectical relation between what people do and what they are supposed to do is probably the most important mechanism for both the maintenance of and change in the moral precepts governing personal relationships.

To be effective, moral precepts must be seen as absolute. But that they differ between societies and change over time suggests that they need not be. Are they followed consistently in real-life relationships? Whatever we feel about what should happen, it is evident that they are not. The potential for selfish assertiveness in every individual and the complexity of social life ensure this. Some conflict between competitive assertiveness and prosociality

is almost inevitable, and social life ensures that we can rarely be single-minded. Even the mother–child relationship involves conflict, the mother being caught between the child’s demands and her own needs. In that case, the conflict has a biological base, but the complexity of modern society makes conflict almost ubiquitous. For instance, exchange is basic to most human relationships: One partner performs a service for the other in expectation of fair reciprocation, perhaps at a later date. Such exchange provides an explanation of the source of many human virtues: Fair exchange demands honesty, trustworthiness, and so on, and one avoids an individual who is known to tell lies. But often the costs incurred and rewards received are not measurable in the same currency. The suitor brings his beloved a bunch of flowers but expects not flowers in exchange but recompense of another sort at a later date. So how can one assess whether an exchange is “fair”? More than that, what matters is not whether an exchange is actually fair but whether it is perceived to be fair by both parties. And there are a number of criteria for fairness—equality, equity (to each what he or she deserves), and social justice (to each according to his or her needs). The potential for disagreement is always present.

Another source of conflict concerns incompatibility between rights claimed and precepts held: Thus, teenagers may claim rights incompatible with parental morality, and inciting racial hatred may be seen as incompatible with freedom of expression. Wherever the partners in a relationship differ in religion or ethnicity, conflict is potentially present. For these and other reasons, moral conflict between alternative courses of action is frequent. One has to choose one course or the other, but may not be entirely happy with the propriety of one’s choice. Thus, we are faced with an anomaly: Moral rules must be seen as absolute but can change with time and situation and cannot always be followed. Too often, perhaps, we invent reasons why “just this time” we should break the rule.

Consistent prosociality is improbable also for functional reasons. An individual who behaved prosocially all the time would never succeed in competition with his or her fellows. Conversely, if competition between group members were unrestrained, the group would disintegrate or lose out in competition with other groups, and its members

would suffer. A balance is necessary between the numbers of prosocial and selfish individuals in the group and between selfishness and prosociality in each member. Here lies the major function of moral codes—to maintain an appropriate balance.

Why Do We Behave Morally?

Why do we behave morally? The moral principles, precepts, and norms are incorporated into the way in which we see ourselves, our self-concepts. One's self-concept includes matters of age, sex and occupation, and aspects of one's relationships, as well as whether one sees oneself as honest, kind, courteous, and so on. In most potentially conflictful situations, conscious deliberation is unnecessary: Moral precepts in one's self-concept ensure appropriate behavior "automatically." An individual who sees himself to behave improperly experiences guilt and a "bad conscience." A bad conscience results from a discrepancy between what one sees oneself to be doing and the precepts incorporated in the self-concept. Individuals try to maintain congruence between their self-images, how they see themselves to be behaving, and how they perceive others to perceive them. A person who sees himself as honest but is accused of dishonesty feels uncomfortable and may try to prove his honesty, or discredit his accuser, or claim that he was behaving honestly "really," perhaps inventing a story in justification. Whether or not he is deceiving himself, in these ways, he overcomes the guilt he may have felt. In any case, minor infringements of the moral code are condoned by others with such sentiments as "After all, we are all human" or "He is doing the best he can."

Of greater significance are cases where departures from the moral code are accepted by others without question. This can happen in several ways. As noted earlier, moral codes govern only behavior to members of the same group. Soldiers are permitted and commended for killing only members of the outgroup. War is, of course, an extreme case, but racial and religious prejudice are common, and nearly all the time we see ourselves as members of one group or another, and tend to favor its members over outsiders. We are more favorably disposed toward members of our own firm, school, team, or nation than we are to outsiders, the

boundaries of the ingroup being where we and our peers see them at the time. Relations with in-laws may be hampered by their unfamiliar values and customs.

Various devices are employed to emphasize or change the boundaries of the ingroup. In wartime, the whole panoply of nationalism emphasizes the differences between the ingroup and the enemy, and denigrates the latter. In the everyday, most groups advertise their identity and relationships with ingroup members may be marked by special methods of greeting, customs, dietary restrictions, and many other ways.

Duty to members of the ingroup may become an overriding concern. The soldier feels an irresistible duty to his buddy, comrades, platoon, or country. Duty to help a friend in need is a defining characteristic of friendship and can override personal needs and duty to nonfriends. In politics, duty to colleagues in the party causes politicians to vote against their consciences (condoned as "political necessity"). And chief executives have conflicting duties to shareholders, employees, customers, and suppliers and their families.

Again, moral rules apply only to those who are seen as "full persons." In many societies (and in our own until not so long ago), women were not seen as full persons. In some cultures, wives can be treated by their husbands in a manner unacceptable in our own: The institution of marriage has different rules from those that pertain in Western cultures. In many cultures, including our own, children are exploited as lacking full rights. And in our own, lawbreakers can be deprived of their liberty in prison: This is seen as an inevitable consequence of the institution of the law, which is necessary for the well-being of society.

As another possibility, rules may change with the situation. Thus, though bargaining in business may pervert the Golden Rule, operating not with *Do-as-you-would-be-done-by* but with *I'm-going-to-get-the-best-out-of-you-because-I-know-that-you-are-trying-your-best-to-get-what-you-can-out-of-me*. This is half-heartedly condoned as "business ethics" and approved of by economists as benefiting the consumer. One hopes the businessperson uses quite different precepts when getting home to his or her family in the evening.

However, gross prejudice against an out-group, gross manipulations of group boundaries, and

gross distortions of the precepts are constrained by the law. The rules can be bent, but not too far.

Thus, we have a series of anomalies. Moral precepts must be seen as absolutes, yet minor infringements can be dealt with by the actor without guilt. In particular contexts, infringements can be condoned or encouraged because they are advantageous to the society. But major infringements are constrained by the legal system. And the law itself must be seen as absolute, and yet can be changed as circumstances change. Thus, personal relationships must be conducted within a complex system of cultural rules. However, although rules can be bent, this in no way implies that breaking the rules is the best option for individuals and society.

MOTHER–CHILD RELATIONSHIPS IN ADOLESCENCE AND ADULTHOOD

Throughout adolescence and into adulthood, mothers' relationships with their children grow more distant. They spend less time together, and children turn to other social ties (e.g., friends, romantic partners) for many supportive and social functions. Nevertheless, mothers remain central in children's lives, and vice versa. Throughout life, the mother–child relationship is the primary intergenerational tie, ahead of relationships with fathers, in-laws, grandchildren, or grandparents. In studies examining

social networks, most mothers and adult children list the other party among their most important social ties. Yet, relationship qualities vary as the child progresses from puberty through the transition to adulthood and into midlife, when the mother grows older and approaches death. This entry highlights differences between children's relationships with mothers and fathers during adolescence and adulthood, examines changes in the nature of the mother–child relationship across this period, and reports some of the contextual factors contributing to differences between particular mother–child relationships.

Differences Between Relationships With Mothers Versus Fathers in Adolescence and Adulthood

In adolescence and adulthood, qualities of relationships between mothers and offspring are often compared with qualities of relationships between fathers and offspring. Relationships between mothers and their children tend to be both more positively and more negatively emotional than do relationships between fathers and children. Throughout adolescence, mothers report more intimacy, greater knowledge of their children's daily activities (or parental monitoring), and more frequent conflicts than do fathers. In early adulthood, offspring typically have more frequent contact with mothers than with fathers and are more likely to turn to mothers for advice and emotional support than to fathers. Likewise, throughout adulthood, offspring report stronger positive and negative feelings, or greater ambivalence, toward mothers than toward fathers. In late life, offspring are more likely to care for mothers when they suffer health declines of old age than when fathers suffer such declines.

Theorists postulate several reasons for the greater intensity of ties between mothers and children in adolescence and adulthood. Qualities of the relationship from early childhood may continue into adolescence, with mothers more emotionally connected to offspring than fathers. For example, during adolescence, mothers tend to be more involved in day-to-day parenting, providing more frequent opportunities for supportive

exchanges as well as conflicts with offspring. Similarly, mothers are “kinkeepers” for the family after offspring enter adulthood. Mothers are more likely to organize holiday gatherings that connect far-flung progeny. Mothers keep track of relatives’ whereabouts and convey such information to offspring. Further, scholars have argued that relationships between mothers and grown children are dyadic in nature, involving only the mother and each child, whereas relationships between fathers and grown children are typically triadic in nature, mediated via the mother. Thus, a typical interaction between grown children and married parents involves a telephone conversation between child and mother, with the mother putting the father on the phone or conveying the gist of the conversation to the father afterward.

Although relationships with mothers are more intense than are relationships with fathers throughout life, the mother–child relationship is not static from puberty to old age. Changes occur in this relationship across those decades.

Changes in Mother–Child Relationships Across Adolescence and Adulthood

Longitudinal data examining the relationship between mothers and children across adolescence are abundant. For example, the adolescence literature substantiates a linear decrease in maternal involvement with children from early to late adolescence. Mothers also typically share values with adolescent children and engage in conflicts regarding more minor issues such as curfews and hair styles. Longitudinal studies examining the mother–child relationship after adolescence are scant. A few longitudinal studies find continuity in qualities of this relationship from adolescence into young adulthood. For example, mothers and adolescents who have positive relationships at age 15 are likely to report similarly positive relationships at age 26. Such associations in relationship quality attenuate over larger gaps in time; thus, associations of relationship quality from age 11 to age 26 or from age 15 to 35 are less strong. Thus, continuities in relationship qualities are limited to relatively short periods, and relationships between mothers and children are characterized by fluctuations during adolescence and adulthood. It is

unclear when and why relationship qualities change, but several current ongoing national longitudinal studies (e.g., Add Health) involve mothers and children who are soon entering adulthood, and researchers will be able to contribute new findings to an understanding of how mothers and children’s relationships change over time.

Methodological innovations in the past decade have already contributed to an altered understanding of mother–child relationships in adolescence and adulthood. For example, through the 1990s, researchers believed that conflict between mothers and adolescents peaked in early adolescence around puberty. These studies included only the mother and one child per family, however, and assumed the family patterns generalize across families. Yet, approximately 80 to 90 percent of families have more than one child. Recently, scholars have focused on within-family patterns. These analyses have revealed that peak conflict with mother varies by birth order. For example, first-born children show a peak in conflict with their mother around age 13, whereas second-borns show such a peak at age 11. A within-family design reveals a different age for peak conflict than that obtained with between-family designs. Likewise, research using within-family designs in adulthood have revealed different patterns of maternal preference for which child should provide care in late life than between family designs suggested. Between-family designs suggest mothers select offspring based on gender and prefer daughters, but within-family designs document maternal preferences for a child who shares their values. In sum, studies relying on between-family designs hold inherent assumptions that the relationship with the mother is similar for all children in the family; studies that include more than one child in the family challenge such assumptions.

Although cross-sectional designs are limited by the inability to describe change, such studies do provide insights into how relationships between mothers and children may vary from adolescence into late life. For example, mothers generally report positive ties to offspring during the transition to adulthood (when offspring are approximately aged 18 to 25), particularly if those offspring have left home. Most U.S. offspring leave the maternal home in early adulthood to pursue an education, to enter the military or other employment, or for other reasons (although some return to their mother’s home

at later times). Mothers and offspring transition from daily contact involving shared living conditions to a relationship allowing latitude in frequency of contact, sharing of information, and regulation of emotional exchanges. Mothers of young adults tend to contrast their current positive view with conflict in the adolescent period. Likewise, a study of African-American females found that those who had left home in late adolescence reported less negative relationships with mothers than did similar-aged adolescents living at home or in transition to leaving home.

Maternal well-being also may be affected by their views of how their progeny turned out. Mothers seem to experience satisfaction offering advice and help to young adults who are following normative and successful trajectories, finding their way in education, relationships, and early work experiences. When offspring suffer problems with such normative transitions into adulthood, mothers tend to experience stress. Young adults also typically report strong ties to mothers and report benefiting from financial and emotional support. In sum, maternal involvement is generally strong and positive for both parties in young adulthood.

As mentioned previously, when mothers incur health declines in old age, offspring often become caregivers. Although providing care to the mother can generate role confusion and distress for both parties, such caregiving is so common, it constitutes an almost normative right-of-passage for middle-aged Americans. Thus, the adolescent, young adult, and maternal end-of-life stages of this relationship involve predictable and common events shared by many mothers and children. From young adulthood into midlife, relationship patterns are more difficult to capture because of the many life changes (e.g., marriage or divorce, birth of children and grandchildren, entering or leaving the workforce) that mothers and children experience across these decades.

Contextual Factors Shaping Mother–Child Relationships in Adolescence and Adulthood

Gender

Gender of offspring may play a key role in the nature of mother–child relationships in adolescence and adulthood. In adolescence, the

familial constellation sets a backdrop for whether maternal relationship qualities vary by child's gender. In mixed-sex sibling sets, dads are more involved with sons and moms are more involved with daughters. When siblings share gender (i.e., all girls or all boys) and in one-child families, mothers and fathers may show a pattern of involvement with adolescent children based on other features of their tie, such as shared interests.

Nonetheless, research reveals that the mother–daughter relationship in adolescence may be particularly intense. Mother–daughter dyads generally involve higher levels of intimacy, sharing, and confiding than do dyads involving fathers or sons. The level of conflict in the mother–daughter dyad also is more intense throughout adolescence than in dyads involving sons or fathers. Moreover, mothers and daughters are more likely to resolve those conflicts via compromise than are dyads involving fathers or sons.

The mother–daughter tie remains the most intense intergenerational ties in time, intimacy, and investment throughout adulthood. Feminist scholars have suggested that daughters do not individuate from their mothers in young adulthood (as sons do) because of women's shared investment in relationships. Throughout adulthood, in comparison with sons, daughters report more frequent contact with mothers, greater feelings of intimacy, and more tensions. Mothers and daughters share an investment in family and are likely to be involved in tasks that bring the family together. Middle-aged daughters and their mothers describe shared enjoyment of get-togethers involving the daughters' children, spouse, or siblings. Daughters also are more likely to take on hands-on caregiving of elderly mothers than are sons. Before mothers require such care, however, recent studies report fewer gender differences between sons and daughters in adulthood than were reported in the studies conducted in the late 20th century. That is, sons have increased contact with their mothers, greater intimacy, and are also more involved in decisions regarding health care of mothers. The increased involvement of sons may reflect greater flexibility in gender roles and men's greater involvement in family life observed among the baby boomers and their progeny.

Marital Status

Maternal marital status also may shape relationships between mothers and children in adolescence and adulthood. When mothers are not married (i.e., never married, divorced, widowed), their offspring are typically their most important social ties and their relationships may intensify. For example, relationships between adolescents and nonmarried mothers may grow more intense rather than more distant throughout adolescence. But if the mother remarries during this period, the relationship tends to grow more distant. Likewise, widowed mothers in late life place greater demands on offspring than do married mothers. Indeed, widowhood is the single factor that best explains why offspring are more likely to care for frail mothers than for frail fathers; fathers are more likely to have a living spouse who provides care.

Offspring marital status is also linked to qualities of the tie to mother in adulthood, but the pattern of findings is complex. Some studies find the relationship grows closer upon offspring marriage, other studies find that it grows more distant, and still other studies find no changes. These findings suggest that marriage affects different mother–offspring relationships in diverse ways. This lack of clarity may reflect other factors that contribute to variability in the tie, such as geographic distance and cultural values or other individual or relationship differences.

Geographic Distance

Geographic distance between mother and grown child is the structural factor that most clearly determines frequency of contact and exchanges of support. Approximately half of U.S. offspring reside within 50 miles of their mothers, allowing face-to-face visits and exchanges of assistance. Residence far from mother does not vary by offspring gender but, rather, seems to reflect economic circumstances such as educational opportunities, jobs, or military service.

Culture and Ethnicity

Finally, culture and ethnicity shape qualities of relationships between children and mothers in adolescence and adulthood. For example, in Asian

families, adolescents report considerably less conflict with mothers than in U.S. families. In African-American families, conflict patterns are similar to those observed in European-American families. Conflict is relatively frequent, low in intensity, and occurs over mundane issues. Yet, studies of African-American mothers also find that they experience conflicting expectations for autonomy and closeness with daughters, stemming from the hope that their daughters will be self-reliant but remain loyal and attached to family in adulthood. In families that have recently immigrated to the United States, mothers and adolescents experience greater conflict if the offspring is more acculturated to the United States than the mother is. Cultural factors interact with other structural factors as well. In farm families, relationships between sons and fathers may be stronger than relationships between daughters and mothers because of the patrilineal pattern of work and inheritance. Likewise, the implications of geographic distance for the relationship may be associated with each party's beliefs about filial obligation or familialism.

In sum, although relationships between mothers and offspring vary across adolescence and adulthood, relationships between mothers and children tend to remain strong during this period. Indeed, the mother–child tie remains dominant throughout life.

MOTHER–CHILD RELATIONSHIPS IN EARLY CHILDHOOD

The mother–child relationship is a unique entity. The relationship starts before the infant is born and normally exists even after the death of either partner by remaining in the mind of the living partner. This long-lasting relationship provides the context for learning what it is to be a human being. The relationship will play a substantial role in determining the child's social and emotional development. For the mother, the relationship will provide a lasting source of emotional connection and an opportunity to connect with the future. The mother–child early relationship, years 0 to 5, lays the foundation for the evolution of the sense of contributing to society for the mother and the intergenerational transmission of beliefs and values for both mother and child. The relationship is the context for learning, regulation of behavior, and other relationships. Whether positive or negative, most adult-age children can identify the character of their relationship with their mother and recall the way it influenced their lives.

Although the early role of the mother is mainly protective until the age the child can both walk and talk, the mother takes on a role of promoting the child's exploration while providing safety as necessary. This entry discusses the fundamental components of the early child–mother relationship, including the introduction of Attachment Theory, sensitivity to developmental challenges for the child, and monitoring of the child's general course.

History and Importance of the Relationship

Several components of a relationship are important for understanding the mother–child relationship.

First, the relationship exists based on the past, present, and future. An important feature is the mother's past history of relationships and well-being. Attachment Theory proposes that when caregivers, usually the mother, respond supportively to their child's signs of distress (fussiness, crying, hunger), children develop an expectation or trust that a specific person can assess their needs and be depended on to provide comfort, food, or stimulation. This expectation is referred to as *secure attachment*. Adults who have secure attachment histories and only moderate life stress bring to the parent–child relationship the ability to be emotionally available to the fetus and child. A mother needs to prepare a place in her family or friend network for the new child; she needs to imagine herself as the mother with all the roles that involve caring for the child. When a mother has had a history of poor (insecure) relationships with her own parents, particularly her mother, she has less of a foundation for making herself available to the child. As David Winnicott declared in the 1940s, there is no such thing as an infant, only an infant and a caregiver.

Attachment Theory: Central to the Relationship

Attachment Theory as presented by John Bowlby is the basis for understanding both the biological and psychological significance of the mother–infant relationship, in which there is total dependence on one member of the dyad. The infant's survival and well-being depend on being cared for by a caregiver. In the beginning, care provided in a sensitive manner requires the caregiver or mother's preoccupation with the dependent infant.

In infancy, the mother controls the interaction and should respond in ways that provide consistency, predictability, and emotional availability. The mother needs to monitor the infant's cues and behaviors and to gradually follow the child's lead in the interaction. Managing the young infant's distress is a primary aspect of the mother–child relationship because the infant has not matured enough to get out of the highly distressed (crying) state. The infant needs external calming to bring his state down to either an awake responsive level or to a sleep state. When his caregiver responds to his distress, the baby is also learning to trust his

environment, and if the mother is indeed responsive, the baby is likely to develop a sense of secure attachment through the repeated responsiveness of the mother or caregiver.

During this early time, the mother is the mediator of the child's world. Psychologically during the pregnancy and for the first months, the mother and baby are one and what pleases the baby pleases the mother. At around 6 month of age, the infant begins the discovery of his or her physical self; fascination with hands and feet keep a young baby's undivided attention. The mother–child relationship begins to have more of a dyadic balance as the child's sense of self emerges.

A condition of establishing the mother–child relationship is the woman's own developmental level. A strong mother–child relationship is best achieved when the woman is emotionally ready to put aside her own needs and be available to attend to another's need. A mother who has experienced an emotionally supportive, trusting relationship has an advantage. Generally, the early mother–child relationship greatly contributes to attachment security or insecurity; however, evidence also shows a type of “earned security” where an individual can learn the lesson of trusting another person through an adult relationship or therapy. Attachment Theory predicts that once security has been achieved with one person, usually the mother, the concept of trusting another can be generalized to new relationships. The supportive care of women during their pregnancy, labor, delivery, and early postpartum by a trustworthy adult will contribute to promoting “good enough mothering” and a positive mother–child relationship, especially for women whose early relationship history did not foster the capacity for trusting others.

Evidence indicates that when mothers work full time during the baby's first year, they may demonstrate less sensitivity to the child. The rationale for why full-time working mothers may be on average less sensitive is related to the time they have with the infant; hours spent watching and responding to the infant are fewer, and therefore, the mother has less of a chance to observe and know her child. When a woman has a history of undependable relationships, little capacity to trust others, and many life stressors, this negative life experience renders her less able to make room for the baby in her emotions. Responsive mothering takes practice; this

acquaintance process takes time, and the mother's capacity to take in the baby's needs is primary.

Being emotionally available to the child means having a capacity for monitoring the child. Louis Sanders proposed a developmental model of the early mother–child relationship that has four distinct stages in the early months of life. The first two stages are the launching pad. The first stage (birth to 3 months) involves homeostasis. The mother is sensitive to the expressions of the baby's need for food, sleep, or activity and provides contingent caregiving acts to meet those demands. Sanders called the second stage (4–8 months) the social-emotional period. During this time, the infant is more responsive to the mother's voice and face and smiles when eye-to-eye contact is made. The foundation for future interaction is set at this time, and the infant becomes social and responsive to the caregiver. The signaling of need by the infant or mother and the dyadic responses are all carefully worked out during caregiving times when the baby is awake during such events as feeding, bathing, and diaper changes.

An important part of the early relationship between the mother and child creates the social-emotional relationship in which both the mother and child reciprocally influence the behavior of the other in a way that is potentially rewarding for each of them. Arnold Sameroff has called this *process transaction* in contrast to interaction, where the behavior of each transforms the response of the other so that both are changed. During the process of interaction, the dyad—the caregiver and the infant—learn to adapt, modify, and change their behaviors in response to each other. The baby's positive emotional responses reward mothering acts, but if the baby is irritable and negative or nonresponsive, the baby's emotional responses make mothering more difficult. For example, it has been demonstrated that when infants cry frequently, mothers tend to become more distant, such as trying to comfort the child with verbal responses from across the room.

Developmental Changes in the Relationship

Initially, the child needs hands-on mothering along with the emotional connection to survive, where in time the relationship prepares the child for becoming

a functional, responsible, socially appropriate adult. The mother–child relationship changes over time framed by the tasks of the developing child. In the early months, the mother–child relationship is largely determined by the mother. For example, the child largely depends in infancy on the adult caregiver for basic care, for temporal regularity, and for decision making, whereas in the preschool ages, the child begins to become independent of the primary caregiver while sustaining a mental model that sustains them during long periods of separation. By early school years, the child gains mastery and learns healthy competition but still needs structure, limits, and rules. During the school-age years, the child explores the outside world and develops a strong sense of self. By the years 8 through 12, the child is developing a sense of self that involves mastery, reliance, control, esteem, and emotional literacy. Children play an increasing role in decision making, so by preteens they are making some of their own decisions and accepting the consequences for them by adolescence.

Mary Ainsworth's research with the Strange Situation demonstrated how the behaviors of young children differed in secure versus insecure attachment patterns, and similar findings have recently been demonstrated in older children. After identifying from a questionnaire whether the school-age child had a secure or insecure attachment, the two groups of children were given a series of photographs to view. Some photos were familiar, such as pictures of their mothers, and some were new or novel. The researchers found that secure versus insecure children processed information differently; the secure children attend more to novelty than the insecure children. Secure attachment frees the child to move on to the next landmark of development, exploration, and learning. From the early relationship, the child develops a secure "mental map" of the relationship. If the child experiences the relationship as positive, responsive, and nonintrusive, a mental template is formed that is generalized beyond the mother–child relationship. The child brings this attachment schema of feeling secure or not into new developmental challenges. The resulting mental template can provide direction and support even without the physical presence of the mother. Evidence suggests the internal working model of self and others, based on the adolescent and mother's relationship,

is associated with the adolescent emerging as an emotionally healthy adult.

MOTIVATION AND RELATIONSHIPS

Motivation refers to the reason or reasons why people behave and are moved to action. Human

intention, will, and desire—all words used to capture motivation—have fascinated psychologists since the field of psychology began. At the heart of both research and theory on motivation is the idea that humans have an intrinsic need for social connection and relatedness. The desire for human connection is so strong that psychologists Roy Baumeister and Mark Leary have posited that humans have a fundamental “need to belong,” a need that is found in all cultures. Infants show an uncanny readiness to seek out and bond with other people, and adults continue to connect with close others throughout the life span. When asked about their life goals, most people list happy and fulfilling social relationships as most important, and those who neglect to place social needs among their top life goals tend to be less happy and healthy.

In the past several decades, psychology and related fields have witnessed considerable gains in understanding the central role of relationships in human motivation. Researchers have conducted many studies that span different kinds of relationships from parent–child relationships to romantic relationships, encompass different phases of relationships from newly developing dating relationships to long-term marriages, and include people at different developmental stages from infancy to old age. This entry examines the factors that influence the motivation for relationships, highlights several specific motives studied by psychologists, presents two prominent classification systems for social motives, discusses the ways in which close others can influence and shape our motives, highlights important changes in social motives across the life span, and reviews different types of methods and measures that researchers use to study motivation in human relationships.

Where Does the Motivation for Human Relationships Come From?

The human desire and need for connection has deep evolutionary roots and is present from the moment of birth. John Bowlby proposed that infants are born with an innate system called the “attachment behavioral system” that motivates them to seek proximity to caregivers in times of need. This system protects human beings of all

ages from threats, but is most directly and transparently observable during infancy. A key idea from Bowlby’s theory is that infants use their caregivers as a secure base: Only when infants are confident and secure that their caregivers will be there for them in times of threat or need can they act on their motivation to explore and learn about the world. The desire to form and maintain social bonds has both survival and reproductive benefits. Groups can share food, provide mates, and help care for offspring. Cues that indicate possible harm, such as illness, danger, nightfall, and disaster, seem to increase the need to be with others, underscoring the protective value of group membership. In the human evolutionary past, people who formed attachments were more likely to reproduce than were those who failed to form them, and long-term relationships increased the chances that offspring would reach maturity and reproduce in turn.

Other important influences on the human need for connection are not rooted in evolution. For example, sociocultural norms dictate that “normal” people ultimately settle down with a partner and have children, whereas single or childless people are seen as abnormal. People internalize these pressures, likely influencing their desire to find lifelong partners and raise families. There are also proximal factors based on an individual’s current social and cultural environment that influence the motivation to form relationships with romantic partners or friends. For example, a teenage boy who just moved to a new town may befriend the first boy whom he meets to cope with his sense of loneliness, but a popular girl in the same school may be choosier about the types of friends whom she lets into her inner circle as her affiliation needs have already been met.

What Kinds of Motives Do Psychologists Study?

Two particularly important social motives have been studied across a variety of relationship contexts. Dan McAdams defines the *intimacy motive* as a preference for close, warm, and communicative experiences with others, whereas the *power motive* is defined as the preference to feel strong and have influence over others. In a series of studies

of close friendships, people with high intimacy motivation reported interacting with and disclosing more to their friends, better listening skills, and more concern for their friends' well-being. In contrast, people with high power motivation reported trying to take charge of situations with their friends, make plans, and persuade others.

Two other motives studied by psychologists involve people's desires to maintain particular psychological states. *Self-enhancement motives* refer to people's desires to maintain positive views of themselves. When people are guided by self-enhancement motives, they are motivated to interact with other people who make them feel good about themselves, reflecting their need to be valued and admired by others. In the realm of interpersonal relationships, research has shown that people are more satisfied with their dating and marital relationships when their partners hold positive views of their qualities and traits. *Self-verification motives*, however, refer to people's desires to confirm and sustain their existing views of themselves. When people are guided by self-verification motives, they are motivated to interact with other people who confirm their self-concepts, reflecting their needs for consistency. For example, research has also shown that in marriages, people are more committed to spouses whose views of them are consistent with their own self-concepts, even when those self-concepts are negative. Both self-enhancement and self-verification motives likely guide people's behaviors in close relationships, and people may be guided by different motives in different situations or with different interaction partners.

How Do Researchers Classify Social Motives?

People pursue many different kinds of motives and goals in their social interactions. For example, people seek out close others to alleviate boredom, to obtain information about the world, to build their social networks, or to boost their own self-esteem, just to name a few. One useful distinction is whether a person acts to obtain positive outcomes (*approach motives*) or to avoid negative outcomes (*avoidance motives*). In the social domain, people can pursue approach motives such as to obtain intimacy, have fun, or grow as a person, or

they can pursue avoidance motives such as to avoid conflict, rejection, boredom, or loneliness. For example, at a party in her new college dorm, a student with strong approach social motives may focus on meeting new people and having a good time, whereas a student with strong avoidance social motives may spend his time monitoring his actions and focusing on ways to avoid rejection. As discussed by Shelly Gable, the distinction between approach and avoidance social motives has been used to understand a variety of topics in close relationships including sacrifice, sexuality, and relationship commitment. Across all these topics, approach motives generally lead to better social outcomes than do avoidance motives. For example, on days when people make sacrifices for a romantic partner for approach motives (such as to connect with or please their partners), they experience more excitement, enthusiasm, and overall relationship satisfaction. But, on days when they sacrifice for avoidance motives (such as to avoid the partner's anger or disappointment), they experience more guilt, hostility, and relationship conflict.

Another useful distinction is whether a person is motivated to perform a behavior that is a chosen and satisfying end in itself (*intrinsic motives*) or is motivated to perform a behavior for instrumental purposes or as the means to another end (*extrinsic motives*). For example, a man who has intrinsic motives may put energy into maintaining his marriage because he shares fun and pleasurable times with his partner, whereas a man with extrinsic motives may do so because he feels obligated to reciprocate the home-cooked meals and comfortable lifestyle his wife provides. Research by Edward Deci and Richard Ryan has shown that couples who are intrinsically motivated to remain in their relationships report greater feelings of love and faith in their relationships than do couples who are extrinsically motivated.

How Do Other People Influence and Shape Our Motives?

People do not make decisions about how to act in social situations in a vacuum. Interaction partners have a powerful influence on the choices that people make and the motives that guide behavior. An important influence on motivation in social

situations concerns the nature of the relationship between the interaction partners. One important distinction made by Margaret Clark and Judson Mills is between *communal relationships* (e.g., most typically, these are relationships with friends, family members, and romantic partners) and *exchange relationships* (e.g., most typically, these are relationships with strangers, acquaintances, and business partners). In communal relationships, people generally help another person out of a genuine concern and sense of responsibility for that person's welfare, whereas in exchange relationships, people tend to help another person to the extent that he or she has already helped them in the past or if they expect to receive help in the future. In short, the motivation to help other people depends largely on the nature of the relationship between interaction partners.

In romantic relationships in particular, partners have particularly strong influences on one another's motives. Because the things that affect one partner often affect the other, romantic partners are especially likely to consider each other's needs and concerns when making behavioral choices. For example, a woman may decide to sacrifice her girls' night out on the town to stay home and care for her sick husband. Or, a man may decide to forgive his girlfriend for making a nasty remark in front of his friends because the long-term peace and happiness of his relationship is his primary goal. When people make decisions such as these, they enact what Harold Kelley and John Thibaut referred to as a *transformation of motivation*, in which their own self-interested desires are replaced by motives that consider the need to coordinate with their partner's wishes and priorities and focus on the long-term future of their relationships. In short, people's social motives can be shaped both by their partners and by their own broader concerns about their relationship.

How Do Social Motives Change Over the Life Span?

Individuals shift their priorities and goals over the life course, including their goals that concern social interactions. According to Laura Carstensen, two central social motives follow different developmental trajectories. One essential human motive

is to seek information about the self and the social world (*the knowledge trajectory*). The fact that infants and children learn so much in the first few years of life reflects the readiness at birth for a great deal of social learning. The knowledge trajectory starts high during the early years of life and declines gradually over the life course as people accrue more knowledge and their futures grow shorter. The second class of human motives is emotional in nature and includes such motives as the desire to feel good, establish intimacy, and verify the self (*the emotion trajectory*). The emotion trajectory is highest during infancy and early childhood when emotional trust and relatedness are initially established, and then rises again in old age when future-oriented strivings are less relevant. Although both of these social motives operate throughout life, with age or other transitions such as moving from one place to another, knowledge-focused motives lose their importance and emotion-focused motives gain importance. As a result, the types of social partners that people choose and the dynamics of social interactions change in fundamental ways. For example, whereas a young child may try out different social behaviors to learn about himself and his role in the social world around him (e.g., by asking his mother many questions), an elderly woman may be more focused on connecting to and maintaining intimacy with those around her (e.g., by writing letters and placing phone calls to close friends).

How Do Researchers Study Motivation in Relationships?

Researchers use many different types of methods to study motivation in human relationships. One type of research involves the use of *cross-sectional surveys*, in which participants report on their social motives at one point in time. Gable has asked participants, at one point in time, to rate their motives in their dating relationships during an upcoming academic quarter. For example, participants indicate the extent to which they intend to try to "deepen my relationship with my romantic partner" (to assess approach social motives) and "avoid conflicts and disagreements with my romantic partner" (to assess avoidance social motives). A

second type of research involves the use of *daily experience surveys*, in which participants report on their social motives repeatedly over a fixed period of time (e.g., everyday for 14 consecutive days). Researchers using these methods are particularly interested in how people's social motives may change from one day to the next depending on variations in the social situation (e.g., how much conflict they experience on a particular day). A third type of research involves the use of *longitudinal surveys*, in which participants are tracked over a period ranging from several weeks to many years. For example, Carstensen has looked at how the same people pursue different kinds of social motives at different points in the life course.

The measures that people use to assess social motives also vary. One type includes *open-ended measures*, in which participants are asked to write or talk about the types of motives that they pursue in their social interactions. From their responses, researchers create coding schemes to distill the large number of responses into a smaller number of meaningful themes, for example themes that focus on intrinsic or extrinsic motives. A second type includes *close-ended measures*, in which participants indicate the extent of their agreement with a list of goals determined ahead of time by the researchers themselves. For example, M. Lynne Cooper and her colleagues developed a close-ended measure of sexual goals, asking participants to indicate the extent to which they engage in sex for approach goals (e.g., "I have sex to feel emotionally close to my partner") and avoidance goals (e.g., "I have sex because I don't want my partner to be angry with me"). A third type of measure includes *implicit measures* of social motives, based on the idea that people may not always have conscious access to their own motives. For example, in some studies using implicit measures, participants look at ambiguous pictures and respond to a set of statements by indicating how they might think or feel in the situation depicted in each picture (e.g., a man taking a test or a woman attending a party).

MULTIGENERATIONAL HOUSEHOLDS

The relationship of families to housing and of housing to family dynamics has interested many social scientists. The concept of multigenerational households has been used in at least two different ways. One is three or more generations in one housing unit or compound or several generations in close proximity. The second meaning includes, as is said in Asian countries, "close enough that the soup doesn't get cold" in transit; in Europe, living in apartments or houses in the same complex; in Central and South America, in the neighborhood, in apartments, and on the farm in a compound. In the United States, living within 1 hour or 100 miles of travel is seen as within easy access for family activities and caregiving. Living in the same dwelling conveys a much closer interaction and shared living, although when there is sufficient wealth many families create areas of privacy and independence within the dwelling. Demographers have been impressed with the decline of multigenerational households as young people have more opportunities. Housing and living arrangements for families and individuals reflect values, available incomes, housing policy, lifestyle choices, and regional and rural-urban opportunities and socioeconomic status. U.S. housing choices are also based on idealization of rural life, seen in an attraction for the suburbs of cities, rather than the central cities. Many fewer U.S. families aspire to live in the big cities than do those in Europe or the developing world. This entry discusses multigenerational households and reviews the history; current practices both in the United States and other countries; and the demographic, social, and economic forces affecting these practices now and in the near future.

Prevalence of Multigenerational Households

Historically, multigenerational households have been associated with family businesses, especially farming and shopkeeping, and current multigenerational households are often associated with shared business or vocational interests. Historians have argued about whether multigenerational households were ever dominant in Western society, with a general consensus that households

often contained boarders and apprentices, but that coresidence was limited to certain periods of life such as early marriage and widowhood. Today, there is a strong preference for relatively healthy elders to live independently and not reside with their children. Coresidence between adult children and their elderly parents has become less common over the decades. Currently the expansion of household structures has been in many more single people living alone. With the increase in longevity, determinants such as health problems, death of former caregivers, financial hardship of both the old and the young, and loneliness, there may be a renewed need for coresidence. When there are few supports for the elderly family care, transfers or sharing of property may encourage such shared living arrangements. The underlying inheritance and in vivo transfers of material resources including housing and other financial instruments may support some members sharing a common residence or location and providing care and support across the generations, especially if supported in the legal structure.

Tradition of Multigenerational Households

The traditional family referred to in much of the multigenerational household literature has been the stem family that has one adult child and one side of the parental generation coresiding and often working together. In many places, the stem family includes the oldest son and his nuclear family living with his parents. In China, the multigenerational house design was usually a single or double hollow square courtyard that provided some separation among the families living there and most commonly included the eldest son's family and any younger or unmarried siblings of his. In Asia in general, the adult children's sense of moral obligation to care for their parents stems from their deep respect and gratitude. There is a belief that parents deserve to be cared for in their elder years by their children as a form of repayment. This filial piety combined with reciprocal affection facilitates the inner workings of the family support system allowing care and security for the elderly parent.

In Central and South America urban areas, having apartments and compounds adjacent or close is

relatively easy, and families may build houses that have separate quarters but connecting doors and access. In small rural communities, the separation among households may amount to little, and people come and go with little notice. In Brazil's big urban centers, large extended families often live within easy walking distance in apartments frequently with the elderly persons close or adjacent to one of the younger adult children. Entertainment may happen in someone's large apartment, but more frequently meeting at a local restaurant brings everyone together.

In Europe, families and close friends often live in the same neighborhood or rural community and may choose to buy vacation homes or trailer park sites in the same place for vacation. The Druze in Israel often work in construction, the military, or education, but maintain a large home in their villages that can accommodate several related families in adjacent structures or within the structures. Some of the houses are always under construction to meet new needs. In Australia, promoting granny flats, which are additions to single-family housing through remodeling, and free-standing units to share the backyard has appealed to some families but has not been as well accepted as hoped by those urban planners who saw promise in such individual solutions to aging care. In the United States, some subcultures such as the Amish and recent immigrants usually try to keep multigenerational households. The Amish build smaller quarters for the grandparents onto farmhouses. The recent influx of immigrants both in North America and Europe suggests many prefer or depend on coresidential living. Some communities within or near big urban areas have houses or apartments that can accommodate larger families and immigrants and are often remodeled to accommodate complex families or individuals who are close family friends or distant relatives sent to them by their families in the home country.

Current Issues in Multigenerational Households

Changing housing markets also make available new options. As middle-class families have bought larger and larger houses, the ability to provide short-term housing for adult children and grandchildren becomes easier. The young adult who a

generation ago would have been unhappy without his or her own apartment now may move to a suite with bath at home after college and be quite content. Similarly, the divorced mother and her children may seek support by returning home, at least temporarily. In addition, some parents find their houses full of their grown children's possessions when they are moving to follow work and mobility opportunities. Doubling up of both generations and siblings happens because of economic or mobility pressures. Though perhaps not the preferred living arrangement, housing shortages and high-cost housing create situations in which shared living arrangements are practical. There is a lingering concern from the long-term assumptions that nuclear households reflect appropriate independence and success that question such practical multigenerational households. In the United States, political rhetoric and programs to promote single home ownership exist even for the poor. Unemployment, which threatens families with loss of their house, may result in moving in with kin or friends. In 2008, the vast unraveling of the mortgage and realty markets may make doubling up a necessity.

Among some minority groups, for example African Americans, such events as family reunions, sending children to their grandmothers for summer vacations, and practices such as aunts being important caregivers in times of stress continue multigenerational ties even without regular coresidence. Although these practices are not limited to minority groups, they are especially useful in keeping family ties and helping networks.

Multigenerational living arrangements depend on infrastructure and community planning. In the United States, local zoning laws frequently isolate different types of housing, and owner-occupied single-family homes predominate. Active older adult communities often prohibit young or even teenage children from staying with their relatives for more than short visits. Elderly adults who chose these communities for their amenities may have a difficult time unwinding these financial arrangements when they are needed to care for their grandchildren over long-time commitment.

In Russia, families lived together because few housing choices were available and pooling of resources was useful. Now many more housing

units have come on the market in cities and those with the means tend to live in nuclear family units, but still try to be close for visiting. Economic and cultural conditions in Europe have continued to produce more multigenerational households in the south of Europe and few in the northern countries. Among the wealthy and upper middle class, having more than one home is a strategy that allows some multigenerational contact without living together full time. Also the ability to create nursing home environments within a household may allow elders to be at home longer or to share a home during the highest needs for care.

Functions and Stresses of Multigenerational Households

Multigenerational households continue to serve important functions, particularly at resource-scarce times or when wealth is available to make them comfortable and convenient. These households make the flow of care and intergenerational transfers of goods, services, and monetary benefices relatively simple. However, interactions within these households may be more complicated, especially when generations have different outlooks or conflicts that are not easily resolved. With the continual pattern of change in family structure, it is critical to closely examine multigenerational households, intergenerational bonds, and family relations from a theoretical perspective. Multigenerational living arrangements can be complex, with intense accumulation of demands placed on its members and family discourse. Successful multigenerational relationships are built upon mutuality and shared respect. Changing the expectations for the essentially adult dynamics of parents and their grown children is not automatic and requires some re-socialization of both parties to the relationship. Exploitation or violence against elders may be a problem in multigenerational households, especially when there are limited resources or long-term conflicts. Solidarity within a multigenerational household allows families to give each other feedback and exchange help and support, although they may also experience conflict and ambivalence.

Grandparent-Headed Multigenerational Households Today

Recently, more attention has been placed on the grandparents' role within these multigenerational households, after the U.S. Census in 2000 revealed a large number of households in which grandchildren were coresident with grandparents, often without parents. Grandparents who are coresident with their grandchildren are more likely to give both routine and extended care to their grandchildren. They often give more help to younger mothers and are important in minority and low-income households. Having a living grandparent (especially a grandmother) is often noted as a protective factor for children at risk.

In sub-Saharan Africa, the AIDS epidemic has left children with none but their grandparents or other older relatives or neighbors to care for them. These skip-generation households might not seem to be what is usually meant by multigenerational households, but as these families try to support themselves and care for each other, they are key to hopes for survival in Africa. In Kenya and South Africa, grandmothers and older female relatives have primarily covered the care and sponsorship of these orphans. Young children may also care for frail elderly relatives who no longer have living adult relatives. The few nongovernmental organizations (NGOs) and state-sponsored orphanages are not able to meet the growing needs for caregiving. In villages, many extra huts are available and not everyone may share the same space, but the few elders try to care for the children and to grow enough food to feed them, often using limited energies and strength with hoe-based gardening.

Conclusion

Multigenerational households are still important for addressing intergenerational relationships and caregiving where resources in the larger society are less dependable and when stressful events require more resources. Proximity is a predictor of helping and caring and for the coresidents the opportunity is real. Both caring for elders and elders caring for grandchildren and the adult caring for disabled or troubled child are simplified

with coresidence in multigenerational households or near proximity of households.

MUTUAL CYCLICAL GROWTH

Jennifer Wieselquist and her colleagues developed a model of *mutual cyclical growth* to explain the across-partner associations among commitment, prorelationship behavior, and partner trust. The model combines concepts identified by Caryl Rusbult and her colleagues in their work on commitment with concepts identified by John Holmes and his colleagues in their work on trust. These analyses are complementary, in that both models rest on the principles of Interdependence Theory. This entry reviews the mutual cyclical growth model, explaining an important aspect of relationship regulation—how close partners influence one another during extended involvement, with each person's motives and behaviors in turn affecting the other's motives and behaviors. Key variables in the model are dependence, commitment, prorelationship behavior, and trust.

Dependence, Commitment, and Prorelationship Behaviors

According to Rusbult's investment model, people develop increasing *dependence* on their relationships as a function of (a) high *satisfaction level*—to the extent that their most important needs are gratified in the relationship (e.g., companionship, security, sexuality); (b) poor *quality of alternatives*—to the extent that their most important needs could not be gratified independent of the relationship (e.g., by a specific partner, the general field of eligibles); and (c) high *investment size*—to the extent that they invest numerous important resources in the relationship, either directly or indirectly (e.g., time, effort, shared friendship network, joint material possessions).

As people become dependent, they develop feelings of commitment to the relationship. *Commitment level* represents long-term orientation toward a relationship, including intent to persist and feelings of psychological attachment. Strong commitment entails motivation to “make a relationship work” not only by persisting in the relationship, but also by engaging in prorelationship acts such as (a) accommodation—when a partner enacts a potentially destructive behavior (e.g., criticism, irritability), committed individuals inhibit the impulse to react destructively in turn and instead behave in a constructive manner; (b) sacrifice—when partners' interests conflict, committed individuals engage in otherwise undesirable behaviors or forgo otherwise desirable behaviors for the good of the partner and relationship; and (c) affirmation—committed individuals work to elicit the best in their partners, even when doing so is effortful or costly. Many of the behaviors that people enact so as to sustain a relationship—including accommodation, sacrifice, and affirmation—are termed *prorelationship acts*, in that such behaviors to some degree are costly or effortful, yet promote the well-being of a partner or relationship.

Diagnostic Situations, Trust, and Dependence

Situations that call for prorelationship acts—for example, situations in which a partner “behaves badly,” or situations in which partners' interests conflict—have been termed *diagnostic situations*.

Dilemmas of this sort are “diagnostic” in that the manner in which people behave in such situations is indicative of their motives. For example, when John sacrifices a long-awaited opportunity to go out with his friends and instead helps Mary plan an upcoming party, Mary can discern the strength of his commitment, in that he has placed her needs and interests above his own. According to Holmes’s model of trust, people develop increased trust when they observe a partner behave well in diagnostic situations—when they observe the partner enact costly or effortful prorelationship acts. *Trust* is thus relationship-specific and represents the strength of one’s conviction that a partner will be responsive to one’s needs, now and in the future. As such, Mary’s trust in John reflects the strength of John’s commitment to Mary.

As partners develop enhanced trust in each other, they are also likely to become increasingly dependent on each other: Trusting partners feel more satisfied with their relationships, and are more willing to drive away attractive alternatives and invest important resources in their relationships. Thus, as Mary develops trust—becoming increasingly confident that John will be responsive to her needs—she becomes more comfortable being dependent on John, which in turn yields strengthened commitment, which in turn causes her to exhibit prorelationship acts. When John perceives such acts, he develops increased trust in Mary, which in turn makes him more comfortable becoming dependent on Mary, which strengthens his commitment . . . and so on, in a pattern of temporally extended, mutually reinforcing across-partner influence. This model also helps explain deteriorating relationships, in that if any component of the model is weakened—for example, if Mary encounters tempting alternatives, or if she stubbornly refuses to enact prorelationship behaviors, or if she finds that she cannot trust John—the mutual cyclical process will stall or reverse, as partners’ motives and behaviors feed back on and influence each other in a negative manner.

Conclusion

Given that each person’s motives and behaviors affect the other, mutual cyclical growth is a process through which partners tend to develop and sustain roughly equal levels of dependence, commitment, and trust, and tend to exhibit roughly reciprocal prorelationship acts. Indeed, mutuality and reciprocity tend to be characteristic of well-functioning relationships. The model also illuminates crucial processes in ongoing relationships by integrating important interdependence principles from two traditional theories—Rusbult’s theory of how partners develop commitment and Holmes’s theory of how partners come to trust each other.

N

NARCISSISM, EFFECTS ON RELATIONSHIPS

Narcissism, or self-love, has a complex series of consequences, both negative and positive, for relationships. This makes it an important topic of study for investigators, practitioners, and students in the area of human relationships. Narcissism can interfere with the ability or desire to form close, caring relationships with others. Although primarily destructive for relationships in the long term, during the initial relationship stages, narcissism can also promote relationship functioning. Interactions with narcissistic individuals are often described as exciting and enjoyable in the beginning. For example, a narcissist may be perceived, at first, as a confident, charming new romantic interest or an exciting, charismatic political leader. These positive perceptions, however, often become negative as the relationship progresses. This entry includes a brief description of narcissism, a view of relationships from the narcissist's perspective, and a view from the perspective of the other(s) in the relationship with the narcissist.

What Is Narcissism?

The term *narcissism* is derived from the Ancient Greek myth of Narcissus, popularized in psychology by Sigmund Freud. Narcissism is a personality trait that is characterized by a positive, grandiose, and inflated view of the self. Narcissists see themselves

as better than others on traits such as social status, ability, creativity, and physical appearance. Narcissists also have an elevated sense of entitlement and believe that they are special and unique. Narcissism is also related to a lack of interest in forming emotionally close relationships with others. Finally, narcissism is linked with efforts to enhance and defend self-esteem. That is, narcissists seek opportunities that will make them look and feel successful and attractive. In its most extreme form, narcissism becomes narcissistic personality disorder (NPD). This is a rare clinical condition that shares characteristics with narcissism.

Narcissism has consequences for a wide range of relationships. A good deal of research has examined narcissism in dating relationships, new or emerging relationships (i.e., acquaintanceships), and leadership and work relationships. There has been relatively little research on narcissism and parenting, marriage, sibling relationships, or long-term friendships. In general, the outcomes of narcissism are similar across the different relationship types; for example, narcissists' charm and confidence are useful for both finding dating partners and obtaining leadership positions.

The Narcissist's Perspective

From the narcissist's perspective, relationships are needed for maintaining and elevating self-esteem. This leads to an interesting paradox in narcissists' relationships. On the one hand, narcissists do not desire emotional closeness with others; on the

other hand, relationships are useful for inflating the narcissists' self-image. Relationship partners can serve this self-esteem enhancing function in several ways. For example, the narcissist can find an admirer or group of admirers, or associate with high-status people.

Narcissists are skilled at starting relationships. This skill allows narcissists to manipulate others into fulfilling their self-esteem needs. Narcissists tend to be confident, socially adept, charming, and manipulative. They report having relatively high numbers of dating and sexual partners and are likely to rise into leadership positions.

Once narcissists initiate relationships, however, they are problematic partners. Narcissists are relatively low in relationship commitment and more interested in finding other, better relationship partners. Narcissists are game-playing as well; for example, they tend to alternate between displaying and withdrawing commitment to a partner. They also are likely to set off two or more partners against each other. At worst, narcissists can be physically and sexually aggressive. This often occurs when narcissists feel threatened or rejected, or do not get their way. For all these reasons, narcissists' relationships tend to be short. When they do get married, the outcome is mixed. Some evidence indicates that narcissists can be satisfied and committed in some circumstances, but also are prone to be physically abusive and sexually unfaithful.

The Partner's Perspective

When relationships are formed with narcissists, they typically start out well. Narcissists are often attractive when first encountered. They are liked when only seen in short video clips of behavior; they are liked in initial group meetings; and they emerge as leaders in short-term groups. The beginning of dating relationships with narcissists can be satisfying and exciting. Over time, however, social ties with narcissists become less positive. In work groups, this is often a consequence of narcissists' self-focus and selfishness, including counterproductive and unethical behavior. In dating relationships, this is a result of narcissists' unwillingness to form emotionally close relationships coupled with a host of destructive behaviors such as emotional control, game-playing, dishonesty, infidelity, and

even aggression. The long-term consequences of narcissism are often highly negative, and those who form relationships with narcissists can suffer for extended periods.

Additional Issues

There are small gender differences in narcissism, with men showing somewhat higher levels. This gender difference is larger in NPD. In relationships, however, men and women with high narcissism scores act in similar ways.

Some limited evidence indicates that narcissists can change for the better in relationships. This change may be brought about by a shift toward taking a caring or connected orientation toward the partner or group. Nevertheless, individuals with high levels of narcissism are unlikely to change in relationships. Because narcissism is often accompanied by higher levels of self-esteem and positive emotion, there is little motivation to change. There are also few clinically validated treatments for NPD, although there are suggested psychodynamic, cognitive behavioral, and behavioral therapies. Narcissists' response to relationship break up and rejection can vary. Evidence indicates that narcissists respond to rejection with anger and aggression and that they are able to distort their memories of rejection so that their self-esteem remains intact.

NEED FULFILLMENT IN RELATIONSHIPS

One reason humans find relationships particularly rewarding is that they serve to fulfill needs. Needs are those necessary conditions and elements that are essential to individuals' physical and psychological well-being. In his seminal 1938 book, Henry Murray provided a set of nearly 30 specific needs that individuals seek to have met in their lives. Of these, many are interpersonal in nature, including the needs for affiliation, autonomy, dominance, nurturance, play, recognition, rejection, and sex. Similarly, other early theorists such as Abraham Maslow and Carl Rogers highlighted the importance of relationships in fulfilling love and belongingness needs and as a source of unconditional positive regard in self-actualized individuals. This entry discusses need fulfillment from several theoretical perspectives and reviews the empirical findings regarding need fulfillment within the context of romantic relationships.

Theoretical Perspectives

Numerous theoretical perspectives and research findings have noted the importance of the fulfillment of interpersonal needs. For example, Edward Deci and Richard Ryan's Self-Determination Theory highlights the importance of relatedness needs (i.e., the need to be connected to others) along with needs associated with autonomy and competence. Fulfillment of this fundamental "need to belong," according to Roy Baumeister and Mark Leary, is an important motivation at the core of much research and theory on many types of relationships, including romantic relationships, friendships, and group dynamics. In short, from a wide range of perspectives, a diverse set of human needs have been identified, and many are linked to interpersonal relationships.

From an evolutionary perspective, many basic human motivations have social and relational

dimensions. To survive and reproduce, organisms must have certain needs met, such as the acquisition of food, safety for oneself and kin, opportunities for mating, and subsequent caretaking of offspring. From this perspective, the continuation of the species is due to humans' abilities to fulfill social needs that promote survival and reproduction.

The Self-Expansion Model, proposed by Arthur Aron and colleagues, is based on the assumption that humans have a fundamental motivation to seek opportunities that facilitate personal growth, promote the development of self-identity, and enhance social and material resources. From this perspective, relationships play an important role in the fulfillment of self-expansion goals because interaction with relationship partners is a primary avenue through which these goals are met. For example, relationships with others serve as a source of self-identity, and knowledge and access to resources are increased through one's relationship partner. Likewise, interactions with a relationship partner may be associated with novel and exciting activities (e.g., having someone to share new experiences with), further enhancing self-expansion.

Furthermore, Interdependence Theory, articulated by John Thibaut and Harold Kelley, is based on the notion that interactions between individuals yield outcomes for those parties involved in the interaction. In other words, people get things that they desire from their relationships. Within a developmental context, as interpersonal needs are met within relationships, those relationships begin to take on more importance to the participants. Over time, individuals begin to rely on their partners for fulfillment of specific needs, thus building a pattern of interdependent interactions between partners (i.e., they depend on each other for need fulfillment). To illustrate, imagine a relationship between George and Susan in which George's needs for intimacy are met through his continued interaction with Susan (e.g., she is a good listener and provides the warmth and closeness he desires). Likewise, George may facilitate the fulfillment of Susan's companionship needs (e.g., she enjoys spending time and engaging in activities with him). As George and Susan's reliance on each other for the fulfillment of their desired needs increases over time, their relationship is strengthened.

The fulfillment of needs within the relationship has a direct impact on individuals' satisfaction in

the relationship; those with their expectations for need fulfillment may experience those relationships more positively. Likewise, if alternative relationships cannot (or are not anticipated to) fulfill needs as well as a current relationship, reliance (called “dependence” in this theory) on the current relationship is strengthened. For example, if George’s intimacy needs are being fulfilled by Susan, and those needs for intimacy could not be met as well in another relationship, satisfaction is increased and alternatives are decreased, and that relationship is likely to persist. In a sense, from an Interdependence Theory perspective, commitment to a relationship and subsequent continuation (or termination) of a relationship is a function of the extent that the relationship fulfills one’s needs, via satisfaction and alternatives (two important components of Caryl Rusbult’s Investment Model of Commitment).

Need Fulfillment in Romantic Relationships

These various theoretical perspectives have given rise to specific needs that are hypothesized to be central in relationships and have been measured in many studies of close relationships. For example, working from an Interdependence Theory perspective, Stephen Drigotas and Caryl Rusbult identified six important relationship needs: intimacy, sexual, emotional, companionship, security, and self-worth. Likewise, Self-Determination theorists suggest the importance of three primary human needs: autonomy (the need to feel in control of one’s behavior), competence (the need to feel effective and capable), and relatedness (the need to feel connected). Similarly, Karen Prager and Duane Buhrmester organize needs along two primary dimensions: communal needs and agentic needs. *Communal needs* relate to social interaction, such as intimacy, affection, fun/enjoyment, nurturance, and sexuality, whereas *agentic needs* include those that relate to the self, such as self-esteem, order/structure, recognition, power/influence, and achievement.

Beyond identifying and organizing types of need fulfillment, research on close relationships has focused on the associations between need fulfillment and interpersonal processes. For example, the fulfillment of intimacy needs in marriages has been shown to be associated with enhanced communication skills and relationship satisfaction.

Likewise, need fulfillment is a good predictor of relationship outcomes such as the decision to remain in or leave a romantic relationship. As shown in a longitudinal study of dating relationships, partners reporting that they relied on their relationship for the fulfillment of sexual, emotional, companionship, security, and self-worth needs at one point in time were more likely to still be in their relationships 6 weeks later. Interestingly, the need fulfillment of “leavers” (i.e., those “dumping” their partners) was significantly lower than for those who were abandoned in their relationships (i.e., those “dumped” by their partners) and those whose relationships persisted, suggesting that having one’s needs go unfulfilled in a relationship precipitates the decision to end that relationship. In addition, a study assessing these same needs indicated that a lack of need fulfillment was associated with susceptibility to engage in relationship infidelity (i.e., cheat on one’s partner).

Furthermore, the fulfillment of relationship needs is associated with well-being and the experience of positive and negative emotions. For example, fulfillment of the needs identified by Drigotas and Rusbult has been shown to be associated with heightened positive emotions and lowered negative emotions, although these associations were found to be lower for those in long-distance relationships. Similarly, fulfillment of autonomy, competence, and relatedness needs is associated with greater well-being, self-esteem, and positive emotions, whereas a lack of fulfillment of these needs predicted experience of negative emotions. Need fulfillment is also associated with low anxiety and avoidance levels in relationships; those with secure attachment orientations report higher levels of relationship need fulfillment.

NEGATIVE AFFECT RECIPROCITY

Negative affect reciprocity (also called *reciprocation of negativity* or *mutual escalation*) refers to the tendency for one person's negative behavior to instigate another's negative behavior. It references a pattern of behavior between two people in relationship to each other, where one person's negative actions, such as criticism or an angry facial expression, are followed by another's similarly valenced actions. Repeated patterns of negative reciprocity turn into *negative spirals*, continued patterns of reciprocity that work to create a poor relational climate and bring about other negative consequences within relationships. This entry discusses the nature and effects of negative affect reciprocity in a variety of personal relationships, focusing on the behaviors that may be involved and the characteristics of relationships likely to have high levels of negative affect reciprocity.

What Behaviors Are Negative?

Negative affect (also called *negative emotion*) may be manifested during interaction in intimate relationships in many ways. The five primary negative emotions or affects are anger, shame/guilt, fear/anxiety, contempt/disgust, and sadness. Anger and contempt are sometimes studied together as *hostility*, and shame and sadness are sometimes viewed together as *despair*.

Whereas these emotions can arise from interacting with others, particularly in difficult situations, the emotions themselves can also lead to behaviors

such as negative forms of *conflict* (e.g., coercion, aversion, or invalidation), *nonverbal behavior*—including silence and frowning, *defensiveness*, *physical aggression* or *violence*, *belligerence*, which can occur with verbal or nonverbal messages—and *withdrawal*, or leaving an interaction either physically or mentally. Additionally, negative affect can show up as criticism, disagreement, disapproval, interruptions, put downs, threats, ignoring, changing topics, and denials of responsibility.

Patterns of reciprocity may begin while a person is speaking or listening to another. So, for instance, one friend may be listening to another's problems with her boyfriend, and the listener may begin to sigh. The speaker may reciprocate the sigh—or some other largely negative behavior—in response. The primary characteristic of affect reciprocity is that one person's negative behavior leads to another's negative behavior, and the second person's behavior is not likely to have occurred if the initial action had not taken place. Patterns of behavior-affecting-behavior can continue or spiral over time, creating long-term and problematic cycles for relational partners. So, when a child yells at his mother, and the mother responds with criticism, the son may respond with an angry retort, and so on, turning it into an interaction that is both undesirable on its own and that can have long-lasting effects.

Who Is Affected?

Behavioral reciprocity is common across all interpersonal interactions (i.e., exchanges that occur between people, such as the mother/son discussed). People in close relationships depend on each other to meet their needs and goals, and reciprocity—both negative and positive—tends to be more pronounced when people know each other well or cohabitate. As people's lives and behaviors become enmeshed, there are more opportunities for—and consequences of—patterned interaction.

Most research on reciprocated affect has been conducted with heterosexual “romantic” couples. Researchers have also looked at reciprocated affect in other familial relationships, including the greater likelihood that siblings will reciprocate each other's negative behaviors than reciprocate their friends' negative behaviors. Most notably, there has been a

focus on reciprocity in parent–child relationships. For example, negative reciprocity is particularly likely between a child and his or her mother during encounters that involve criticism or discipline and between fathers and their children at play.

Other work looks toward the *outcomes* of mutual escalation (i.e., when one behavior leads to another, which leads to another and another, the pattern escalating in intensity or frequency of negative affect), particularly on children. Research suggests that, because children learn about affect from their parents primarily, reciprocity patterns exhibited in the household—both negative and positive—condition children for affective patterns with others later in life. Some scholars argue similarly that negativity between two people in a family—such as the parents—can “migrate” to other family members. Mutual negativity between parents can even lead to parental abuse of their children. Parents’ negativity reciprocity has also been linked to greater youth delinquency, poor interaction skills, and even mental illness. In some families, the negativity has led to or is created by high levels of stress. Although negative reciprocity can occur in many circumstances, a combination of high stress and affect reciprocity can be particularly volatile.

Negativity reciprocity appears particularly pronounced when children reach adolescence. Perhaps because of the greater emotional intensity that occurs during puberty, reciprocity of both positive and negative behavior is even more likely than during early childhood. Negative reciprocity when children are teens has been found to influence parenting skills and problem solving negatively (i.e., difficult behavior spirals may create environments where other competencies become harder to enact). Moreover, negativity reciprocity during adolescence predicts similar behavior later in adulthood. Thus, its effects can be found beyond the interactions in which such patterns occur.

What Predicts Negative Reciprocity?

Reciprocity is the most common response to negative behavior across relationships. But reciprocity is more likely in relationships that have certain qualities. Research has focused on three:

unhappy relationships, violent relationships, and relationships in which one or more people are alcoholic or substance-addicted.

Negative Affect Reciprocity and Relationship Satisfaction

Researchers have found that dissatisfied couples are more likely than are satisfied couples to reciprocate each other’s negative behavior. Whereas the causal link between dissatisfaction and negative affect reciprocity is unclear, some evidence indicates that dissatisfaction may lead to negative reciprocity. When people are unhappy in their relationships, they tend to notice, evaluate unfavorably, and respond in kind to their partner’s negative actions. Conversely, negative reciprocity can shape the nature of relationships over time, *leading to* greater dissatisfaction. Behaviors that occur consistently become part of the relational script (i.e., predictable patterns of behavior), influencing partners’ expectations for each other and helping form a larger conception of relationship that is judged as more or less satisfying.

As noted, negative reciprocity tends to occur in all relationships, regardless of satisfaction level. One explanation for why negative reciprocity is less frequent and less harmful in satisfying relationships concerns satisfied couples’ greater ability to escape from negative patterns by using positive affect to de-escalate the negative spiral. For instance, if a wife frowns at her husband when he comes home late, instead of responding by replying with criticism, a more satisfied husband might go up to his wife and hug her, stopping the reciprocity and changing the affective climate.

Expressions of positive (or even neutral) affect may work by “soothing” their recipient, and this change in affect can be particularly important when the recipient is male, as males’ greater tendency toward physiological arousal in negative interactions is at the base of many harmful communicative patterns in couples’ relationships. Despite the potential to de-escalate negative patterns of behavior, and the likelihood that those in satisfied relationships will break the cycle with positive or neutral behaviors, even satisfied couples do not often do so.

Negative Affect Reciprocity in Abusive or Violent Relationships

Because negative reciprocity can develop easily in relationships, and because it can be hard to break, researchers have been keenly interested in its manifestation in relationships that are already prone to negative behavior, such as abusive relationships. The tendency to reciprocate negative behavior is more likely in violent rather than non-violent marital or intimate relationships, especially during conflict. Moreover, patterns of reciprocity usually last longer between physically aggressive couples because nonviolent couples exit negative affect reciprocity patterns more easily than do violent couples.

Negativity escalation does not happen always or with all negative behaviors, but it is a strong trend and occurs most often in the form of withdrawal matched by withdrawal. Some researchers argue that withdrawal patterns are particularly harmful to relationships because conflict remains unresolved, and greater hostility may emerge later as a consequence. Other forms of negative reciprocity appear to be common, particularly for men who are in unhappy, violent relationships. Such men may react more negatively and predictably than do any other group, although men in happy, but violent, relationships are also likely to reciprocate their female partners' negative behaviors.

The tendency to react to a partner's negative behavior with similarly negative behavior—particularly during conflict interactions—may be based on the level of anxiety or arousal some couples feel during those interactions. Whereas most people tend to feel aroused/anxious in difficult interactions, for some people in violent relationships, heightened arousal levels make controlling their reactions more difficult, and this may be more pronounced for males. Other researchers point to the ways in which certain couples think about or make sense of each other's behaviors. Specifically, people in physically aggressive relationships tend to pay considerable attention to their partners' behaviors, and they may be more likely to blame their partner for any perceived "misbehavior." Such ways of thinking increase the likelihood of reciprocity, although this is just one of many potential causes for physical aggression.

Negative Affect Reciprocity and Alcohol Use

For aggressive couples in particular, alcohol often increases the extent of negative affect reciprocity. As with most people, alcohol use impairs their ability to think in ways they would without the alcohol. For example, a woman who has been drinking may be more likely to see her partner's behaviors toward another woman incorrectly as flirtatious rather than friendly. This cognitive impairment is one of the forces behind the increased tendency to react to negativity with negativity. Such impaired cognition is particularly likely in men who are in aggressive relationships, although it occurs for both sexes. Other reasons that have been given for negativity reciprocity and alcohol use include the tendency for alcohol to make some people more coercive, impulsive, dominant, and antisocial, all ways of being that may encourage additional negativity.

Consuming alcohol does not predict negativity reciprocity in all cases. Long-time, steady drinkers, for example, are less likely than are those who drink "episodically" to reciprocate behaviors. Episodic drinkers are also more violence-prone than are steady drinkers, so reciprocity of violent behavior may be more common in relationships with episodic alcohol consumption. The strongest patterns of negative reciprocity when alcohol is consumed are in relationships where physical abuse is common, particularly when the violence-prone drinking partner is male.

NEGATIVE INTERACTIONS DURING LATE LIFE

The beneficial effects of social relationships on mental and physical health across the life span are well documented. Yet, close relationships do not always function as sources of support and companionship. They can also be a source of conflict, demands, and disappointments. Negative interactions with social network members tend to occur less often than positive interactions do, but the effects of negative interactions appear to be more potent. These observations have given rise to a literature on the nature and effects of negative interactions. Individuals of all ages occasionally experience tensions and frustrations in their

relationships. This entry reviews the literature on negative social interactions in later life, a time when having to deal with declining health, loss of relationship partners, and other difficult life circumstances may precipitate or magnify the impact of negative exchanges. The entry begins by exploring the implications of negative exchanges for health and well-being in later life, and then examines variations in both exposure and reactivity to negative exchanges.

Impact of Negative Social Interactions on Health and Well-Being

Research that examines the impact of negative social interactions on health and well-being has often compared the effects of positive and negative interactions. A point of departure for such work has been the extensive body of evidence documenting health-related benefits of social ties. Across the life span, structural (e.g., network size, frequency of social contact) and functional (e.g., perceived support availability and quality) aspects of social networks significantly affect health and well-being. Social network members often provide emotional and instrumental support that dampens the adverse effects of life stress and provide opportunities for companionship and shared activities. Not surprisingly, people who have meaningful social relationships report less depression and susceptibility to chronic disease, and greater life satisfaction and longevity. The generally positive impact of supportive social relationships extends into later life; research with older adults indicates that supportive ties have a beneficial impact on mental and physical functioning.

Yet, interactions with social network members are not exclusively positive. Some network members, despite good intentions, engage in selfish, insensitive, or simply clumsy behavior at times. Analyses of social network composition indicate that although most network members function predominantly as a source of positive exchanges, many function as a source of both positive and negative exchanges, and a vexing minority function solely as a source of negative exchanges. These negative exchanges have the potential to elicit negative affect and arouse stress in their own right, thereby threatening well-being.

Negative interactions can take many forms. A review of the literature, however, suggests that they can be classified in four relatively broad categories. Although some degree of overlap exists across these categories, the categories have been validated and found to have distinctive effects in representative samples of older adults. These categories are insensitive or critical behavior by others, intrusive or unsound advice provided by others, failure by others to provide tangible or instrumental support in times of need, and rejection or neglect by others. These are directly parallel to four broad categories of positive exchanges that are consequential for well-being: emotional support, informational support, instrumental support, and companionship.

Although these different kinds of negative interactions can occur at any point in the life span, age differences may exist in the life contexts in which they tend to occur and the specific factors that precipitate their occurrence. For instance, older adults often experience stressful life events and transitions that elicit feelings of loneliness and emotional distress and that increase their needs for support and companionship. Events such as marked declines in physical functioning, the loss of loved ones, and residential relocation involve major life changes that may create long-term needs for support and care by social network members. If social network members are unable or unwilling to provide needed social support and companionship, older adults may be especially likely to experience emotional distress and feelings of rejection or neglect.

Research indicates that negative exchanges arouse considerable distress, as evidenced by strong associations with negative affect, depressive symptoms, and feelings of loneliness among older adults. Even though negative exchanges generally occur less frequently than positive exchanges, the adverse effects of negative interactions on health and well-being appear to outweigh the beneficial effects of positive interactions. This disproportionate impact of negative exchanges, referred to as the *negativity effect*, may be attributed to several factors. One explanation is that negative exchanges violate a fundamental expectation that close network members can be counted on to be supportive and caring. Another explanation is that negative exchanges can serve as sources of acute or chronic

stress. In fact, studies examining different kinds of daily stress have found that stressors of an interpersonal nature (e.g., disagreements and misunderstandings) are among the most distressing. Social relationships in which difficulties persist over time are especially likely to elicit health-damaging negative affect and feelings of stress and to erode perceptions of control among older adults.

Interpersonal stressors also have detrimental effects on physiological processes (e.g., neuroendocrine and immune responses) involved in the human stress system. This may explain why social relationships characterized by recurring problems have been linked to compromised immunological, neuroendocrine, and cardiovascular functioning in later life. Negative exchanges contribute to physical symptomatology, accounting for more variance in physical health symptoms than life stress, daily hassles, or social support. Furthermore, negative exchanges predict more distal health outcomes, such as the onset and progression of physical disability in later life. For example, in one longitudinal analysis of community-dwelling older adults with little to no baseline physical disability, individuals who reported consistent, frequent negative interactions over 2 years were more likely to experience functional declines (e.g., difficulty with activities of daily living).

Moreover, well-intentioned social support can backfire. Providing and receiving instrumental support (material aid, services) appears to be a particularly sensitive issue in later life. Support that recipients perceive to be unwanted, inappropriate, or incongruent with their needs may threaten their feelings of self-efficacy, competence, independence, and overall well-being. For example, among older adults with a physical disability, instrumental support—particularly if overprotective—may foster dependence and reduce confidence in engaging in self-care and physical activities that are essential to preserving physical functioning. Consequently, recipients may feel resentful, and providers may feel unappreciated. Even in the absence of such negative feelings, older adults who need extensive care and close network members who seek to provide such care may experience considerable awkwardness and uncertainty while struggling to negotiate this transition in their relationship. The receipt of instrumental support, ironically—but perhaps not surprisingly from this perspective—has

been shown to predict an increased risk of disability onset and recurrence over time among older adults.

Variations in Exposure to Negative Interactions in Later Life

Although declining health and other circumstances in later life may sow the seeds for misunderstandings and disagreements in older adults' relationships, not all adults are equally vulnerable to negative interactions. Moreover, not all negative interactions experienced by older adults emerge anew in later life; some such interactions reflect problems of long-standing duration in their relationships.

A key factor that influences the nature of older adults' social relationships—and, in turn, their exposure to negative interactions—is the extent to which they are able to selectively manage their social contacts. According to Socioemotional Selectivity Theory (SST), older adults have a growing awareness that their time left to live is limited, and thus are driven to satisfy emotional needs. Consistent with this idea, evidence indicates that as people age, they selectively prune their social networks and shape their social environments to spend time with emotionally rewarding partners. As a result, older adults are better equipped to prevent, resolve, and recover from interpersonal tensions, and hence, report fewer problematic ties. This may explain why, despite declining rates in the frequency of social contacts and reductions in network size with advancing age, relationships in later life tend to be of better quality and characterized by greater emotional closeness and less negativity.

Nonetheless, variability in life circumstances and individual differences may affect older adults' attempts at selectively managing their social interactions and, in some cases, increase their exposure to negative interactions. As previously mentioned, age-associated life events (e.g., declining mobility, widowhood, or residential relocation) may preclude older adults from engaging in rewarding interactions. Thus, older adults may experience feelings of loneliness, rejection, and neglect. Moreover, as older adults develop limiting physical conditions, they tend to rely more on family members than on friends. This shift may elicit

negative interactions, as interpersonal tensions are more likely within the context of kin, rather than nonkin, relationships.

Although changes in life circumstances may precipitate negative exchanges, longitudinal work on negative interactions, though sparse, indicates that among some older adults, negative exchanges are chronic and show stability over time. This, again, may be particularly true to the extent that older adults' networks contain a large proportion of kin. Unlike voluntary ties with friends, kin ties are obligatory and difficult to terminate. Family ties that are unrewarding or persistently problematic may serve as chronic sources of stress. Evidence also suggests that some older adults report negative exchanges across multiple partners (for example, friends, children, *and* spouses), implying that their personal characteristics may play a role in prompting the chronic interpersonal difficulties experienced in later life. Traits such as depressive tendencies, neuroticism, poor social skills, and lack of self-esteem may make some older adults more vulnerable to negative exchanges, as is true in younger age groups. Furthermore, declines in cognitive functioning may render some older adults more susceptible to chronic negative interactions. For example, evidence suggests that declining cognitive inhibition and executive dysfunction contribute to socially inappropriate behavior and negative social interactions. These individual differences and life circumstances may increase older adults' exposure to negative interactions, and may influence their ability to deal with such interactions when they occur.

Variations in Reactivity to Negative Interactions

When confronted with acute or chronic interpersonal tensions, older adults may engage in a number of coping strategies. These strategies typically fall into one of two categories—problem-focused or emotion-focused. Problem-focused coping involves efforts aimed at changing the stressful situation itself, such as confrontation, seeking a compromise, or seeking support from others about how to handle the situation. Emotion-focused strategies are internally directed and aimed at reducing negative emotions elicited by

the event, such as trying not to think about the event, trying to reframe it to feel less stressful, or trying to suppress emotional distress. Whereas younger adults are more likely to use problem-focused coping, older adults tend to use a mixture of strategies. This is due, in part, to older adults' enhanced ability to regulate their emotions and differentiate among multiple strategies for coping with stressors. Accordingly, older adults report less negative affect and anger in response to negative exchanges and remain distressed for shorter periods than do younger age groups.

Moreover, the type of coping strategy employed depends on the person's coping goals or objectives, which also may differ across the life span. Like their younger counterparts, older adults' interpersonal goals range from problem resolution and ending the aversive pattern of interactions, to reducing emotional distress. But, unlike their younger counterparts, older adults may assign special importance to the goal of maintaining harmony and goodwill in their relationships. This helps explain why older adults are more likely than are younger and middle-aged adults to respond to negative interactions with conciliatory coping strategies (e.g., forgiveness, self-blame, and less avoidance). Older adults' use of coping strategies geared toward preserving harmony have been shown, in turn, to predict less emotional distress and greater perceived goal success.

NEGOTIATION

Negotiation refers to the communication to reach agreement between two or more conflicting parties. Parties may be, for example, husband and wife, parent and child, colleagues in the same department, or a house owner and an interested buyer. Oftentimes, parties represent or even involve larger groups of people, as in the case of negotiation between the representatives of labor union and corporate management. In negotiation, parties perceive their interests to be opposed to those of their counterpart. Such negotiation can be formal, as in the case of union–management negotiations, or more informal, as in the case of a husband and wife negotiating responsibility for household chores.

Regardless how formal or informal, negotiation involves a set of basic principles and psychological processes that will be briefly discussed in this entry. One key first element of most negotiations is that they involve, at least potentially, several issues rather than one single issue. Husbands and wives discuss responsibility for household chores and may discuss income and child care. Unions and management discuss wages as well as health care, pension plans, vacation time, and training and development. In short, negotiations often concern multiple issues, and in case they do not, parties can bring new issues to the table, or break issues into several smaller ones.

Creating Value in Negotiation

Negotiating about several issues at the same time can have interesting advantages. A famous story is told by a pioneering scholar of negotiation, Mary

Parker Follett, about two sisters quarreling over an orange, who end up splitting the orange in two equal parts. One sister squeezes her part, throws away the peel, and drinks the juice. The other squeezes her half, throws away the juice, and grates the peel to flavor a cake she is baking. Had these sisters talked about their interests they could have reached a mutually more beneficial agreement (the entire peel to one sister, all the juice to the other) than they reached by quarreling over one single issue—the orange.

Another illustration of the benefits of discussing multiple issues comes from the Camp David negotiations between Israel and Egypt in 1977. Since the Yom Kippur war in 1973, Israel had occupied the Sinai Desert, which Egypt wanted back. Instead of dividing the desert in more or less equal parts, it was decided that Egypt would get back the desert to satisfy its historical claims and restore its reputation in the Arab world. But, critically, Egypt would keep the desert demilitarized so that Israel's need for security was satisfied. Both parties thus achieved a better deal by talking about reputation as well as about security, rather than focusing on the single surface issue of who gets what part of the Sinai Desert.

Agreements that take advantage of the fact that the various issues involved in a conflict may not be equally important to all parties are called *integrative agreements*. In integrative agreements, parties concede on issues that are unimportant to oneself but important to the other (e.g., the peel, reputation among Arab neighbors) but stand fast on issues that are important to oneself but unimportant to the other (e.g., juice, security). Compared with simple “split-the-difference” compromises or victory-to-one settlements, studies have shown that integrative agreements tend to be relatively stable, create positive feelings of satisfaction and pride, and install a sense of self-efficacy, allowing parties to approach later negotiations in a more optimistic, problem-solving oriented manner. In addition, parties are more committed to their part of the bargain and more motivated to honor their promises. Integrative agreements create more value to both parties than any other type of agreement. This in turn fosters stability, harmony, and sometimes even economic prosperity; failure to reach (integrative) agreements may create frustration and conflict, distrust and weakened social ties, and

may hurt economic progress. In the long run, failure to agree and continue conflict may lead to relationship dissolution (e.g., divorce, employees leaving an organization).

Psychological Principles in Negotiation

Many scholars in psychology and other social sciences have tried to understand when and why people fail or succeed in reaching integrative agreements. Pioneering work was done by Sidney Siegel and Lawrence Fouraker, Harold Kelley, and Dean Pruitt, among others. These authors created experimental situations in which two persons negotiated over several issues (e.g., the price of the car, delivery time, method of payment), some of which were valuable to the seller but not to the buyer, and some of which were not valuable to the seller but were important to the buyer. By trading the less important issue for the more important one, buyer and seller were able to earn more personally and collectively than by splitting the difference on these issues. But because each party entered the negotiation without knowing what was valuable or not to the counterpart, they were unaware of the possibility to trade off and do well collectively—they had to uncover this possibility through negotiation. This is exactly what the researchers were interested in: Why do some individuals discover the integrative possibilities and others do not?

This pioneering work showed that individuals and groups have great difficulty achieving integrative agreements. According to a structural-motivational account, this is primarily because negotiators simultaneously face a cooperative incentive to reach agreement with their counterpart (i.e., agreement is better than no agreement) and a competitive incentive to do well personally. Whereas cooperative incentives motivate negotiators to make and reciprocate concessions, to lower their demands, and to exchange information openly and accurately, competitive incentives motivate them to withhold and retract concessions, to remain tough in their demands, and to deceive and mislead their counterpart. By implication, if cooperative incentives become relatively more important and available than competitive incentives, negotiators will engage in more

cooperative behavior and are less likely to reach a mutually harmful stalemate.

Cooperative incentives gain or lose prominence relative to competitive incentives because of aspects of the negotiation setting. *Power* is one example. When a negotiator has a good alternative to the current negotiation (e.g., someone else already made an attractive offer), this may fuel the competitive incentive to increase personal outcomes from the negotiation. Or when a negotiator has a punitive capacity, as in international conflicts where some countries have bigger armies than others, such power preponderance may induce a tough stance to elicit concessions from the other, rather than making concessions oneself. Put differently, when power increases relative to one's partner, negotiators generally become reluctant to make and reciprocate concessions. When power is less than that of one's counterpart, the motivation to cooperate and concede increases. Especially when concessions are made on issues that are important to the low-power party, the likelihood of reaching integrative agreement is reduced.

Another factor influencing the balance between cooperative and competitive incentives is *time pressure*. Time pressure may emerge because the goods (e.g., fish or fruit) that are being negotiated may deteriorate, or because an external or self-imposed deadline is approaching (e.g., the market closes at 5 PM; divorce papers are being filed and take effect soon). Time pressure focuses parties on agreement and, in general, fosters concessions and cooperative exchange. Again, if time pressure fosters concessions on important issues, the likelihood of reaching integrative agreement is reduced.

When negotiators operate on behalf of a constituency, as when a small group of workers negotiates on behalf of a union, they need to consider their own (and perhaps their counterpart's) needs and desires, as well as those of their constituents. Research has shown, for example, that negotiators tend to comply with their constituents' desires—when the constituents take a competitive stance toward the other side, representatives negotiate more competitively than when their constituents are eager for an agreement. Interestingly, there is considerable evidence that when constituent goals and desires are unknown or unclear, negotiators tend to assume they should compete rather than cooperate. The mere fact that an individual

represents one or more others generally increases toughness and competitive behavior.

Dual Concern Theory

Bargaining strength, time pressure, and accountability to constituents all lead negotiators to focus on their own outcomes and resist making concessions. Other variables have been shown to influence the extent to which negotiators are mindful of the outcomes of their counterpart. For example, when negotiators are friends or spouses, they may be particularly concerned about their counterpart's outcomes, so they won't jeopardize their relationship. Or when negotiators expect to work together in the future, they are more motivated to search for an agreement that satisfies their counterpart. Dual Concern Theory, developed by Dean Pruitt and Jeffrey Rubin, summarizes these tendencies among negotiators. When concern for own outcomes is high (e.g., there is high power) and concern for other's outcomes is low (e.g., one does not expect to work together in the future), negotiators engage in tough, competitive behavior aimed at dominating the partner. They are reluctant to make concessions, and do not consider others' demands and needs. When concern for own outcomes is low (e.g., time pressure is high) and concern for others' outcomes is high (e.g., the other is a friend), negotiators engage in conciliatory behavior aimed at pleasing the partner. They are willing to make (unilateral) concessions, and cater to the others' demands and needs. When parties engage in mutual force—when each has high concern for own outcomes and low concern for their partner—the negotiation is likely to end in a mutually harmful stalemate, and integrative agreements are unlikely. Likewise, when parties engage in mutual yielding—when each has low concern for own outcomes and high concern for the partner's outcomes—the negotiation is likely to end in a quick, fifty-fifty compromise. Again, integrative agreements are unlikely. The theory predicts that integrative agreements come about when each party has a high concern for both own and other's outcomes. In this situation, negotiating parties resist making concessions because doing so hurts personal interests but they want to make concessions to help the other's interests.

This dilemma leads negotiators to search for creative solutions that integrate both own and other's interests optimally.

Bounded Rationality in Negotiation

Dual Concern Theory is all about motivation and not about the cognitive underpinnings of integrative negotiation. Cognition and information processing are, however, critically important in negotiation. Individuals cannot process all relevant information—they are bounded in their rationality because cognitive ability is limited, and not all relevant information is or can be made available. Also, negotiators may try to mislead and deceive each other, and thus, some of the available information is deliberately inaccurate and cannot be trusted. To deal with this cognitively taxing task, negotiators tend to rely on cognitive heuristics—mental shortcuts that help them make fast and satisfactory judgments and decisions. Thus, negotiators may act on the basis of stereotypes—union representatives may assume management representatives are reluctant to give raises, much as management representatives may assume that union representatives are unaware of macro-economic developments and increasing competition.

Max Bazerman and Maggie Neale developed their Behavioral Decision Approach, in which they discuss many of these cognitive shortcuts and how they affect the likelihood of integrative agreements. An example is the “fixed-pie” assumption—at the outset, negotiators tend to assume that what is important to them (e.g., juice, in the orange-sharing example) is equally important to the other party, and what is irrelevant to them (e.g., peel) is equally irrelevant to the other. Given the fixed-pie assumption, it makes no sense to search for an integrative agreement; all a negotiator can do is to try to get the biggest share of the pie (or orange). And this is indeed what has been found many times: Most negotiators, novices and experts alike, tend to begin with a fixed-pie assumption and search for victory or, when fairness concerns prevail, fifty-fifty compromises. Only when negotiators realize that their fixed-pie assumption is erroneous do they start searching for integrative agreements.

Levels of Information Processing

Recent studies have invoked the notion that negotiators may switch between more automatic information processing—in which case relying heavily on cognitive heuristics—and more systematic information processing. Under systematic information processing, the influence of cognitive heuristics attenuates and negotiators are more likely to reach integrative agreements. Negotiators engage in more systematic information processing when they have low rather than high power, when time pressures are mild rather than intense, and when they are held accountable. These and other factors thereby help negotiators achieve more mutually beneficial, integrative agreements. Taken together, the combination of high concern for own outcomes, high concern for others' outcomes, and a willingness to engage in deep and deliberate processing of information appears to be the optimal mix to arrive at mutually beneficial, integrative agreements.

NEIGHBOR RELATIONS

Once an important component of social life, relationships with neighbors may be decreasing in importance in the modern world because of people's increased mobility. However, relationships with neighbors can still be an important source of friendship and practical assistance. This

entry discusses the factors that facilitate interactions with neighbors and the benefits that may be gained from positive relations with neighbors.

Predictors of Interacting With Neighbors

A variety of factors predict how extensively people interact with their neighbors. The best predictor of how frequently people interact with their neighbors is residential stability—how long the individual has lived in the neighborhood and the average length of time that his or her neighbors have lived in the neighborhood. Investment in the neighborhood, primarily indexed by home ownership, also predicts more frequent interactions with neighbors. On average, rural residents interact more frequently with their neighbors than do urban residents. Older people, especially those who have retired, also interact more frequently than others with neighbors. People with higher incomes know more of their neighbors, but on average, visit them less frequently than do persons with lower incomes. It appears that more affluent people are less likely to invest time and effort in relationships with neighbors, perhaps because of the many options for social relationships that are open to them.

Close proximity to neighbors increases the probability of becoming acquainted, such as living next door in an apartment complex. Involvement with neighbors is higher if other family members also live in the neighborhood. Family members may introduce each other to their immediate neighbors, thus broadening each family's network of acquaintances. Fear of victimization is among the strongest deterrents to interacting with neighbors. Thus, neighborhoods with high levels of crime tend not to foster close relationships among neighbors. Neighbors may, however, be united by common concerns that they face by virtue of their shared environment, such as pollution, crime, poor school quality, and limited access to services and retail outlets (e.g., the absence of grocery stores in inner-city neighborhoods). Under certain circumstances, neighbors form strong bonds as a result of joint efforts to address neighborhood problems.

Benefits of Neighbor Interactions

Neighbors can be important sources of help in times of need. Practical support (for example,

babysitting, or a ride to the doctor's office) is often provided by neighbors. People who live in neighborhoods with a stronger sense of community tend to experience a greater feeling of belonging and report lower levels of loneliness and isolation than do those in neighborhoods without cohesion. Older adults who can rely on their neighbors report greater feelings of autonomy and well-being when factors such as limited mobility, deteriorating health, and financial constraints might otherwise lead to social isolation. In particular, older women living alone (often following the death of a spouse) come to rely on the neighborhood as an integral part of the social network, with a higher sense of belonging to the neighborhood associated with more social support, lower stress, and better physical and mental health. Importance of neighborhood social ties has been established for younger age groups as well. Studies on adolescents suggest that the neighborhood serves as the center of activity for many young people, and a neighborhood sense of community protects against feelings of loneliness even when accounting for connectedness with family and school.

People who live in low-income neighborhoods are more likely to experience depression than are people who live in more affluent neighborhoods; however, those with high social support from their neighbors are able to cope effectively, even in adverse neighborhoods. A famous study found that people who are involved in their community and have ties with others in their neighborhood and workplace actually live longer, even when the researchers accounted for how healthy the people were at the beginning of the study, and other health-related behaviors, such as smoking and drinking alcohol.

Influence of Neighbors on Behavior

Beyond the benefits of personal relationships with individual neighbors, research has shown that the kinds of people who live in the neighborhood may influence people's lives, even if they do not know these neighbors personally. One of the most consistent findings is that children perform better in school and go on to complete more education if there is a higher percentage of affluent and highly educated people in their neighborhood. Children

experience this educational boost regardless of the affluence or education level of their own families. Neighborhood residents can also influence the extent to which youth engage in delinquent behavior. When neighbors make an effort to know one another, monitor the behavior of each others' children, and report youth transgressions to parents or school authorities, neighborhood rates of delinquency are lower than when neighbors avoid becoming involved with one another. One study found that when neighborhood involvement improved over a 5-year period, parents in the neighborhood subsequently began to supervise their children more closely and to express more warmth toward them. In turn, children's behavior improved significantly. Neighborhood involvement of this type is more likely to develop in neighborhoods high in residential stability.

NEUROTICISM, EFFECTS ON RELATIONSHIPS

Whereas some people are calm and emotionally stable, others are extremely nervous and emotionally volatile. Most people fall somewhere between

these two extremes. This dimension of personality is captured by a characteristic called *neuroticism*. Many researchers who study relationships are interested in how neuroticism is associated with interpersonal functioning and with how it affects the stability and quality of romantic unions. This entry provides background on neuroticism and summarizes research linking this trait to relationships, particularly romantic relationships.

What Is Neuroticism?

The broad personality dimension of neuroticism captures individual differences in the tendency to experience negative emotions such as anxiety, anger, and sadness. Individuals who are relatively high in neuroticism are easily distressed. Neuroticism also involves a negative self-image and chronic patterns of thinking associated with distressing emotions. People relatively high on this dimension have a negative outlook on life, themselves, and the people in their social worlds.

Neuroticism is considered a fundamental personality trait because it appears in nearly all models psychologists use to classify personality characteristics. For example, many psychologists currently argue that five broad domains can be used to organize the most important personality characteristics. These so-called Big Five are Neuroticism, Extraversion, Agreeableness, Conscientiousness, and Openness to Experience. Likewise, neuroticism is one of the three major traits in the personality model developed by Hans J. Eysenck, and traits that are synonymous with neuroticism appear in other popular models of personality created by Raymond Cattell and Auke Tellegen. In short, neuroticism is one of the most discussed and studied adult personality traits in psychology.

Neuroticism is a fairly stable individual characteristic by adulthood. Individuals who are high (or low) in neuroticism in their 30s tend to be high (or low) in neuroticism in their 40s. This does not mean that some people do not change in their levels of neuroticism, nor that individuals do not become more emotionally stable as they mature; it simply means that there is a good deal of consistency in this trait for most adults. In other words, if a person is high in neuroticism at one point in

time, then it is likely she or he will be high in neuroticism in the future.

Aspects of neuroticism are evident in even very young children. Some infants and young children are easily upset, whereas others are calmer and harder to distress. In both young children and adults, it appears that the same neurobiological system underlies the general tendency to become emotionally distressed. This system is called the *behavioral inhibition system*, or the *behavioral avoidance system*, and appears to govern one's overall sensitivity to a potentially punishing stimuli. Individuals with a strong behavioral inhibition system are more sensitive to threat and therefore are more likely to experience anxiety and other negative emotions.

Researchers are beginning to map the neurological pathways, brain structures, and genes that underlie neuroticism. Indeed, evidence from twin studies indicates that individual differences in neuroticism are partially genetic in origin. For example, identical twins are much more similar in their levels of neuroticism than are fraternal twins. All in all, neuroticism is an important personality trait that has a significant biological basis.

Neuroticism and Romantic Relationships

Given that neuroticism appears to be a fundamental individual difference, there is considerable interest in understanding how this personality characteristic is associated with relationships, especially romantic relationships. Studies have examined the association between neuroticism and marital quality for more than 70 years. For instance, Louis Terman and his associates published one of the first psychological studies of marriage in the 1930s, and they used terms such as *emotionally stable* to describe men and women who were happily married. Since that time, dozens of studies have examined the association between neuroticism and marital outcomes. The sheer number of studies illustrates the interest in this topic, but can make it difficult, even overwhelming, to summarize the research.

Fortunately, researchers can use a statistical technique called *meta-analysis* to summarize the results of a large number of studies. Meta-analytic techniques essentially average information across

the available studies and make it easier to gain a broad perspective on a research topic. These techniques provide a systematic and quantitative summary of findings across studies. Benjamin Karney and Thomas Bradbury conducted a meta-analysis in 1995 and found that neuroticism was negatively associated with marital satisfaction and marital stability. As scores on neuroticism increased, both marital satisfaction and marital stability decreased. In 2004, Daniel Heller and his associates conducted a more recent meta-analysis based on 40 studies and found that neuroticism was negatively correlated with marital satisfaction. Heller and his colleagues noted that the association between neuroticism and marital satisfaction was among the largest of all of the Big Five traits. Thus, there is consistent evidence that neuroticism is negatively associated with marital satisfaction and stability.

Recent research has tried to better understand the nature of the association between neuroticism and relationship satisfaction. One promising approach is to make a distinction between the *actor* and *partner* effects of personality traits. Actor effects occur when an individual's level on a trait affects that individual's level on a relationship attribute: for example, the degree to which a husband's level of neuroticism is associated with his own level of marital satisfaction. Partner effects occur when an individual's level on a trait affects a relationship partner's level on a relationship attribute; for example, the degree to which a husband's level of neuroticism is associated with his wife's level of marital satisfaction. Both kinds of effects are potentially important; however, the existence of partner effects provides good evidence that personality traits are associated with interpersonal processes, dynamics that are particularly interesting to relationship researchers.

The estimation of actor and partner effects requires the application of a specialized statistical procedure that can only be applied to studies that assess both members of a romantic relationship (e.g., wives and husbands). Relatively few studies have specifically examined actor and partner effects for neuroticism compared with the number of studies that have simply documented associations between neuroticism and relationship outcomes. Nonetheless, several studies have indicated that neuroticism has both actor and partner effects when predicting measures of relationship

satisfaction. Emerging evidence indicates that neuroticism has interpersonal effects insofar as partners of individuals who are higher in neuroticism appear to be less satisfied with their relationship when compared with partners of individuals who are lower in neuroticism.

The presence of both actor and partner effects for neuroticism raises a fundamental question: Why is neuroticism linked with relationship quality? Researchers are just beginning to answer questions concerning the precise mechanisms linking personality traits to relationships. John Caughlin and his associates found that measures of neuroticism were associated with interpersonal negativity: Individuals higher in neuroticism were more hostile and critical of their romantic partners. Similar findings have been reported by other researchers who found that neuroticism was related to interactions involving hostility and interpersonal negativity. Thus, it appears that one reason why neuroticism has partner effects for predicting relationship dissatisfaction is that more neurotic individuals seem to engage in more negative interactions with romantic partners when compared with less neurotic individuals.

In sum, neuroticism is linked with lower relationship satisfaction and more negative interpersonal behaviors within relationships. Given these findings, it is not surprising that several studies have linked neuroticism to an increased risk of divorce. Moreover, according to a recent meta-analysis by Brent Roberts and his colleagues, the risk for divorce associated with neuroticism appeared to be larger than the risk for divorce associated with low socioeconomic status.

Neuroticism and Other Kinds of Relationships

In comparison with the fairly large literature demonstrating associations between neuroticism and aspects of romantic relationships, less evidence links this trait with other relationships. One important relationship involves the bond between parents and children. Grazyna Kochanska and her associates found that mothers who scored high on neuroticism were observed to have interactions with their infants that were less positive than were mothers who scored low on neuroticism. Similarly, researchers in Finland found that neuroticism was

linked with less parental nurturance. This work is more or less consistent with earlier work that studied how depressed mothers interacted with their children. Some evidence links neuroticism to difficulties in parent-child relationships.

Research relating neuroticism to adult relationships besides romantic dyads and parent-child relationships is relatively scarce. One collection of studies found that neuroticism in men (but not women) was linked with diminished social status in groups such as fraternities and college students living in the same dormitory. The authors suggested that high scores on neuroticism violated gender norms for men, which may account for diminished social status. Another study found links between neuroticism and conflict in friendships, a result that appears consistent with work on romantic relationships. It is likely that research linking neuroticism to important relationships beyond romantic unions will accumulate in the coming years.

Future Directions

Although researchers know a considerable amount about neuroticism and relationships, there are many unanswered questions and areas for further study. Three issues seem to stand out. First, additional work will continue to specify the mechanisms that link neuroticism to experiences in relationships. Second, future work will move to integrate studies of broad traits like neuroticism with other individual differences that have been implicated with relationships such as attachment styles, rejection sensitivity, and self-esteem. This avenue promises to help researchers develop a richer and more comprehensive understanding of the links between individual characteristics and relationships. Last, there will be continued attention to the biological underpinnings of neuroticism. Indeed, a major goal for further research is to develop a precise understanding of how biological, psychological, and contextual factors work together to shape human relationships.

NEWLYWEDS

Newlyweds are recently married couples, and newlywed research generally focuses on the first 2 to 4 years of marriage. This early stage of marriage is one of transition, requiring adjustment to being a committed couple, negotiation of new roles, and development of an intimate foundation for the future. About 50 percent of first marriages in the United States are expected to end in divorce, and the divorce rate peaks within the first 4 to 5 years of marriage. Thus, young marriages are at risk for distress and divorce within the first 5 years, and the seeds for later negative outcomes appear early in the newlywed stage.

This entry describes characteristics of newlyweds, common problems and challenges that newlyweds face, and factors that predict changes in satisfaction. Although an emerging literature focuses on marriage in non-Western countries, this entry focuses on couples from North America. In some U.S. states, Canada, and many other countries, marriage between same-sex partners is legally sanctioned, but almost all research on newlyweds is concerned with heterosexual unions. Thus, this entry focuses on heterosexual newlywed couples.

Characteristics of Newlywed Couples

Marriage rates have been steadily declining since the early 1970s, and the rate of cohabitation as a first conjugal union has been increasing. Despite declines in marriage rates, more than half of all men and women are married, and about 80 to 90 percent of people are expected to marry at some point in their lives. Newlywed couples are engaged for an average of 9 months and over half cohabit before marriage. About one third of newlywed couples receive premarital counseling, which is overwhelmingly church-based. Marriage is common in all cultures and ethnic groups in the United States, and marriage rates are similar for Caucasian, Hispanic, and Asians. African Americans are less likely to marry, and do so at an older age than do couples from other racial groups. Overall, couples are delaying the decision to marry and the average age at marriage has steadily increased; the average age at marriage in the United States is 25.5 years for women and 27 years for men.

Marital Satisfaction in Newlyweds

Newlyweds are almost universally happy in their relationship and experience high levels of love and commitment that are relatively stable during the first year of marriage. However, satisfaction and affection then steadily decline for most, although not all, couples. Much of the research on newlywed marriage focuses on understanding predictors of the erosion of loving feelings, which can be grouped into four classes of variables: static historical and sociodemographic factors, enduring personal dispositions, external stresses and strains, and dyadic interaction processes.

Historical and Sociodemographic Predictors

Relatively static factors such as history of parental divorce, difficult family-of-origin experiences, marrying at a younger age, a shorter dating period, and cohabiting before marriage are associated with negative marital outcomes. Some researchers argue that cohabitation is associated with less religiosity and more permissive attitudes, which are likely to be associated with seeing divorce as a viable option, thus, it is not cohabitation per se that leads to less stable marriages. Others have noted that the timing of cohabitation and level of commitment when cohabitation decisions are made matters. Couples who cohabit after becoming engaged do not seem to experience the same increase in risk for divorce as do couples who live together before becoming engaged.

Enduring Personal Characteristics

Individuals enter relationships with certain enduring dispositions, or personality traits that affect how they manage their relationships. For example, relative to five major personality factors (i.e., the popular Big Five model), newlyweds who are prone to experiencing negative emotions (i.e., neuroticism), less agreeable, less extraverted, less conscientious, and less open, tend to have less satisfying relationships. Spouses who are more prone to negative emotions (i.e., neuroticism) are also more likely to experience steeper declines in their satisfaction over time. Attachment insecurity (i.e., anxiety about availability of their partner or avoidance of intimacy and dependence) is also associated with less satisfying marriages, and with steeper declines in relationship satisfaction.

How spouses think about and process information about their relationship also predicts changes in satisfaction. For example, newlyweds who hold idealized (but not unrealistic) views about their relationship or about each other are happier and more supportive toward each other during the first few years of marriage. Spouses who generate benevolent explanations (i.e., attributions) for partners' negative behavior are also more satisfied. Spouses who reconstruct memories of their relationship and who believe the relationship has improved, even when it has not, also experience less decline in satisfaction.

External Stresses and Strains

External stresses and strains—events or circumstances external to the dyad that pose some difficulty or challenge—can also negatively affect newlywed marriage. Stress may arise from chronic ongoing difficulties such as difficult family relationships, or acute stressors or life events such as job loss or family illness. Chronic or acute stress makes it difficult to successfully manage the challenges of newlywed marriage. Stress may drain energy and divert time and resources away from maintaining the newlywed relationship. It is more difficult for couples to resolve conflict well, to be supportive, and to forgive transgressions when they are also dealing with other substantial problems. Stress arising in relationships with friends and family can be potent risk factors for marital distress; however, if functioning well, and if there is overlap in spouses' social networks, family relationships and friendships may support the developing newlywed marriage.

Another important life event that may create stress is the transition to parenthood. Although the transition to first parenthood may happen at any stage of marriage, newlyweds who are happier in their relationship are particularly likely to choose to have children earlier in their marriage (i.e., within the first few years of marriage, but not before marriage). Becoming parents results in steeper declines in marital satisfaction compared with nonparent newlyweds, but these declines are offset to the degree that couples began their marriages feeling more satisfied and they planned to become parents.

Dyadic Interaction Processes

Dynamic processes, such how newlyweds interact with each other, how they resolve conflict, and how they support each other are established early in marriage and predict stability and changes in satisfaction, regardless of initial levels of satisfaction.

Affection

Following their wedding, newlyweds begin spending less time together in recreational activities, become less affectionate (e.g., kissing and hugging), discuss intimate matters less frequently, and do fewer nice things for each other. The

erosion of positive behaviors and the establishment of negative interaction patterns set the stage for later dissatisfaction and dissolution. In a longitudinal study of marriage, Ted Huston and his colleagues found that patterns of behavior established as newlyweds presaged marital outcomes 13 years later. Spouses who experienced less loving feelings, who showed less affection, and who saw their partners as unresponsive in the first 2 years of marriage were later more likely to divorce or to be unhappily married. Thus, early differences as newlyweds distinguish those couples who go on to have successful and stable marriages in the long term and those who do not.

Conflict

Early in marriage, couples report the most significant sources of conflict are managing tempers and moods, financial concerns, dealing with in-laws, and communication. These areas remain problematic at least through the first few years of marriage, but conflicts around in-laws become less frequent and severe as the marriage progresses, and other issues such as managing household chores and sexual problems become more prominent. These temporal patterns suggest that some issues, such as dealing with in-laws, are generally resolved or become less salient, but that other issues, such as dealing with bad moods and communicating effectively, are likely to persist.

The way newlyweds cope with marital conflict is more important for relationship satisfaction than what they argue about. Researchers have investigated newlyweds' communication skills by bringing them into the laboratory to record and code their behavior and emotions displayed while discussing a conflict. The interaction between what couples say and their emotion predicts trajectories of satisfaction. When spouses are relatively more negative (e.g., devaluing the partner, justifying, denying responsibility, demanding, and invalidating) and less positive (e.g., being open and direct about needs and attitudes, compromising, paraphrasing, asking interested questions, and showing understanding) during problem-solving discussions in the lab, experience declines in satisfaction only when their conversations also lack positive emotions (e.g., interest, affection, humor). Thus, poor conflict resolution skills are not uniformly problematic for relationships and only lead

to faster declines in satisfaction when humor, interest, and affection are also uncommon in couples' conflict discussions.

Aggression

About half of all newlyweds report some physically aggressive behavior within the past year. Physical aggression is usually reciprocal, minor (e.g., shoving and slapping), and infrequent (e.g., once or twice in a year). Low levels of physical aggression remain relatively stable over time, generally occur during conflict, and are more likely when newlyweds are experiencing high levels of stress. More severe levels of physical aggression decline fairly quickly over the first few years of marriage.

Mutual aggression is common in newlywed couples but it is detrimental to the developing relationship and predicts divorce 4 years later. Physical aggression is more related to dissolution of marriage, whereas negative behaviors such as contempt and criticism are more related to couples staying unhappily married.

Social Support

Early research predicting marital change from couples' interactions was based on the idea that resolving conflict well is the cornerstone of a stable and satisfying marriage. Although the way newlyweds resolve problems is undoubtedly important, low-to-moderate associations between early conflict-related behavior and later marital success indicates that other important marital domains contribute to stability and satisfaction. One area that has garnered increasing attention is how newlyweds seek and provide support. Newlyweds' support behaviors are unrelated to initial levels of marital satisfaction, but predict marital change over time. Open and direct expressions of concerns and responding to partner's concerns with understanding, validation, and interest are related to less decline in relationship satisfaction during the first 2 years of marriage, independently of how newlyweds resolve conflict.

Future Directions

Two important areas of future research are exploring differences in newlywed marriage for same-sex couples, for couples in nondominant cultural and

racial groups, or for interracial couples. Relationships of same-sex couples do not differ in many important ways from those of heterosexual couples, but critical tasks facing same-sex couples, such as family acceptance and coming out, could affect marital adjustment. There is a small literature on cultural differences in marriage, but little psychological research on cultural differences in the transition to marriage and predictors of marital change for newlyweds. Early predictors of distress and instability are being established, but marital researchers know relatively little about how these processes unfold over time and how changes affect the developing relationship. Researchers are studying newlyweds who are at relatively similar stages in their relationships (e.g., beginning first marriages, without children, and at similar ages) and following them over time. Repeated assessments of relationship factors using multiple methods—interview, self-report, physiological data, and observational data—will allow for a richer picture of how relationships develop in the early years. Understanding the development of newlywed marriage will be crucial to helping couples develop effective ways of relating to each other and maintaining positive behaviors that maximize chances of relationship success.

NONVERBAL COMMUNICATION, STATUS DIFFERENCES

Many of our social interactions can be described along a dominance, power, status, or other dimensions suggestive of higher versus lower position. Our work environment is characterized by hierarchies with people in different statuses. But also in intimate relationships, power or status differences between partners (e.g., differences in earning power, differences in dominant interpersonal behavior) are not rare. Even in unstructured groups of people with initially equal status, status hierarchies form readily. Some hierarchies are quite pronounced, such as in the military, and others are quite flat, such as in many nonprofit organizations. Some hierarchies are explicit such as the differences in executive decision-making power between a CEO and an office clerk, and others are more implicit, such as the differences in influence on the decision to watch a particular movie among a group of friends. What is common to all hierarchies is that there is a dominance, power, or status difference among group members. Though there are differences between these concepts, for convenience this entry uses the term *status* to describe all these aspects of vertical position. *Status* has been defined in many different ways. It can be defined as having or striving for privileged access

to restricted resources (e.g., money, time) or as having or striving for influence over others. A hierarchy is defined as the status difference among two or more individuals. It has to be noted that a high-status position per se cannot exist alone because it necessitates somebody with low status.

This entry discusses whether and how people are able to infer the status of their social interaction partners, how people use nonverbal behavior to make status inferences, and which nonverbal behaviors people in actual high-status or low-status positions typically express.

Nonverbal Behavior: Definition and Importance

Nonverbal behavior encompasses communication without words. The distinction between verbal and nonverbal communication is not always easy to make. In verbal communication, each word has a specific meaning and people can be held accountable for what they say. Most nonverbal communication, however, is ambiguous with respect to meaning. Situational aspects such as the relationship between the conversation partners or the topic they are talking about can greatly influence the meaning of specific nonverbal cues. Some of the most commonly investigated nonverbal behaviors are facial expressions, eye gaze, body movements (such as gestures), posture, touching behavior, and vocal behavior, such as tone of voice, speech modulation, or speech duration, just to give a few examples.

Whether verbal or nonverbal behavior matters more as a source of information depends on the situation. When a verbal message is unclear or ambiguous, nonverbal cues play a particularly important role. Nonverbal cues become especially salient and important when they contradict the words being spoken or when people doubt the honesty of a verbal communication. Consistent with this, lie detection is more successful when people rely on nonverbal rather than verbal cues. Nonverbal cues are also important in the expression of emotions. In addition to expressing emotions, however, nonverbal cues have many other functions—for example, to signal attention, reflect physical states such as pain, coordinate turn-taking in conversations, reveal personality characteristics,

and signal interpersonal orientations such as friendliness or dominance.

Expression and Perception of Status Through Nonverbal Behavior

Egon Brunswik's lens model has shown itself to be a useful framework for studying expression and perception of interpersonal characteristics such as status. In a lens model perspective, a target's behavior forms the basis of perceivers' judgments about the target's status. If, for instance, a high-status person talks more than a low-status person, speaking time can be considered an indicator of actual status. A perceiver observes the exhibited behavior, for instance, that one person talks more than another, and infers that the person who talks more is higher in status than the person who talks less. Thus, speaking time is used as a cue of elevated perceived status. If perceived status corresponds to actual status, the assessment is called accurate. Within the lens model, one can ascertain which cues are believed to be associated with status (relation between specific cues and perceived status) and which cues are actually associated with status (relation between specific cues and actual status).

Although most of the cues studied within a lens model approach are either verbal or nonverbal behaviors, other cues can work as identifiers of people's status. Appearance can be another cue people use to assess others' status. For instance, high-status people are perceived as taller than low-status people. In the same vein, formal dress is usually associated with expressed and perceived high status.

Expressing Status Through Nonverbal Behavior

Studies looking at nonverbal behavior and actual (as opposed to perceived) status have defined status in terms of personality, structural status (e.g., rank in an organization, socioeconomic dominance, emergent leadership within a group), or assigned status (e.g., in a psychology experiment). In meta-analyses on the expression of status in nonverbal behavior, only a few behaviors have been related to actual status. High-status people show more bodily openness (arms and legs), interact

at closer interpersonal distances, have louder voices, interrupt others more often, and talk more than low-status people do. Studies also show that high-status people have higher visual dominance—defined as the ratio of percentage of looking while speaking to percentage of looking while listening—than do low-status people.

Surprisingly, only a few nonverbal behaviors actually indicate high status on average across studies because people often think that there are many clear indicators of high and low status. Indeed, people use many more nonverbal cues when they try to infer another person's status, as discussed in the following section.

Perceiving Status Through Nonverbal Behavior

Varied research paradigms have been used to study the perception of status. For instance, target stimuli have been schematic faces, photographs of posed facial cues (e.g., smiling versus nonsmiling or lowered versus raised eyebrows), candid photographs of naturalistic interactions, short video clips of people interacting, or face-to-face interactions.

Nonverbal behaviors that are used systematically by observers to assess the status of target individuals have also been investigated in meta-analyses. Perceivers rate targets higher in status if they show more gazing, lowered eyebrows, a more expressive face, more nodding, less self-touch, more touching others, more gestures, more bodily openness, more erect or tense posture, more body or leg shifts, smaller interpersonal distance, a more variable voice, a louder voice, more interruptions, less pausing, a faster speech rate, a lower voice pitch, more vocal relaxation, and more talking. Also, observers use the visual dominance ratio defined earlier as an indicator of high status.

Many of these status–nonverbal behavior relations are influenced by other variables such as, for instance, gender. More specifically, some nonverbal behaviors show parallel differences in gender and in status (e.g., high-status people tend to talk more, men more than women can be found in high-status positions, and men tend to talk more than women, at least in opposite-gender interactions). Nevertheless, this parallelism does not necessarily mean that the status differences in

nonverbal behavior can be explained by underlying gender differences. Furthermore, for a number of behaviors, this parallelism was lacking. More studies going beyond this parallelism and showing causal relations are needed to clarify this question.

That people use a long list of nonverbal behaviors to judge status reflects the existence of clear stereotypes about the nonverbal behavior of high-status (and low-status) individuals. Fewer nonverbal behaviors are characteristic of people with an actual high or low status than there are nonverbal behaviors perceived as indicators of status. Thus, perceivers seem to use nonverbal cues that do not necessarily indicate the status dimension. People harbor expectations—or stereotypes—about which nonverbal cues are related to high or low status. These expectations are not always correct. If this is the case, are people still accurate in judging another person's status?

Accurately Assessing Status

Whether people are able to tell who is the boss and who is not in a social gathering seems important because it can bring about distinctive advantages. For instance, it can improve effective communication (e.g., directly addressing a request to the person who is able to make a decision), prevent social faux pas (e.g., inappropriately addressing a high-status person), or help a person to maneuver in status hierarchies because knowing who has high and who has low status helps one to plan strategic moves.

Although the findings are not unequivocal, it seems that status can be assessed at better than chance level. For instance, better than chance accuracy was found when perceivers judged which of two target people in a photograph was the other's boss. Other research has found that people could assess the status of university employees based on photographs and observers were able to assess targets' assertiveness in videotaped interactions at better than chance level.

So how can we explain that even if perceivers use many invalid nonverbal cues to assess a target's status, they are still accurate in their assessment? First, the potential nonverbal cues targets emit are endless, so in a given study, the investigators might

not have measured genuinely diagnostic cues. To remedy this drawback, future research should measure a more comprehensive list of behaviors, including verbal and nonverbal behaviors and appearance cues. Second, not all cues contribute equally to accuracy. If, for instance, speaking time is more diagnostic for expressed dominance than is gazing, using speaking time correctly and using gazing incorrectly might still result in considerable accuracy. Third, the correct assessment might be based not on single cues but on combinations of different cues. Accuracy would then be a more “Gestalt”-like impression formation process. There is indeed some evidence suggesting that the pattern of how the different nonverbal and appearance cues used to assess status corresponded to the pattern of how status was expressed in these nonverbal and appearance cues. In other words, there is a positive correlation between beliefs and actual status effects. Thus, accuracy is possible because the way people use the array of nonverbal cues to judge status (i.e., how they weight the relevance of each cue to be an indicator of status) corresponds largely to how much each nonverbal cue is a valid indicator of actual status.

Conclusion

The status dimension is inherent to many different social encounters and thus affects how people interact with each other verbally and nonverbally. However, the fact alone of possessing high (or low) status might only marginally explain the exhibited nonverbal behavior. For instance, a high-status leader can adopt a directive leadership style and show behaviors such as frequent interruptions, a loud voice, and averting gaze while the other is speaking. By contrast, a high-status leader can equally well adopt a participative leadership style and show behaviors such as infrequent interruptions, a soft voice, and looking at the other while he or she speaks. Thus, personality factors or the specific motivation or emotion experienced during an interaction can affect the nonverbal behavior on top of, or even more so, than status per se.

NONVERBAL INVOLVEMENT

Nonverbal involvement refers to the behavioral immediacy between people in social settings. Increased nonverbal involvement is a cumulative product of several behaviors, including closer distance, higher levels of gaze, touch, forward lean, more direct body orientation, and greater expressiveness in facial, gestural, and vocal channels. In general, higher levels of nonverbal involvement signal more intense interactions. High involvement may be positive, as in the embrace of lovers, or negative, as in the brawling of enemies. Because nonverbal communication is typically more important in face-to-face interactions than is verbal communication, nonverbal involvement plays a critical role in the formation and maintenance of

relationships. This entry specifically examines the determinants, functions, and dynamics of nonverbal involvement.

Determinants

A variety of factors combine to shape our interactions and, more specifically, our patterns of nonverbal involvement with others. The first and most basic factor is *biology*. During evolution, patterns of high involvement with mates, offspring, and friends were selected because they promoted reproduction and survival. Closer contact and visual attention to others around us also provide opportunities for social support and adaptive information about our surrounding environments. Next, *cultural norms* prescribe specific patterns of behavior that facilitate order and predictability consistent with societal values. For example, in some Asian, collectivistic cultures, individuals tend to be less expressive in public settings than are individuals in more Western, individualistic societies. Third, *gender differences* in nonverbal involvement are the product of both biology and culture. That is, some behavioral differences between males and females are the result of biological hardwiring, but societal norms can also enhance or diminish the expression of those differences. For example, evolution facilitated women's ability to read the nonverbal behavior of others, but the social norms in many societies also promoted greater sensitivity and caring for women than for men. Next, individual differences in *personality* affect stable preferences for nonverbal involvement in interactions. For example, anxious and introverted individuals usually maintain greater interpersonal distances, lower levels of gaze, and less expressiveness in interactions than do nonanxious and extraverted individuals. In effect, biology, culture, gender, and personality constitute the "baggage" that both precipitate and constrain the practical range of nonverbal involvement in specific social settings.

Nevertheless, behavioral involvement is also affected by the physical design of social environments, the norms in the setting, the particular goals of individuals, and the characteristics of interaction partners. This latter set of situational factors introduces considerable variability in the

way that the same people behave across different settings. For example, the "fanny pats" by many masculine sports heroes following a great play are not likely to be seen with the same people after a successful business meeting. The next section discusses the functions of nonverbal involvement, that is, the utility of nonverbal patterns in the give-and-take of interaction in all types of relationships.

Functions

Similar patterns of nonverbal behavior can serve different functions in different situations. That is, the meaning and impact of a particular nonverbal pattern depends on the determinants and situational influences mentioned earlier. For example, at a funeral, a person might console an opposite-sex acquaintance with a hug, but the same hug might be inappropriate in the workplace. Conversely, a particular function may be manifested with various combinations of nonverbal behavior. For example, comparable levels of liking may be expressed with a moderately close, directly facing approach, and sustained gaze, or by a closer adjacent approach, touch, and a much lower level of gaze. Despite the ambiguity of isolated nonverbal behaviors across situations, there are regularities in the functions of the larger, coordinated behavior patterns. A given pattern of involvement also can simultaneously serve multiple functions.

A first and basic function of nonverbal involvement is that of *providing information* to our partners. Before a word is spoken, intentions are nonverbally communicated to our partners. Although people can manage their behavior in trying to cover their intentions, we can usually tell if an impending interaction is going to be positive or negative from expressions, posture, and movement of a partner. Furthermore, during interaction, patterns of nonverbal involvement qualify the meaning of verbal messages. As a speaker's expression, gaze, and gestures change, so does the impact of the specific comments. For example, if a speaker's nonverbal behavior is inconsistent with the verbal content, the listener might doubt the speaker's candor. Sometimes individuals' own behavior informs them about their feelings toward a partner. That is,

people can “discover” their feelings toward a partner *after* reflecting on their behavior toward the person. Nonverbal involvement between partners also provides relationship information to others. As two people walk hand-in-hand, it is clear that they are a couple.

A second function of nonverbal involvement is *regulating interaction*. Nonverbal behavior is critical in facilitating and inhibiting contact with others. From encounters as brief and mundane as walking past a stranger on the sidewalk to greeting a loved one, specific nonverbal patterns promote or discourage additional interaction. The initiation of gaze is a critical step in facilitating an interaction. If a glance toward the other is combined with a more direct body orientation and a smile, the likelihood of the partner reciprocating attention increases. In contrast, avoiding gaze, turning away, and maintaining a neutral expression inhibit contact. Nonverbal behavior even helps regulate the verbal side of interactions. For example, listeners typically look more at speakers than speakers do at listeners because listeners have to monitor speakers' expressions to comprehend the full meaning of the message.

A particularly important function of nonverbal involvement in relationships is *expressing intimacy*. A close approach, smile, touch, and gaze are common elements in the expression of liking and love and often have a greater impact than verbal sentiments do. This may be partially because of the assumption that nonverbal behaviors are more difficult to control than are words. Nevertheless, nonverbal involvement, like verbal intimacy, may be deliberately managed to create a particular impression. For example, a subordinate might smile excessively to “kiss up” to an intensely disliked boss. In general, the closer the relationship, the more comfortable partners are with higher levels of nonverbal involvement.

As relationships develop over time, rapport increases between partners and is manifested behaviorally in three relatively distinct components. First, mutual attention, in the form of increased gaze and a more direct orientation, reflects concern and investment in a partner. Second, positivity, typically shown in increased gaze, touch, and smiling, is an expression of the strong affective attachment between partners. Finally, coordination is displayed in the behavioral

synchrony between partners and the tendency to match or mimic a partner's movements and posture. In romantic relationships, positivity may be high early in the relationship and decline gradually over time. In contrast, coordination typically increases over time, with long-term couples able to anticipate a partner's behavior. Thus, their interactions are smoother and more efficient as they more or less automatically engage in similar, synchronous postures and movements. The changing course of positivity and coordination over time may be a reflection of the change from passionate love early in a relationship to companionate love later in a relationship.

Behavioral involvement may also be applied in *exercising influence*. That is, across all types of relationships, increasing or decreasing involvement can serve in subtly manipulating the partner toward a specific consequence. A close approach, touch, and gaze can increase compliance to a simple request. More powerful and higher-status individuals typically have the prerogative of initiating high involvement toward a less powerful person. For example, a manager's close approach, gaze, and firm grasp of the subordinate's shoulder while giving an assignment is more intense than simply stating the same instructions from across the room.

Another means of exercising influence is providing feedback and reinforcement to others with increased involvement. A combination of a glance, smile, and touch may often be more effective than verbal reinforcement, just as a scowl and active avoidance may be more effective than negative verbal feedback. Nevertheless, in recent years, concerns about teacher abuse in schools and sexual harassment in the workplace have led to prohibition against touch in some settings. Although the goal of protecting vulnerable individuals is laudable, it may come at the expense of the positive benefits of benign, supportive touch in interactions. Even in our everyday interactions with close friends and family members, a gentle touch and a smile can be initiated to manipulate loved ones. Sometimes it is not the intensity of involvement, such as a touch, but rather, its form that is influential. Specifically, one person's influence may increase when that person copies or mimics the postures and movements of a partner.

A final function is that of *managing impressions*. Sometimes people use their nonverbal behavior

strategically to create particular identities or images. Thus, an individual's behavior is not primarily an affective response to a partner but, rather, a display intended to promote a particular impression to observers. For example, at a party, two individuals might hold hands or wrap an arm around the partner to signal that they are a couple. These displays can be mutual and collaborative or primarily initiated by one member of a pair. In the latter case, an arm around the partner may be a signal that this person is already "taken." Sometimes these behavioral presentations are not only deliberate, but also deceptive. A feuding couple, on the verge of divorce, might hold hands and smile at each other at a family gathering to present the façade of a happy marriage. Thus, they collaborate in the display, but both parties know that it is deceptive. A similar circumstance may be seen with deliberate minimal involvement between romantic partners in social settings. Lovers might try to cover their office romance by literally keeping their distance from each other and minimizing gaze when others are present. These deceptive presentations are clear examples of the occasional and meaningful inconsistency between interpersonal behavior and interpersonal affect.

Thus, nonverbal involvement serves a variety of functions in all types of relationships. The give-and-take at the nonverbal level is, however, shaped by the determinants and situational constraints discussed earlier. Nevertheless, there is some regularity in the particular course of nonverbal exchange over time in interactions. The next section examines these dynamic changes.

Dynamic Processes

Although partners' goals, social norms, and even environmental factors influence the course of interactions, there is typically pressure for stability and predictability in our contacts with others. The most common pattern of exchange in interactions among acquaintances, friends, and loved ones may be described as *reciprocation*, that is, the involvement initiated by one person is matched or reciprocated by the partner. This kind of adjustment may be reactive in that the second person responds to the first person's initial behavior with a similar change in involvement. For example, the first person might

lean forward and smile (increased involvement) and the partner responds with increased gaze and a friendly touch. Alternatively, both parties may react simultaneously with scripted exchanges, such as greetings. Simultaneity of behavior and mimicry, another form of reciprocation, are more likely in long-standing relationships than in newer ones. Although reciprocation of increased involvement is facilitated by positive affect toward the partner, such patterns may also be independent of affect and manipulative in intent.

A contrasting pattern of nonverbal exchange may be described as *compensation*. This pattern is more likely when one person is uncomfortable with the partner's involvement level and compensates for it by moving in the opposite direction. For example, a too-close approach by a stranger might result in a person decreasing involvement by turning away and avoiding gaze. Conversely, if a good friend is less involved than usual, the partner might increase involvement by approaching closer, touching, and initiating gaze. In both cases, an inappropriate or uncomfortable level of involvement precipitates a compensatory adjustment toward a more comfortable level of involvement. Again, such adjustments may be more than a simple response to negative affect, that is, they may be strategic reactions to influence the partner. Over time, both patterns promote stability and facilitate comfortable interactions with others. To the extent that these dynamic changes are successful in creating a relatively stable exchange for both partners, the interaction will tend to run its normal course. If they are not successful, the instability is likely to lead to terminating the interaction early.

NORMS ABOUT RELATIONSHIPS

Social norms are rules that both guide and constrain behaviors in social interactions or relationships. Acting as guides, social norms are theorized to be powerful influences on behavior. Some social norms guide behavior across many different interpersonal relationships, with other norms being unique to specific relationships (e.g., marital). Researchers theorize that several types of social norms influence behavior in different ways. This entry describes three common types—descriptive, injunctive, and subjective—and considers how these types help us understand how social norms influence interpersonal behavior.

Descriptive Norms

Descriptive norms provide guidance to what “most” people are doing. It is the norm of what “is” being done by others or what is “normal.” These norms are influential because they provide a guide to what is useful or normative behavior in a situation. For example, if a student is aware that most of her high school peers are dating, this knowledge can act as a descriptive norm for behavior influencing the student’s own wish to date. Descriptive norms do not always lead to positive behaviors. Among friends, risky sexual behavior may be common and a descriptive norm, although the behavior itself is unhealthy.

Injunctive Norms

Injunctive norms refer to what behavior would be approved or disapproved of, or the norm of what

“should” be done. For injunctive norms, the motivation to follow them is to avoid disapproval or gain approval for performing the “right” behavior. There are many examples of interpersonal injunctive norms, for example, a person’s parents might disapprove of premarital sexual behavior and cohabitation. Breaking these norms can lead to disapproval from others, whereas meeting the norm can lead to approval.

Subjective Norms

Like injunctive norms, subjective norms are based on a perception of whether important others would approve or disapprove of a behavior. However, subjective norms are composed of two constructs: normative beliefs and motivation to comply. Normative beliefs are the awareness of whether a particular person would approve or disapprove of a behavior. Motivation to comply refers to how willing one is to comply with the source of the normative belief. If a person is not motivated to comply with a source of normative beliefs, then those beliefs will not be influential, but if motivation to comply is high, those beliefs will be influential. Within interpersonal relationships, subjective norms should influence the behaviors that are performed within the relationship. For example, one study has shown that people in a romantic relationship who received supportive subjective norms from friends and family for remaining in the relationship were more likely to stay in the relationship over time.

Each of these three types of social norms can motivate interpersonal behavior, although they do so in different ways. Before a social norm can motivate behavior, it must first be learned. A social norm can be transmitted in many different ways.

Sources of Relationship Norms

Norms regarding relationships come from many sources. Many descriptive and injunctive norms represent societal level guides for behavior. These norms can be communicated through folklore, cultural tales, religious stories, and the formal or informal education provided to children and adults. Different subcultures, religious groups, ethnic groups, and regions of a country likely have

somewhat different descriptive and injunctive norms.

The media (movies, television, etc.) provide an important source of social norms. Researchers have suggested that the media present a general set of culturally based values. The interpersonal behaviors (descriptive norms) and the behaviors that result in approval or disapproval (injunctive norms) presented in the media are often in line with the general societal norms. However, studies in the United States have found the media overrepresents sex and violence, and adolescents' viewing of sex on television is associated with viewing promiscuity as normal behavior (descriptive norm). This suggests that the media can contribute to social norms, although how this occurs is complicated.

Social norms are also developed by observing the behaviors of others, or by observing how others expect a person to behave. For children, it may be school or neighborhood peers; for college students, it may be fellow students; for military personnel, it may be others in a unit; for some people, it may be coworkers, neighbors, fellow churchgoers; and so on. For example, perceptions of how many of other college students are sexually active (descriptive norm) can be associated with whether a student becomes sexually active. How much approval or disapproval (injunctive norms) would be received from fellow churchgoers for a divorce may predict remaining in a marriage.

Both friends and family can be sources of descriptive, injunctive, and subjective norms. Behaviors exhibited in parents' marriages can be carried on and replicated in a child's own future relationships. In addition, parents may provide injunctive norms regarding whom a child should be friends with or who they should marry. As motivation to comply with friends and family will likely be higher than for more general acquaintances, normative beliefs from these groups should be particularly influential.

Other researchers have focused on norms that develop in a specific context. In a particular situation, unique norms may develop and guide behavior. For example, if you are at a party where others are singing and dancing, you may do the same, but you would be unlikely to engage in these behaviors if no one else was. These types of norms can be context and situation specific but still influential in that context.

Perception Versus Reality in Relationship Norms

Researchers have noted that people are often inaccurate in their perceptions of social norms. For example, students often overestimate how much other students use alcohol and are sexually active. Children may be inaccurate in predicting what behaviors their parents would approve of. College students overestimate approval from friends for remaining in a romantic relationship. Generally, it is assumed that a person's perceptions of social norms, whether these perceptions are accurate or not, will be a strong predictor of behavior within relationships.

When Do Social Norms Predict Behavior?

Understanding how social norms influence behavior is difficult because many different norms may be relevant to behavior and some norms may be incompatible with each other. For example, an adolescent may receive injunctive norms against premarital sex from parents but perceive that most of his or her peers are having sex. To resolve this issue, norms-researcher Robert Cialdini and his colleagues proposed the focus theory of normative influence. This theory argues that the norm that influences behavior is the norm that is most focal or salient when the behavior is performed. For example, if an adolescent is discussing sex with friends, sexual descriptive norm from peers, rather than parental injunctive norms, will be likely to be more salient and influence behavior.

Along with social norms, attitudes, beliefs, values, personality, and other factors have been found to influence cognition and behavior. So how do we predict which variable will influence behavior? Focal theory predicts that more focal social norms will be more likely to predict behavior over more personal variables (attitudes, beliefs, etc.). However, outside a laboratory setting (where how focal a norm is can be manipulated or measured), it is difficult to determine which variable will predict best.

General Norms

Many different norms are relevant to relationships, including norms for friendships, romantic

relationships, coworkers, and so on. There are norms that are idiosyncratic to a subculture, religious group, region, corporation, high school, and so on. Some social norms are relevant in a specific context (wedding norms), but other norms have relevance across many types of relationships and situations. It is not possible to list all of the relationship norms, so this entry discusses certain specific norms that have relevance for many types of relationships and provide examples of how social norms function.

Norm of Reciprocity

Reciprocity is the action of providing benefits back to a person who had previously provided benefits to the person reciprocating. For example, a person given a birthday gift can reciprocate by giving a birthday gift in the future. The norm of reciprocity refers to the finding that people often feel an obligation to reciprocate benefits provided by others.

The reciprocity norm can be descriptive as friends, family, coworkers, and so forth often model reciprocity in gift-giving, helping behaviors, social support, and other beneficial behaviors. The norm of reciprocity can also be injunctive, for those who break the norm may receive social sanction and those who follow the norm receive praise. This norm of reciprocity is argued to be so important that, with few exceptions, relationships in which it is regularly violated are predicted to be unhappy and possibly result in relationship termination (parent-child relationships are a notable exception). The norm of reciprocity is powerful, occurring across cultures, and has been argued to be a basis of cooperation in human societies.

Filial Piety

Social norms can also be part of maintaining larger social institutions and upholding cultural rules for behavior. For example, researchers in certain cultures have identified the concept of filial piety. Although the nature of filial piety can vary some across regions, cultures, or historical periods, it has generally been considered to direct young people to be obedient to, respectful of, and care for elders, especially parents and family members. Filial piety has been studied in Asian cultures and

a similar concept of “familism” exists in Mexican and Latino cultures.

A young person in these cultures would see other people showing respect and obedience to elders (descriptive norms), receive approval for respecting elders (injunctive norms), and would know that important others want them to be obedient to elders (subjective norms). These norms, in part, contribute to the maintenance of filial piety or familism in those cultures. However, filial piety or familism is maintained by other means, including societal values, beliefs, morals, and religious beliefs that are taught to children. Filial piety is a good example of how social norms can be one component of how a complex social system of beliefs and behaviors can be maintained within a society.

Gender and Marriage Social Norms

The effect of social norms depends on the nature of a relationship and the characteristics of the people in the relationship. For example, research on marriage has often considered how traditional gender role beliefs influence the division of labor within marriages. Gendered divisions of labor can be supported (or undermined) by social norms regarding gender and marriage. A couple may observe that their fathers were the primary breadwinners while their mothers were the primary caregivers for the children (descriptive norms). The couple may receive approval for maintaining a traditional division of labor from parents, family, friends, and religious sources (injunctive norms). Finally, the couple may perceive that important others want them to maintain traditional gendered division of labor (subjective norms).

The influence of social norms will depend on and compete with other variables. The couple's attitudes regarding equality in marriage, personality, skills, and knowledge will partly determine the division of labor in the relationship. For example, couples with beliefs in equality in marriage will likely develop more equal distributions of household work despite norms from parents supporting unequal roles. The division of labor will also depend on the characteristics of the relationship. If the wife's income is higher than the husband's, they may decide the husband will stay home to care for children and the wife will work. Social

norms are experienced within the context of interpersonal relationships, and characteristics of the relationships and the members of it will change how social norms are expressed.

Relationship Development and Norms

Relationships exist over time with a beginning, development over time, and eventually an ending. Social norms are relevant for each stage of a relationship, although norms may differ across relationship types or cultural context. For example, researchers have identified normative behaviors for a first date, but not every culture has “dating.” Instead, cultural relevant social norms lead to other ways of meeting potential partners including matchmaking, arranged marriages, and families interacting.

As relationships progress, some norms will stop being relevant and others will become more important. Beyond the first few dates, a person in a romantic relationship will begin to examine descriptive norms from long-term dating or married couples. As relationships progress, injunctive norms will change as different behaviors are approved of at different stages in a relationship.

Relationship Norms Over Time

Norms are not static, unchanging standards of behavior but instead are responsive to changes in the social, cultural, and historical context. Seventy years ago in the United States, descriptive and injunctive norms would have inhibited interracial friendships. Today in the United States, far fewer people would report descriptive or injunctive norms against these relationships. Romantic and sexual norms have changed in the United States. Both descriptive and injunctive norms have become more approving of premarital sex, cohabitation, and delaying age at marriage. As societies change, social norms will change.

Conclusion

Social norms are powerful predictors of behavior within interpersonal relationships. It is important to remember, however, that the influence of social

norms is complex because there are different types of norms and different relationships and different cultures with different social norms. This complexity adds to the power of social norms but also can make it difficult to predict how and when a person will be influenced by social norms.

NOSTALGIA

This entry provides a historical overview of conceptualizations of nostalgia. It contrasts past treatises, which viewed nostalgia as a neurological disease and a psychiatric disorder, with a contemporary approach, which views nostalgia as a predominantly positive, self-relevant, and social emotion. The entry reviews empirical evidence indicating that nostalgia is integral to interpersonal relationships. This evidence shows that

nostalgic memories frequently feature the self in a social context, that nostalgia is triggered by loneliness, and that nostalgia increases secure attachment, interpersonal competence, and perceived social support.

Historical Sketch

The word *nostalgia* was coined in the 17th century by the Swiss physician Johannes Hofer, but references to its meaning can be traced back as far as Homer's *Odyssey*. It is a compound of the Greek words *nostos* (return) and *algos* (pain). The literal meaning of nostalgia is the suffering caused by a desire to return to one's place of origin. In the 17th and 18th centuries, as well as most of the 19th century, nostalgia was thought to be a neurological disease with such varied symptoms as persistent thinking of home, despondency, bouts of weeping, irregular heartbeat, and smothering sensations.

By the end of the 19th century, nostalgia came to be regarded as a psychiatric or psychosomatic disorder. Symptoms included anxiety, sadness, loss of appetite, insomnia, and fever. As the psychodynamic perspective gained strength in the mid-20th century, nostalgia came to be viewed as a regressive disorder reflecting the subconscious desire to return to an early stage of life. Under this influence, nostalgia was downgraded to a variant of depression rooted in incomplete mourning and an inability to cope with the challenges of adulthood, including grief and loss. In this light, it is perhaps not surprising that nostalgia was often equated with homesickness.

Nostalgia did not acquire a unique conceptual status until the latter part of the 20th century. Sociologist Fred Davis laid the groundwork for this new look on nostalgia by showing, for instance, that participants associated words such as *warm*, *old times*, *childhood*, and *yearning* more frequently with nostalgia than with homesickness, suggesting that participants could discriminate between these two concepts. Recently, nostalgia has become the topic of social-psychological inquiry focusing on three issues: the content of nostalgic experiences, the triggers of nostalgia, and the psychological functions of nostalgia. Preliminary answers to these questions highlight

the link between nostalgia and interpersonal relationships.

Interpersonal Relationships and the Content of Nostalgia

Studies on the content of nostalgia have analyzed autobiographical narratives of nostalgic experiences. In one study, researchers retrieved and content-analyzed narratives published in the periodical *Nostalgia*. Another study followed a vivid-recall protocol in which undergraduate students wrote a detailed narrative account about a nostalgic experience, which was content-analyzed. In both studies, the narratives revealed that individuals most frequently felt nostalgic about close others (family members, old friends). Further highlighting the social aspect of nostalgia was the finding that nostalgic narratives almost exclusively featured the self in interpersonal context. Although many narratives contained descriptions of disappointments and losses (separation, death of loved ones), positive and negative aspects were often juxtaposed to create a redemption sequence—a narrative pattern that progresses from a negative to a positive life scene.

Interpersonal Relationships and Triggers of Nostalgia

Research on the triggers of nostalgia has been guided by the idea that nostalgia often occurs in response to negative psychological states and may help the individual to restore psychological equanimity. Most empirical attention has been focused on the discrete negative affective state of loneliness. In experimental research, loneliness was manipulated by giving British (in one study) and Chinese (in another study) undergraduates false feedback regarding their score on a test that ostensibly assessed loneliness. For some participants, the feedback indicated that they were high in loneliness, for others that they were low in loneliness. Participants then completed a measure of nostalgia, rating the extent to which they missed various aspects of their past (e.g., “someone I loved,” “feelings I had”). British and Chinese participants in the high-loneliness condition were more nostalgic than were those in the low-loneliness condition.

Two correlational studies with Chinese participants further showed that loneliness was positively correlated with feelings of nostalgia and that this loneliness-nostalgia association was stronger among high- than among low-resilience individuals. These findings raise the interesting possibility that individuals, particularly those high in resilience, recruit nostalgia to counteract the adverse effects of loneliness.

Interpersonal Relationships and the Psychological Significance of Nostalgia

How might nostalgia help individuals cope with negative subjective states such as loneliness? Research on the psychological functions of nostalgia has identified several pathways. In a typical experiment, some participants are instructed to write about a nostalgic experience and other participants are instructed to write about an ordinary experience from their past. Participants who write about a nostalgic experience (compared with an ordinary experience) show significant increases in positive affect and in positive self-esteem. Furthermore, these experiments provide evidence that nostalgia increases social connectedness. Nostalgic

participants scored higher than did control participants on state measures of secure attachment, perceived social support, and interpersonal competence. Nostalgia, then, can make individuals feel loved and capable of loving others.

OBSERVATIONAL METHODS

“You can observe a lot just by watching,” baseball great Yogi Berra once said. Researchers interested in human relationships have done a lot of watching, developing varied methods that improve our understanding of human relationships. This entry focuses on these methods and covers the difference between analogue and naturalistic observation, the types of studies employing observation, the use of observation in clinical assessment, and the measurement and statistical considerations involved in observational research.

Naturalistic and Analogue Behavioral Observation

Behavioral observation involves any situation in which an assessor (e.g., a researcher or clinician) systematically watches how people act. Although assessors may also see what effect the situation has on the participants’ thinking, feeling, or physiological reactions, the key focus is on observable action.

Behavioral observation comprises two forms. Naturalistic observation involves the measuring of behavior in its typical context without artificial constraints by the observer.

The prefix “analogue” in *analogue behavioral observation* (ABO) is derived from the same root as “analogy”; an analogue is like something else. In this case, the analogue situation is like a real-life

situation, one that is set up by the observer to see more intriguing things than would happen naturally. Thus, in more scientific terms, ABO can be defined as a situation designed by, manipulated by, or constrained by an assessor that elicits a measured behavior of interest. Observed behaviors can be either verbal or nonverbal (e.g., overt actions, observable facial reactions, verbalized attributions). This entry focuses more heavily on ABO, both because ABO is by far the predominant form of observation used in family studies and because it involves slightly more decisions.

Studies of couples’ communication are a prime example of ABOs in the study of human relationships, with hundreds of such studies in the published literature. In a typical study, psychologists bring a couple into the lab, give each of them a questionnaire (or interview) to find out what the biggest areas of conflict are (e.g., she would like him to spend more time with the children). The observer then brings them into a room (equipped with cameras and microphones) and asks them to discuss the problem and try to resolve it as they might at home. They are then left alone for 10 to 15 minutes as the video records. This process is often repeated for additional conflicts.

Researchers structure conversations in this way because they have a theory that conflict is important; observers set up the situation so that there is a high probability that it will happen while the video is recording. The likelihood that a conflict would occur if the observer watched any random 15-minute segment of the couple’s at-home behavior is low. In fact, one of the originators of the

conflict-oriented ABO method, psychologist John Gottman, set up a wired apartment in Seattle and had couples stay for 24 hours. Unlike his other studies that tested theories about how couples handle conflict, Gottman saw little conflict. There was so little that he and his colleagues had to come up with a different set of behaviors to study, for example how one partner would try to get the other's attention and whether these attempts worked.

ABO exists on a continuum of naturalism, ranging from highly contrived situations (e.g., How quickly do people walk down the hallway after being exposed to subconsciously presented words about aging?) to naturalistic situations arranged in unnatural ways or settings (e.g., How do couples talk with one another when asked to discuss their top problem topic?) to naturalistic situations with some (but minimal) experimenter-dictated restrictions. Pure naturalistic observation involves no restrictions at all (e.g., How many acts of aggression occur during recess on a school's playground?).

ABO is used as a hypothesis-testing tool for three purposes: (a) to observe otherwise difficult-to-observe behaviors (e.g., conflict behaviors), (b) to isolate the determinants of behavior (e.g., conflicts when a woman is asked to press for a desired change versus when a man is asked to press for change), and (c) to observe qualities of social interaction that unfold over time (e.g., anger escalation between mothers and children during a 15-minute period when the playing with certain objects in the room is forbidden). Although naturalistic observation might be preferable (i.e., observers would not need to guess about how comparable the behaviors were to those in real life situations), the first two purposes require controlled experimentation, necessitating ABO; for the third purpose, ABO is often preferable because it allows the observer to "stack the deck" to make it more likely that the behaviors (and the cause-effect relations) of interest will occur when the assessor can see them.

Types of Studies Using Observational Methods

ABO studies can roughly be divided into those that study the effects of specific situations on individual behavior and those that are interested in behaviors that arise in social situations. The goals

of first type of study are to manipulate the setting and test individual differences in response. That is, the situation is set and variations in individuals' behavior are observed. This type of study is common in developmental psychology (e.g., visual cliff experiments), social psychology (e.g., prosocial behavior experiments, emotion regulation experiments), and clinical psychology (e.g., social anxiety assessment).

Studies of social situation employ ABO mostly as a convenience in assessing quasi-naturalistic interaction. The goal of such assessment is typically to understand behavior and its determinants in situations in which participants influence each other while interacting (e.g., groups, families, couples). Understanding generalizable factors that promote or maintain problem behaviors in such systems typically requires more naturalistic approaches than those used in controlled, manipulated situation studies.

Naturalistic observation is used when the behavior of interest happens frequently (e.g., a spouse's or child's bid for attention), predictably (e.g., a mother dropping off a child at daycare), or is demarcated in a way that allows for efficient culling (e.g., loud arguments can activate a recorder with a particular decibel threshold; recorder is activated by the parent at salient times).

Clinical Assessment

Behavioral observation is a useful tool in clinical assessment, although relatively few paradigms have been developed specifically with this application in mind. To be clinically useful, behavioral observation must efficiently provide reliable, valid, nonredundant, and cost-effective information. Because most systematic, empirically sound observation is done in research studies with methods that are impractical in common clinical practice, clinical observational assessments are typically impressionistic rather than formal and statistical. That is, clinical observation almost always is used simply to flesh out self-report information. For example, clinicians observing couple or parent-child interactions do not typically use validated coding systems and calibrate their coding reliability systematically and regularly. Regrettably, the use of any formal,

systematic observation in clinical assessment is relatively rare. This oversight is especially pronounced with couples, families, and children (who typically are accompanied by at least one parent), as the social situation that causes, helps maintain, or can help ameliorate problems is already in the potential observer's office; obtaining such social situations with individual clients is considerably more difficult.

Measurement Considerations

Each behavioral observation paradigm and its accompanying coding systems must be separately considered for "psychometrics"—measurement issues such as interobserver agreement (for systems using human observers), reliability, validity, and utility. *Interobserver agreement* is the concurrence of two or more observers that a particular behavior occurred or occurred at a particular intensity. *Reliability* is the reproducibility of observations (i.e., that the findings are stable and not a fluke). *Validity* is establishing that an observational task or coding measures what it intends to measure. *Utility* refers to the usefulness of results.

The coding of behaviors turns observation into a true tool. Creation or use of a coding system is a theoretical act, and the following questions should have answers before proceeding: Why are you observing? What do you hope to learn? How will it affect your hypotheses (i.e., either research questions or case conceptualization questions)? This is especially true because coding of many observed target behaviors is difficult to do in a reliable, valid, and cost-effective manner.

Sampling

The major sampling strategies are event sampling (the occurrence of certain behavior is coded, ideally in sequential fashion), duration sampling (the length of each behavior is recorded), interval sampling (the observational period is divided into time blocks; during each time block, the occurrence of each code is noted), and time sampling (intermittent observations are made, typically in a duration or interval sampling manner).

Behavioral Targets

Some behaviors are so concrete that the observer serves more as a recorder than as a coder (e.g., the length of time a child stays seated during a time out). Other behaviors require at least some degree of inference (e.g., parallel versus solitary play in young children). Researchers will typically provide a coding manual with prototypical examples, but exhaustive, universal definitions are not possible; thus, the coder is considered a "cultural informant" and uses his or her common sense of the culturally normative meaning of behaviors to infer that a combination of situational, linguistic, paralinguistic, or contextual cues amounts to a behavior that can be coded. Cultural informants will not always agree, for example, whether a particular utterance should be considered "hostile" in a couples coding system; the strength of the system is based largely on a reasonably high level of agreement among coders on the putative hostility of the behavior, on agreement between the coders and the developer, and on the ability of the system to make sensible discriminations (e.g., couples in therapy are likely more hostile than are happy couples) and predictions (e.g., hostile couples may be more likely to divorce). Concrete codes are not necessarily better than informant-inferred codes; sometimes one allows for a more valid measurement of a construct, sometimes the other does. In accord with Occam's razor, coding should be as simple as possible to reliably capture the behavioral constructs of interest.

Global (i.e., molar) coding systems make summary ratings for each code during the entire observation (or across large time intervals). Codes tend to be few, representing behavioral classes (e.g., negativity). Microbehavioral (i.e., molecular) systems code behavior as it unfolds over time and tend to have many fine-grained behavioral codes (e.g., eye contact, criticize, whine).

Topographical coding systems measure the occurrence of a behavior (including, potentially, its duration). Dimensional coding systems measure the intensity of the behavior. Microbehavioral systems tend to be topographical; although global systems tend to use rating scales, they may summarize frequency rather than intensity. Dimensional coding of intensity, especially on moment-by-moment basis, has been used sparingly in observation.

Conclusions

Behavioral observation can be a good theory testing tool because (depending on exactly how it is employed) it minimizes the need for inferences to assess behavior, it can facilitate formal or informal analysis of cause and effect, it can provide the assessor with experimental control of situational factors, it can facilitate the observation of otherwise unobservable behaviors, and it can provide an additional source of useful information in a multimodal strategy (e.g., questionnaires, interviews, observation). Finally, because the assessor can set up a situation that increases the probability that behaviors of interest will occur during the observation period, ABO can be high in clinical utility and research efficiency.

Like any tool, however, observation's usefulness depends on its match to the resources and needs of the person considering using it. Observation is often a time-, labor-, and money-intensive assessment strategy; the use of research-tested protocols and coding is often impractical in clinical settings; adaptations of empirically supported observational methodology in clinical settings may render them unreliable and of dubious validity; the conditional nature of validity may make it difficult to generalize observed behavior to the broad variety of real world settings; and, the less naturalistic the ABO situation, the more nagging the concerns about external validity (i.e., applicability to real-world situations).

OBSESSIVE LOVE

Models of romantic love postulate sets of distinct qualities, such as (a) passion, intimacy, and commitment; (b) attachment, caregiving, and sexuality; (c) passionate and companionate love; and (d) caring and needing. These qualities can occur in various combinations and differing levels of intensity during a relationship. Obsessive love is a unique type of romantic love characterized by a dominant cognitive pattern of recurrent and persistent thoughts, impulses, or images about being with another person in a romantic or sexual relationship. Obsessive love may overlap with other attachment systems (e.g., maternal attachment) and love in other contexts (e.g., familial love; friendship love), but this entry is limited to obsessive love as a type of romantic love.

Obsessive love can occur during different phases of a romantic relationship. It may exist before any interaction and be the precursor to a developing relationship that results in more complete love (e.g., intimacy and commitment). It may be a component of romantic love that is complemented by other attributes (e.g., intimacy). Obsessive love may also be a consequence of a terminated romantic relationship where, in the absence of further interaction and other attributes (e.g., commitment), the cognitive obsession for the love object persists.

The cognitive components of obsessive love would both contribute to and be a result of motivational systems (e.g., attachment, mate selection) and biological systems (e.g., sexual arousal) that have interpersonal, intrapsychic, and biological origins. These systems can fuel the obsessive cognitions and result in emotions that are intense, enduring, and seemingly uncontrollable. Thus,

obsessive love, much like other forms of romantic love, is accompanied by a motivation to approach a potential partner to fulfill needs for affiliation, closeness, intimacy, attachment, and sex; however, unlike other forms of love, obsessive love is marked by unequal commitment, lack of reciprocation, and repulsed approaches. Obsessive love is similar to infatuation, lust, a "crush," and limerence, all of which are viewed as an involuntary and emotional state of intense romantic desire for another person.

Obsessive love may also be perceived by the individual as being dystonic because it leads to distress and anxiety. Obsessive love has some characteristics in common with the perspective that views love as an addiction. The dystonic qualities of addictive love are viewed as tied to psychological inadequacies and interpersonal incompetencies of the individual because the obsession may be a means of shifting attention away from the self and toward an external object.

The most substantial feature of obsessive love is persistent and recurring thoughts, impulses, and images coupled with cognitive distortions. These cognitive distortions are characterized by an intense need to be with the love object, biased interpretation of the love object's actions, and the belief that this person alone can fulfill romantic desires. In addition to idealization and incorrect or inappropriate interpretations of the love object's intentions, the lack of commitment by the love object runs the risk of producing consternation when love is unreciprocated or rejected. Active attempts to suppress the predominant cognitions may only increase their frequency and prolong their duration. Thus, these ruminations tend to increase interest in the love object and to reinforce the importance of the love object for obtaining a satisfying relationship, while diminishing the self if that love is unrequited.

Obsessive love can be a benign infatuation that is private, never results in interpersonal romantic behaviors toward the love object, and, with time, passes. Or, obsessive love may lead to a fulfilling lifelong relationship after a period of unreciprocated pursuit. Obsessive love, with its preoccupation for the love object and its desire for greater intimacy, can lead to both appropriate and inappropriate actions that attempt to establish and develop a relationship. As positive as such

potential outcomes may be, the behavioral manifestations of obsessive love can be counterproductive, undermine establishing a relationship by driving the love object away, and potentially be catastrophic for both individuals. Thus, the behavioral concomitants of obsessive love represent a continuum of behaviors that (a) can be as simple as loving from afar and initiating the development of a relationship through (b) courting the love object with the goal of a permanent long-term relationship to (c) stalking and obsessive relationship pursuit.

Obsessive love is a high-stakes gamble in which the potential for producing an enduring relationship justifies, in some instances, the use of unscrupulous, Machiavellian, and immoral tactics (although the pursuers do not perceive them as such) along with the risks of failure, embarrassment, and lowered self-esteem. For the love object, this obsessive love can be emotionally trying from the standpoint of having to continually reject another and respond to unwanted advances.

Because of the mix of frustration resulting from rejection and the prospect of a potential relationship that might yet develop, obsessive love is accompanied by both positive and negative emotions. The obsessive lover may view rejection as indicating interest by the love object in a relationship (i.e., playing hard to get). These ruminations and emotions may change during the relationship as rejection mounts.

Although not clinically pathological, obsessive love does share characteristics with obsessions that are pathological (e.g., obsessive-compulsive disorder, criminal stalking) in that obsessive love may involve cognitions that seem inappropriate, they may intrude in ways that distract the individual during routine activities, and they may be perceived as uncontrollable. Typically, the intensity and duration of these attributes are not extreme enough to warrant a clinical diagnosis and are, therefore, considered part of normal phenomena.

OBSESSIVE RELATIONAL INTRUSION

It is not uncommon for two individuals to possess incompatible goals and intentions for a shared relationship. For example, one person may desire romance but the other prefers a platonic friendship; one person may want to terminate a relationship that the partner wishes to continue. Such disjunctive relationships can lead to obsessive relational intrusion (ORI), in which one person persistently pursues interdependence with another person that the other explicitly eschews. This entry summarizes manifestations of ORI and reviews the factors that contribute to the occurrence of this phenomenon.

Many of the patterns of behavior that characterize ORI closely resemble ordinary relationship pursuit behaviors. The pursuer engages in activities designed to establish proximity, foster contact, seek affinity, reduce uncertainty, and cultivate closeness and interdependence. Because these behaviors are prosocial, and because the intention behind them may be unclear, the incompatibility of relational goals may take some time to be revealed. When these patterns of behavior are repeated or intensified despite overt rejection by the pursued individual, they become excessive and intrusive.

A single episode of unwanted pursuit does not qualify as ORI. Rather, ORI involves a pattern of unwanted behaviors across multiple episodes of interaction. The relative severity of ORI depends on the *persistence* of the obsessive pursuer. Mild

persistence is annoying and pestering, but not particularly distressing. Indeed, some of the inconvenience experienced by the pursued person may be counterbalanced by simultaneously feeling flattered by the unwanted attention. Mildly persistent pursuit involves flirtation, ingratiation, and attempts to be in proximity to the pursued. This can include such behaviors as giving gifts, requesting dates, using third parties to obtain information about the pursued, approaching the pursued in public places, and making contacts via phone calls, instant messages, and the like. When pursuit becomes moderately persistent, it is more frustrating and troublesome to the pursued. The extended duration of ORI as well as the nature and frequency of the unwanted behaviors render the pursuit more exasperating and intrusive. Moderate ORI can include surveillance of the pursued person (e.g., spying, following); trespassing; harassing the pursued's family, friends, or coworkers; spreading false rumors about the pursued, and other behaviors that seem "creepy." Severely persistent ORI is annoying and intrusive, as well as frightening and extremely worrisome. As such, it legally qualifies as stalking. Although stalking can occur for various motives, its most common impetus is the desire to establish or reestablish a relationship with the stalking victim. Ironically, some rejected relationship pursuers engage in threatening and abusive forms of harassment, sometimes in a desperate attempt to forge the desired relationship, and sometimes as a form of revenge for being rejected.

Various explanations for the occurrence of ORI have been proposed. Common among these are social skill deficits, personality aberrations, and mental disorders. Some persistent pursuers lack social skills that would permit them to seek affinity in appropriate ways and to recognize when their pursuit is unwanted and obsessive. It is not uncommon for some pursuers to have a history of failed relationships, and insecure attachment, particularly a preoccupied attachment style, is perhaps one of the most common explanations for ORI. Some obsessive pursuers are prone to experiencing possessiveness and morbid jealousy in their close relationships. Other pursuers suffer from disorders ranging from borderline personality to schizophrenia, and in rare cases, erotomania.

In addition to these explanations, there are other accounts for persistent unwanted pursuit

that are grounded in the complexities of negotiating ordinary personal relationships. Relationships are coconstructed through implication and tacit communication, thereby allowing much room for the mismatching of relationship goals and intentions. Thus, ingratiating behavior that is motivated by the desire to increase relationship closeness can be interpreted by the recipient as mere friendliness. At the same time, the recipient's reciprocation of friendly behavior may be incorrectly taken as a sign of reciprocation of the hidden motive to escalate intimacy. In this way, the manifest behaviors of the pursuer and the pursued seem compatible, but the latent meanings each person attaches to the behaviors are incongruent.

Further contributing to mismatching of relational goals is the fact that unwanted bids for relationship connection tend to be rejected in an indirect and polite fashion. The rejecting person "lets the pursuer down easily" to avoid appearing heartless or cruel, to expiate some of the guilt felt when conveying rejection, and to mitigate some of the rejected person's hurt or embarrassment. This sugarcoating of rejection messages is intended to minimize the loss of face for both parties, but the unintended consequence is to render the rejection itself unclear. The pursuer, who is inclined to rationalize that his or her relational intentions will be reciprocated, often regards the soft rejection as ambivalence or encouragement.

Finally, relationship pursuit occurs within a cultural milieu where persistence in striving for important outcomes is both expected and rewarded. We learn early in life, from actual experiences and from depictions in popular culture, success in achieving goals is a function of effort. The mentality that "quitters never win, and winners never quit" extends to the pursuit of desired relationships. To some degree, this persistence is fueled by the perceived occurrence of token resistance. Potential relationship partners sometimes "play hard to get" to avoid appearing too eager. This reinforces the view of relationship pursuers that persistence, even in the face of apparent rejection, is expected and sometimes welcomed.

OPENING LINES

An opening line or gambit is a verbal or nonverbal tactic employed by an individual to initiate interaction with a stranger whom the individual finds attractive. In the entertainment media, the leading man is often portrayed as a savvy hunter who bags a doe-eyed female by taking an unerring shot with a captivating line. In the 2005 film *Hitch*, Will Smith portrayed the title character, who offered coaching on opening gambits and relationship initiation to male clients. His emphasis was on both confidence and clever meetings. Hitch claimed, "No matter what, no matter when, no matter who . . . any man has a chance to sweep any woman off her feet; he just needs the right broom." This entry discusses different categories of opening lines and the role of opening lines in the sequence of courtship stages.

The Internet provides numerous Web sites that propose to offer the right broom, in the form of "pickup lines." Many of the pickup lines are intended to be humorous, based on the hope that the display of wit will both convey desirable mating attributes to the opposite sex, and break the ice. The site linesthataregood.com for example, offers more than 1,200 possibilities. Many of the opening lines are based on light-hearted compliments to the other person's general beauty and attractiveness:

I think I can die happy now, 'cause I've just seen a piece of heaven.

What does it feel like to be the most beautiful girl in this room?

Is there an airport nearby or is that just my heart taking off?

It is only a short step from complimenting the person's general attractiveness to a comical focus on their body and sexual attractiveness:

Greetings and salivations!

Was your father a mechanic? Then how did you get such a finely tuned body?

Are those space pants? 'Cuz your body is out of this world!

From mentioning the person's sexual desirability, it is but one more step to a humorous sexual proposition:

If I told you that you had a great body, would you hold it against me?

Do you know, your hair and my pillow are perfectly color-coordinated?

(Give the person a bottle of tequila) Drink this, then call me when you're ready.

Rather than focus on the other person's attractiveness, some pickup lines focus on the self's purported desirability, or lack thereof:

Do you believe in love at first sight, or should I walk by again?

Baby, I'm no Fred Flintstone, but I can make your Bedrock!

I bet you \$20 you're gonna turn me down.

Researchers have classified pickup lines into three categories. Cute/flippant lines are compliments, sexual innuendos, and playful challenges, like those listed earlier. Innocuous pickup lines are bland conversational statements such as "Hi" or "What do you think of the band?" Finally, direct opening lines involve a simple, self-deprecating statement, such as "I'm a little embarrassed about this, but I'd really like to meet you." Field tests were conducted on the various categories of opening lines using nearly 300 young adults. Moderately physically attractive males approached females in crowded bars without observing the preliminary nonverbal steps described previously. The direct

and innocuous lines were equally effective, and resulted in the successful initiation of a conversation approximately 50 percent of the time. Cute/flippant lines, by contrast, produced female rejection about 80 percent of the time that the males tried them. Follow-up studies suggested that males who tried cute/flippant lines were seen as less intelligent and less responsible than were males who tried other approaches. Studies conducted in Great Britain produced results similar to those in the United States, finding that those opening lines that involved jokes, empty compliments, and sexual references received poor ratings. By contrast, when the male revealed his helpfulness, generosity, athleticism, culture, and wealth, he was rated more highly, at least in a hypothetical vignette.

Research has focused on opening gambits in face-to-face relationships, but it seems likely that opening gambits based on exaggerated compliments, sexual humor, and bragging are likely to backfire online, just as they do in real life. Such repartee may be enjoyed among cross-sex friends who share some romantic feelings toward one another, but research indicates that few women welcome or accept sexual pickup lines from total strangers. Instead, women tend to be mindful of the risks of pregnancy, sexually transmitted diseases, or threats to the self-concept, and dodge unexpected arrows from would-be cupids. Like the game of chess from which the term *opening gambit* was derived, initial conversations between strangers take place in the context of implicit norms and scripts.

The pickup line generally occurs in the middle of a sequence of courtship steps, most of which are nonverbal. In the first step in this sequence, a female subtly expresses her interest in companionship, such as by scanning the room, grooming herself, or moving in time to music. A male who is interested will try to make eye contact, and exchange smiles. If the female reciprocates his attention, the male has conditional permission to approach. If the male approaches a female who is not interested in social attention, or who approaches without first making eye contact and implicitly gaining permission for an advance, his chance of success is diminished. But, getting the nod is not enough. If the male's nonverbal behavior while coming closer suggests that he is too dominant and predatory, or too shy and

awkward, the female's interest may evaporate, dooming further efforts to failure. Assuming that the female's interest remains, only then does the male have an opportunity to deliver a pickup line. If the content and delivery are pleasing, then the couple can move forward to flirtatious conversation.

This discussion has focused on males approaching females, but what about the converse situation, in which a female approaches a male? Females often generate all of the attention that they desire by wearing appealing clothing and flashing an attractive smile, but in one observational study, approaches by females to males accounted for nearly 20 percent of the opposite-sex encounters. Field research indicates that females are successful at initiating such conversations approximately 90 percent of the time, regardless of whether they use a cute-flippant, innocuous, or direct opening line. When it comes to short-term relationships, males have much less to lose and lower standards than do females.

OPENNESS AND HONESTY

Openness and honesty are often identified as key characteristics desired in personal relationships. This entry explores how openness and honesty affect personal relationships and discusses whether openness and honesty are always the best policy.

Openness

To be in relationship means to be open. Early work by Irwin Altman and Dalmas Taylor demonstrated this by suggesting that relationships vary in the *breadth* and *depth* of topics that partners discuss. For example, a casual acquaintance relationship with a neighbor is characterized by limited breadth and depth (e.g., the new addition to one's house and the weather are all that are talked about). As such, the relationship has limited openness. If the neighbor is one known for some time and who would be considered a good friend, the breadth and depth of discussion, necessarily, increases substantially (e.g., sharing parenting struggles).

Openness implies giving a partner access to one's self. This access may be manifested in four specific ways. First, relational partners may give each other access to information. The more open one is in a relationship, the more information that is known about him or her. Second, partners may give social access. Social access is characterized by time spent together. For example, one can be open socially by talking on the phone, texting, or physically spending time together. Third is physical access. Physical access includes being open to various forms of touch, such as playful touch and affectionate touch. The final form of access is psychological. Psychological access occurs when one is open about how one feels and thinks (for example, sharing one's deepest fears).

Openness across these four dimensions increases the level of intimacy in a relationship. This increase in intimacy is a result, in part, of the relationship risk that each partner shares. This risk is the result of the increased possibility that partners might use private information in hurtful or inappropriate ways. Increased trust is necessary for partners to manage the increased vulnerability that is a

consequence of relational openness. As such, intimacy is developed not merely through openness, but through openness that facilitates closeness and trust.

Scholars have also identified openness as part of a dialectic that is central to most personal relationships: openness—closedness. Dialectical theorists argue that relationships experience a number of internal tensions that are the result of constant negotiation between opposing or contradictory tendencies (e.g., interdependence—independence; judgment—acceptance). From this perspective, individuals in relationships are constantly being pulled between the desire to be open with one's partner and the desire to maintain privacy.

Societal norms and expectations regarding openness made a significant shift in the 1960s. For example, 50 years ago, there was less expectation that one's romantic partner would also be one's best friend—this was especially true for lower socioeconomic couples. Arthur Bochner has suggested that the countercultural movement of the late 1960s polarized social conduct into two camps: instrumental and expressive. Instrumental conduct emphasized certainty, predictability, restraint, and strategic communication. Expressive conduct was characterized by openness, honest talk, and freedom of expression. Phrases like “tell it like it is” and “let it all hang out” illustrate the expectations that individuals in close relationships should be “totally open” with one another (perhaps with little concern for the other person's feelings). However, multiple studies have indicated that individuals in satisfying intimate relationships (e.g., married couples) are selective in their self-disclosure. Happy spouses are characterized by sharing in moderate amounts with each other. Part of this results from the high levels of self-disclosure experienced in growth stages of the relationship, but it also seems that healthy couples have the ability to sense *what* is important to talk about and *when* and *where* and *how* to talk about it.

Honesty

The role of honesty is important when considering the previous findings. Research has demonstrated a strong positive relationship between honesty and positive relationship outcomes. One

can't be open when giving false information or willfully creating a false image or withholding important information for the purpose of misleading one's partner. However, in light of the findings for openness, it's important to recognize that lack of full self-disclosure (openness) may be appropriate and effective when designed to achieve honesty with one's partner in ways that facilitate understanding—as they say, “timing and delivery is everything.”

It's clear that friends and romantic partners value both openness and honesty as part of the “rules” of the relationship. Honesty has been demonstrated to be positively correlated with feelings of relational closeness, whereas a lack of honesty and openness has been related to abuse in relationships.

A common perception is that deception is appropriate at times within personal relationships. For many, the classic question, “Do these pants make me look fat?” precipitates a dishonest response. However, it has been argued that in close relationships, appropriate responses to difficult questions should be more a matter of timing and phrasing that facilitate honest understanding, rather than strategic deception that may include incomplete, indirect, and unclear responses, to avoid conflict or relational hurt. Dishonest responses tend to decrease openness in the relationship, limit the other's potential responses, and limit the ability to dialogue and respond to one another in creative and supportive ways. Thus, three criteria are central to creating a strategic and effective response to difficult questions. First, what is the function of the question? For example, is the question designed to find out information (“Do I really look fat?”) or is it designed to achieve social support (“I just want to know that you think I'm attractive.”). Second, think about *what*, *when*, *where*, and *how* questions to construct a message that the receiver is likely to understand without becoming defensive. For example, if the pants are not flattering, one might suggest another outfit (“I've always loved you in your black pants.”), then, a few days later, give an honest opinion about the “fat” pants. Third, the speaker needs to consider her or his own level of comfort in sending various types of messages (e.g., many would find it difficult to say, “You look great!” if they didn't really believe it).

Interestingly enough, openness and honesty have also been identified as two of six major personality characteristics. Research on what has become known as the Big Five or Five-Factor model of personality characteristics has included openness as a central personality characteristic in the form of *openness to experience*. Openness to experience is not typically understood in relational terms and, yet, future research may discover that one's tendency to be open through aesthetic appreciation, inquisitiveness, creativity, and unconventionality may be linked to openness in personal relationships. More recent examinations of personality dimensions—the Honesty-Humility (H), Emotionality (E), Extraversion (X), Agreeableness (A), Conscientiousness (C), and Openness to Experience (O) model (HEXACO)—include a sixth dimension of *honesty-humility* that is characterized at one extreme by honesty, fairness, sincerity, and modesty.

Openness and honesty are significant in negotiating personal relationships. Both are strongly associated with rules and expectations for friendships and romantic relationships. The vulnerability that openness and honesty potentially create and the constant relational tension that exists between openness and closedness, and free expression and strategic communication, keep both of these constructs at the center of creating meaning in close relationships.

OPTIMISM, EFFECTS ON RELATIONSHIPS

One enduring lesson from social and personality psychology is that beliefs affect social behavior. Beliefs can proactively shape the ways that individuals perceive and make sense of social situations, and beliefs can affect how individuals behave toward others. A belief orientation that has received a great deal of attention in a variety of domains is *optimism*. The focus of this entry is on how optimism is related to relationship processes and outcomes. This entry begins by defining optimism, reviewing some of the outcomes generally associated with it, and presenting a general theoretical model that explains why optimists enjoy more favorable outcomes in many areas of life. It then considers the role of optimism in relationships, discusses some of the positive relationship outcomes that have been associated with optimism, and highlights the adaptive relationship processes through which optimism brings about those outcomes.

What Is Optimism?

Optimism is defined as a tendency to expect favorable outcomes. Research has demonstrated that there are individual differences in global optimism—that is, some individuals are more inclined than are others to expect good things across a variety of life domains. A global, dispositional tendency to be optimistic will typically manifest itself in a variety of more specific beliefs tied to particular times, situations, or life domains, and beyond any dispositional tendency, optimistic or pessimistic beliefs may be activated or diminished by short-term factors (for example, people in happy or angry moods are more optimistic than are people in fearful moods). Optimism and pessimism are generally conceptualized as opposite sides of a continuum. Thus, when this entry refers to *optimists* or *pessimists*, that is used as

shorthand for relative differences along such a continuum, not for qualitatively different types of people.

Research on dispositional, global optimism helps paint a picture of the personality traits and outcomes typically associated with being an optimist. This research has shown that optimists tend to have somewhat higher levels of extraversion and self-esteem, and lower levels of neuroticism, stress, anxiety, and hopelessness. Optimism is associated with a number of favorable outcomes in various domains of physical health and psychological functioning. For example, optimism assessed before a stressful life transition has been shown to predict fewer physical symptoms in patients and better immune system functioning during the transition. Optimism is also correlated with lower depression, fewer mood disturbances, and fewer negative interpersonal interactions. Optimism has been shown to predict less negative affect, depression, and stress during major life transitions.

A subset of optimism research has investigated outcomes in interpersonal relationships. Research has shown that individuals with optimistic outlooks are better liked by others and are socially rejected less often, have fewer negative social interactions, have longer-lasting friendships, and experience lesser social alienation and anxiety. In romantic relationships, both optimists and their partners enjoy greater relationship satisfaction, and optimists' relationships are at lower risk of breaking up.

How Optimism Influences Outcomes

Charles Carver and Michael Scheier, who have theorized and written extensively about optimism, have proposed that the associations between optimism and positive outcomes can be explained using an expectancy-value model of self-regulation and goals. Their model starts with the key assumption that nearly all behavior is driven, implicitly or explicitly, by goals. According to an expectancy-value model, goal-driven behavior is energized by two factors. The *value* of a goal refers to its desirability to the individual. *Expectancies* refer to beliefs about the attainability of goals. Goal pursuit is a joint function of value and expectancies: All else held equal, an individual will be more

persistent in pursuing a goal when that goal is greatly valued and when the individual expects to be successful in attaining the goal. The proposed role of optimism within the expectancy-value framework is that optimists tend to have more favorable expectancies. Thus, one would expect optimists to be more persistent in pursuing desirable goals, and thus to attain better outcomes.

In support of this model, research on coping strategies has indicated that optimists are indeed more persistent and more successful in pursuing goals. When faced with challenges or obstacles, optimists are more likely to use approach-oriented coping strategies like active coping, planning, positive reinterpretation, and less likely to use avoidance-oriented coping strategies such as denial and behavioral disengagement. Optimists are also more likely to use coping strategies that target a problem directly when doing so would be effective, but when a problem is unresolvable or uncontrollable, they make use of emotion-based strategies like acceptance, humor, and positive reframing to lessen the problem's impact. Optimists' persistence is not limitless or self-destructive, however: Optimism is also associated with behavioral flexibility in coping with a stressor, such that optimists disengage from hopeless tasks and shift their attention to more tractable problems, rather than proceeding with nonproductive persistence.

Self-regulation theories propose that progress toward goals can affect mood. Consistent with this idea, optimists experience less negative emotion (such as shame, depression, and anger) when their progress toward goals is disrupted, presumably because they anticipate being able to overcome the obstacles. Indeed, optimists regulate their behavior during goal pursuit by working toward their goals and engage in more proactive steps to promote well-being and prevent stress, suggesting that they are better able to prevent their emotions from interfering with their behavior. Optimists' use of emotion-based coping buffers some of the negative emotions that might otherwise accompany failure or unresolvable problems.

Global Optimism and Relationship Processes

Global, dispositional optimism is not explicitly defined as a relational construct, and the most

commonly used measure of global optimism (the Life Orientation Test) makes no reference to beliefs about relationships. Nevertheless, as mentioned earlier, several lines of research on optimism and relationships show that a globally optimistic outlook is associated with a variety of positive social outcomes. The following sections consider how optimism helps bring about positive outcomes in relationships.

Perceived Social Support

One key factor that researchers have focused on is *perceived support*. Perceived support refers to the belief that others will be available to provide assistance and comfort if needed. Perceived support is only modestly related to objective indicators of the actual social support received. Thus, it is more than just a realistic reflection of others' supportive behaviors; perceived support appears to also reflect stable, persistent beliefs about others' likely future behavior. As such, it can promote adaptive responses to stressors and obstacles: Before actual support is even necessary, perceived support can lead an individual to appraise a situation as less stressful (because the individual expects that he or she will be able to draw on others' help to cope with the stressor), lowering the demand for objective support or other coping. Perceived support beliefs show some consistency across multiple others, but they can also vary between types of relationships or between specific individual others. For example, an individual can see a romantic partner as very supportive and a friend as not very supportive, or vice versa.

Research indicates that perceived support is associated with several of the same processes as global optimism, including adaptive coping, favorable expectancies, and positive affect. Recently, several studies have provided more direct support for a link between optimism and perceived support. Optimism has been associated with perceived support among air crash rescue workers, bereaved men, romantic couples, and students transitioning to college. It appears that, if global optimism is a general tendency to expect good things, perceived support is a more specific manifestation of optimism in which one expects a particular good thing (social support) in a particular context (close relationships).

Supportive Behaviors in Relationships

Another way that optimism can lead to positive relational outcomes is through actual social support, both offered and received by optimists. One factor to consider is the sheer availability of supportive others. Optimism is a socially valued trait, and as a result optimists tend to be well-liked by others and have larger social networks. Thus, one of the benefits of optimism is to simply have more people available to offer support in difficult times.

Beyond sheer quantity of support, however, optimism affects the quality of support given and received in close relationships. According to the expectancy-value framework, optimists will expect that conflicts with partners can be successfully resolved. As a result, optimists can be expected not to withdraw from conflicts and instead to engage in flexible, constructive, and cooperative problem-solving behaviors with partners. Withdrawal or disengagement from conflict is a major risk factor for relationships; optimism should therefore lower the probability of this risk. Research has supported this prediction: When discussing conflicts with partners, optimists are more likely to listen to their partners and demonstrate interest, and less likely to criticize or withdraw from the conflict. Of particular interest is that the partners of optimists engage in the same constructive behaviors as optimists. In other words, the partner of an optimist will reciprocate the optimist's flexible engagement in problem-solving, regardless of the partner's own level of optimism. These reciprocal, constructive problem-solving processes are a major mechanism by which optimism brings about positive relationship outcomes (i.e., high relationship satisfaction for both partners, and low probability of breakup or divorce).

Specific Optimistic Beliefs

This entry so far has addressed global, dispositional optimism—the general tendency to expect favorable outcomes. A complementary approach is to define optimism with respect to some particular time, situation, or life domain. Thus, rather than focusing on (global, stable) optimists versus pessimists, one might instead consider the importance of particular optimistic beliefs. As discussed

earlier, the two ways of thinking about optimism are not entirely unrelated. A global tendency to be optimistic (“good things are going to happen”) can give rise to more specific optimistic beliefs, such as perceived support (“my partner will still love me after this argument”), that act as more specific expectancies to support flexible and constructive pursuit of relational goals. As a practical matter, however, an emphasis on specific beliefs highlights avenues for intervention and change: Whereas it might be difficult to change someone’s global outlook, it is more reasonable to target specific beliefs in domains where they are causing the most harm (i.e., through therapy or self-improvement).

Generally speaking, research on optimistic beliefs about relationships has shown that they lead to adaptive outcomes. Research by Sandra Murray and others has shown that partners who have *positive illusions* about each other—meaning more positive views of a partner than the partner has of himself or herself—have more satisfying and longer-lasting relationships. Such positive illusions are most adaptive when they are quite general in their content: A belief that “my partner is a good person” tends to be beneficial for the relationship, even if the believer has to overlook a few of the partner’s foibles and failings. However, unrealistically optimistic beliefs about partners are less adaptive when they are so specific that they create opportunities for tangible disappointment. For example, a belief that “my partner is a neat and tidy person” can raise high expectations that come crashing down when faced with a sink full of dirty dishes night after night. Researchers Lisa Neff and Ben Karney have identified “global adoration and specific accuracy” as an especially adaptive pattern in marital relationships.

Conclusion

Optimism brings about positive outcomes in relationships by promoting favorable expectancies, which in turn cause individuals to pursue their relationship goals more flexibly and persistently. This core principle helps explain why other individual differences that correlate only modestly with optimism, such as a secure attachment style or low fear of negative evaluation, appear to lead

to many of the same outcomes: They are multiple pathways to favorable expectancies. This principle also suggests avenues for therapeutic intervention or self-improvement. The benefits enjoyed by optimists may be accessible to individuals who work on changing their beliefs. By identifying and revising irrational or pessimistic beliefs about a partner, through therapy or introspection, it may be possible to cultivate a mindset that will lead to more constructive interactions with a partner, and ultimately, to a more satisfying and longer-lasting relationship.

OSTRACISM

Ostracism—ignoring and excluding others—is one of the most fundamental strategies for regulating behavior among all social animals, including humans. Social animals such as lions, primates, and even bees ostracize burdensome members to protect and strengthen the group.

Among social animals and in tribal communities, ostracism typically results in death of the ostracized member. Humans also ostracize to strengthen the group, in addition to gaining control over the outcast member, to increase cohesion among the other ostracizing members, to protect themselves from similar treatment by others, and to punish. Ostracism can lead either to ultimate expulsion or can motivate the ostracized member to adjust his or her behavior to be acceptable to the others. In close relationships, a relational form of ostracism is a common occurrence—in Western cultures, it is called *the silent treatment*. At least 70 percent of adults in the United States report being given the silent treatment by a loved one. The silent treatment consists of several behaviors, including silence by the ostracizer to the target of the ostracism, but also lack of responsiveness (verbally and nonverbally), and aversion of eye gaze.

Many experimental studies are now aimed at assessing the impact of ostracism, as well as related concepts such as social exclusion and rejection. Methods for inducing ostracism range from humiliating and public forms of rejection and expulsion, to seemingly innocuous instances of being excluded in a virtual ball toss game (called Cyberball) with strangers. Additionally, telling people that others do not wish to work with them, that their personalities indicate a future alone, or even asking them to imagine past or future instances of exclusion are sufficient to induce the painful consequences of ostracism. A handful of qualitative or interview studies assess the long-term impact of persistent ostracism, as well as role-play and diary studies. This entry discusses three stages of ostracism's impact on the individual: immediate (or reflexive) responses, short-term (reflective) coping reactions, and long-term (resignation) reactions.

First Stage: Reflexive Pain

The impact of ostracism on the target follows three stages. During the initial ostracism episode itself, the target feels pain and distress. This pain has been documented by self-reports, pain estimates, and activation of the dorsal anterior cingulate cortex (dACC), the same region of the brain

that is activated when individuals experience physical pain. The ostracized individual then experiences a threat to four fundamental human needs: the need to belong, to maintain a reasonably high self-esteem, to perceive control over his or her environment, and to feel worthy of attention and recognition, also known as meaningful existence. Mood shifts, such as increased anger and sadness, also occur.

Diary research shows that individuals are ostracized about once a day, but many of these instances are relatively minor, such as being ignored by strangers in elevators, and lead to swift recovery. However, when ostracized by important others or by a loved one, recovery is slower and is more distressing for the individual. Nevertheless, the initial pain experienced by any episode of ostracism, regardless of how minor or irrelevant it may seem, appears to be experienced similarly by everyone. Studies have shown that individuals experience the same levels of need threat and distress when ostracized by ingroup members, outgroup members, despised others, even when they know it is being done by a computer. Further, ostracism is similarly painful when one benefits financially from exclusion and when inclusion is costly. Even when one expects to be ostracized in a virtual ball toss game with strangers because the individual's computer is not yet communicating with the other players' computer, distress is experienced. All these findings suggest that detecting ostracism is quick and crude, seemingly bypassing interpretations that would logically lead to easy dismissal. That is, logically, it should be easy to dismiss ostracism by a computer, or by a despised outgroup, but the immediate or reflexive response is still to feel pain.

Second Stage: Reflective Appraisal and Fortification of Threatened Needs

In the second stage, individuals strive to fortify the needs that are most threatened, through thoughts and behaviors that increase a sense of belonging, affirmation, control, and recognition. The individual increases his or her inclusionary status by becoming more sensitive and likable to others, especially when belonging and self-esteem are most threatened. If control and desire for

recognition are most threatened, the individual may resort to provocative behaviors and even aggression toward the ostracizers and even naïve others.

Thus, research tends to demonstrate two diametrically opposed behavioral clusters. When control is not overly jeopardized (as when reinclusion is possible or one has his or her control reinstated even in another domain), ostracized individuals are more likely to attend to social information (compared with nonsocial information, and in contrast with included individuals), nonconsciously mimic (i.e., copying the behaviors of another without awareness) another person, especially one who shares ingroup membership, strategically behave more cooperatively, conform more to a new group that is unanimously incorrect in its members' perceptual judgments, comply more to requests from a stranger, and behave more likably to others. However, when future inclusion is unlikely or when a sufficient amount of control has been thwarted, individuals have also been shown to be aggressive to ostracizers and naïve others alike, to be uncooperative and unhelpful to those in need, and to be less able to engage in helpful self-regulation.

Third Stage: Resignation

When individuals face repeated or persistent episodes of ostracism from their groups or relationship partners, their ability to allocate resources to fortify their thwarted needs becomes compromised. At some point, they lack the resources, energy, or hope to build up what has continually been torn down. No longer able to attract others or be reincluded, they are more likely to become alienated and resentful of others. For instance, rarely succeeding in the affirmation that inclusion affords, they become depressed. Whereas initial barriers to control lead to reactance (attempts to take control), continued experience with no control leads to learned helplessness, giving up, and depression. Knowing one is unworthy of attention and not being capable of directing others' attention and recognition of the self leads to despair and dysfunctional and unhealthy life choices. Thus, for individuals whose partners give them the silent treatment, either continuously

over the years or routinely after every displeasing act, their options appear to diminish along with their self-esteem. They, in essence, follow the course of an abused spouse who remains in the relationship because they see no other alternatives. In interviews with individuals who have experienced lifelong ostracism, they report suicidal ideation or actual attempts, promiscuity or isolation, depression, eating disorders, and poor health.

People who routinely engage in ostracizing behavior (or the silent treatment) appear to be similarly distressed in the long run. They report that the habit is so strong that it becomes the first line of defense rather than the method of last resort. They report losing close relationships with important others, transforming their targets into, as one research participant said about his son, "a spineless jellyfish," and stripping away their targets' sense of self. Once they have opted to engage in long-term ostracism, they report the inability to reconcile or to begin a "talking treatment" that will heal the relationship. Silence begets silence, and the target eventually reciprocates it.

Conclusion

The emerging literature on ostracism, social exclusion, and rejection suggests that it saps one of the most primitive and core requirements of human nature—belonging to others in a reciprocal and responsive interaction. Given that ostracism is (or was) an adaptive behavior by those who use it, methods to decrease its use will be difficult. Animals use it, children use it, and institutions use it. Parents and teachers give "time-outs" as a form of punishment and behavioral discipline. Ostracism is ingrained in our lives. Thus, the more hopeful course of action will be to seek ways in which targets can immunize themselves to ostracism's self-perpetuating spiral of self-loathing, and to either improve their social skills or to offer them cognitive plans to be included by other individuals and groups.

PARENT–ADOLESCENT COMMUNICATION

Adolescence is generally viewed as a difficult period for both adolescents and their parents. The popular perception is that the quality of parent–child relationships declines precipitously during adolescence and teenagers become moody, rebellious, difficult, and disobedient to parents. Yet the overwhelming evidence from decades of psychological research indicates that alienation, rebellion, and very conflicted relationships with parents are the exception, not the norm, and that they occur in only about 10 to 15 percent of all families. Moreover, when found, they usually have their origins in very negative and conflicted relationships prior to adolescence. Research suggests that there is a great deal of continuity from childhood to adolescence in the quality of parent–child relationships. Nevertheless, parent–child relationships and communication change normatively during adolescence. Conflicts and disagreements with parents increase during adolescence, and closeness and adolescents' disclosure to parents about activities declines as teenagers spend less time with parents and more time with their friends. The following sections describe our understanding of adolescent–parent communication, including age-related changes in the amount of time adolescents and parents spend together, conflict and closeness in relationships, adolescents' willingness to disclose to their parents, and adolescent–parent interactions.

Time Spent Together

Psychological research has shown that, with increasing age, teenagers and parents in both the United States and Europe spend progressively less time in each other's company. Psychologists often have assessed the amount of time spent together by employing the "experience sampling method," a daily diary method. Research participants carry pagers for 1 week, and when signaled at random intervals, they report on their location, activities, companions, experiences, and moods. Reed Larson and his colleagues have used this method in many studies and found that the amount of time adolescents spend with their family drops dramatically and steadily across adolescence, from about a third of their waking hours to only about 14 percent. Interestingly, at least in early to middle adolescence, the drop in time spent interacting with the family is because teenagers spend more time alone rather than out of the house. Moreover, there are age-related shifts in the types of activities families report. With age, they spend less time together watching TV and increased time talking together, particularly when siblings are present and more with mothers than with fathers. Family conversations increasingly focus on interpersonal topics, especially for girls. During the high school years, declines in amount of time spent together are partially due to other out-of-home opportunities and "pulls," like jobs or having a driver's license. Thus, although the amount of family time spent together diminishes, there is more direct interaction with parents.

Negative Interactions and Adolescent-Parent Disagreements

Research using the experience sampling method also has shown that there are developmental changes in adolescents' daily emotional experiences within their families. Negative emotional states increase with age, and there are fewer extreme positive states, although the downward trend stops in late adolescence. Early adolescents' emotions are in flux, but there is increasing stability in their daily emotional experiences as they progress through adolescence. These findings parallel the results of both questionnaire studies and observations of family interactions, which typically find that negative interactions increase during adolescence. Across adolescence, girls report less negative affect, as measured on a daily basis, than do boys, but girls also report a wider range of daily variations than do boys in their positive and negative emotions. Also, across adolescence, increases in negative moods are strongly and consistently associated with increased daily stress.

Accompanying the age-related increases in negative emotions, parent-adolescent relationships are typically characterized by modest increases in bickering and disagreement, particularly during early adolescence. Conflicts are usually over everyday, mundane issues such as doing chores around the house, the adolescent's appearance, getting homework done, choice of leisure time activities, and preferences for music, TV, and movies. Thus, conflicts often pertain to adolescents' styles and preferences, rather than to differences in values; in fact, there is a high degree of similarity in religious and political values across generations. Psychologists generally agree that conflict in early adolescence is a normative and temporary perturbation that helps to transform family relationships from a more hierarchical organization (with parents in charge) to a more equal relationship. Research has shown that moderate levels of conflict with parents are associated with better psychosocial adjustment than either no conflict (because a willingness to express different opinions and points of view is considered a healthy aspect of all relationships) or very frequent conflict and that moderate conflict in early adolescence does not influence the quality of later parent-adolescent relationships.

Researchers have distinguished between the rate of conflict (how many conflicts occur and how often they occur) and their intensity (how angry participants get). The evidence indicates that the rate of conflict peaks in early adolescence (ages 12 and 13) and then declines, whereas conflict intensity increases from early to middle adolescence. Adolescents typically have more frequent and intense conflicts with mothers than with fathers, and mother-daughter dyads are usually more conflictive than mother-son dyads (or father-child dyads). Furthermore, similar age trends in parent-adolescent disagreements are found among American families from different ethnic, racial, and cultural backgrounds and also have been observed among Asian youth in Hong Kong and the People's Republic of China, although perhaps at a lower frequency than among European-American youth.

Different explanations have been offered for the increased conflict observed in early adolescence. Laurence Steinberg has proposed that conflicts are due to the biological changes of puberty. Pubertal maturation and the accompanying physical changes in height, weight, and appearance signal adolescents' increasing maturity to parents. Research has shown that as puberty progresses, adolescent males gain more power in the family. Thus, prior to puberty, fathers typically are the most powerful family members, followed by mothers and then sons. After boys pass the peak of pubertal change, the hierarchy shifts, and sons gain more power than mothers (but remain below fathers in terms of dominance). Similar changes in the dominance hierarchy following puberty have been observed among primates, leading some researchers to assert that this is an evolutionary adaptation. In a similar vein, psychoanalytic theory has been used to assert that adolescents separate and detach from parents at puberty and that this is necessary to form new attachments to romantic partners.

Andrew Collins has proposed that the rapid physical, cognitive, and social changes occurring in early adolescence lead to violations of expectations. Parents expect more mature behavior to accompany these observed physical changes, and discrepancies in expectations and behavior cause conflict. Finally, Judith Smetana has found that adolescents and parents interpret conflicts in different ways. Parents reason about conflicts primarily in terms of enforcing social-conventional and

normative standards (“It’s my house, so you need to follow my rules”) and the need for social coordination and responsibility, whereas teenagers overwhelmingly view conflicts as issues of personal choice and prerogatives (“It’s my room—it’s my choice”). When parents attempt to control issues that teenagers believe should be personal, parents may be perceived as overly intrusive and controlling (referred to as parental psychological control), and high levels of parental psychological control have been associated with both greater depression and anxiety and greater conduct problems among teens. Although teenagers want more personal freedom from parents, parents must decide whether teenagers have the competence or maturity to take on new privileges, and parents also are concerned with safeguarding adolescents’ health and safety.

Although the explanations vary, all of these approaches agree that moderate levels of parent-adolescent conflict, especially in the context of supportive parent-adolescent relationships, lead to adolescents’ greater independence from parents. In addition, Susan Silverberg and Laurence Steinberg have pointed out that many parents are coping with their teenagers’ developmental changes at the same time that they are also confronting their own midlife developmental issues and that this can impact parents’ well-being. Conflict with adolescents among parents who are facing midlife issues can lead to increased depression and life dissatisfaction, particularly for mothers.

Overall, most of adolescents’ conflicts with parents are resolved by walking away or giving in to parents, but at least among European-American youth, there is some transfer of power with age, with adolescents getting their way more often. In minority families, it is more common for parents to have the final say in disputes, but as adolescents of other ethnicities become more American acculturated, they resemble European-American youth more in their patterns of conflict resolution. Researchers have claimed that learning to resolving conflicts effectively provides teenagers with developmentally appropriate opportunities to learn negotiation skills that can be used in other relationships.

Divorce and remarriage lead to structural changes in the family and temporarily disrupt adolescent-parent relationships. They also typically lead to increased parent-adolescent conflict, particularly in the first 2 years following a divorce

and with a new stepparent. However, there appears to be less adolescent-parent conflict in stably divorced, mother-headed households than in two-parent households perhaps because mother-adolescent relationships in single-parent, divorced families tend to be less hierarchical and more egalitarian. Both chronic and sudden economic strain due to job loss and unemployment are associated with more negative parent-adolescent relationships, including greater parent-adolescent conflict and more negative emotions.

Research on within-family (sibling) differences in adolescent-parent relationships suggests that conflict increases for both siblings when the first born transitions into adolescence. Furthermore, recent research also has demonstrated that parents’ prior childrearing experience with their first borns influence their expectations for their younger child’s adolescence, even when researchers take the child’s temperament (personality) into account. Parents have less conflict with and greater knowledge of daily activities for later-born than first-born adolescents.

Closeness and Warmth

A well-established finding, obtained in both questionnaire studies and in laboratory studies where trained raters observe parent-adolescent interactions, is that support, closeness, cohesion, and intimacy with parents decline during adolescence. Similar patterns of age-related declines in warmth and cohesion have been observed in ethnic minority and majority youth, but closeness tends to decline at later ages among minority youth and youth from other cultures than among European-American teenagers. A number of studies also suggest that relationships with parents also improve once adolescents leave home.

Relationships with mothers and fathers differ in both quality and substance. Studies consistently show that, across ages, adolescents are closer and spend more time in direct interaction with mothers than with fathers. Mothers have been described as providing more emotional support to their children, whereas fathers provide informational and material support. In keeping with this finding, adolescents also talk more about private matters like dating and sexual attitudes and information with

mothers, but discuss impersonal issues, such as schoolwork, future plans, and social issues, equally with mothers and fathers. In addition, girls discuss private matters with mothers more than do boys.

Parental Monitoring and Adolescent Disclosure

A long-standing conclusion in psychological research is that parental monitoring is increasingly important in adolescence because it allows parents to keep track of their adolescents' activities, peer associations, and whereabouts while permitting greater autonomy. Recently, however, Margaret Kerr and Hakan Stattin found that even accounting for the quality of the parent-adolescent relationship, parents' knowledge of adolescents' whereabouts and activities comes more from adolescents' voluntary disclosure to parents than from parents' attempts to obtain information, track their activities, or control their behavior.

Researchers have identified different strategies that parents use to keep track of adolescents when they are out of the house. Parents may use active methods, such as asking teens directly, asking others (like teachers or their spouse) about what teens are doing, or actively participating in activities with teens (such as driving the child to activities). They also can obtain information voluntarily from others, like the teen or their spouse. Research suggests that mothers and fathers obtain knowledge in somewhat different ways, with mothers using more active means and fathers relying more on obtaining information from their spouses. Mothers and fathers who employ a relational style that includes more voluntary disclosure from teens and more listening and observation tend to know more about their middle adolescents' activities than parents who use other strategies, and, in turn, this greater knowledge has been linked to lower levels of risky behavior over time. For fathers, obtaining information from spouses has also shown significant over-time associations with parental knowledge and subsequent reductions in risk.

Disagreements with parents are a fact of life during adolescence, but as adolescents spend more time out of the house and in the company of peers, they have increased opportunities to decide whether to disclose or withhold information about their activities

from their parents. Evidence suggests that adolescents disclose less to parents in middle adolescence, just when conflict frequency declines and conflict intensity peaks, than at earlier ages. Thus, with age, adolescents may choose to conceal information rather than confront their parents directly. Researchers believe that adolescents' information management provides another route to autonomy development.

Adolescents rarely tell their parents all the details of their whereabouts, associates, or activities, especially when they disagree. According to Nancy Darling, however, when adolescents fully disclose to parents, they do so primarily because they feel obligated to disclose and less frequently because they believe that their parents can legitimately regulate the issue, because they hope to change their parents' minds, or because they feel they cannot get away with not disclosing. Several studies have shown that adolescents' willingness to disclose information to their parents is associated with more responsive parenting, greater trust in parent-adolescent relationships, greater parental behavioral control, and greater parental acceptance. It is also associated with adolescents' better psychosocial adjustment. Also, girls tell their parents more about their activities than do boys.

Adolescents' management of information can range from acts of omission (e.g., avoiding the issue or providing partial information) to deception or lying. Several studies have found that nearly all adolescents report not disclosing information at least some of the time, and their primary strategies include telling parents some of what they want to know while leaving out important information or avoiding the topic altogether. Adolescents do not interpret these forms of information management as lying because they are not intentionally misleading parents by providing them with untrue statements. Lying is less frequent than these other strategies for information management, although researchers have found that nearly all high school students have lied to parents at least once during the past year about money, friends, sexual behavior, friends, parties, dating, and alcohol and drug use. Lying to parents is considered more acceptable among high school than college students and among boys than girls. Adolescents' lying to parents has been associated with poorer adjustment, greater tolerance of deviance, and poorer adolescent-parent

relationships. Although adolescents view dishonesty to parents as morally wrong, they view it as justified when parents treat them unfairly or infringe on their personal prerogatives. Psychological research is just beginning to investigate disclosure, secrecy, and strategies for information management among adolescents of different ethnic, racial, and cultural groups.

Adolescent-Parent Communication and Interactions

Observational studies of family interactions indicate that parents and adolescents reciprocally influence each other. Studies including adolescents of different ages, as well as studies following the same adolescents over time, have found that family interactions that allow adolescents the opportunity to express independent thoughts and feelings while maintaining closeness and connection to parents lead to more mature development and better psychosocial adjustment, including better self-esteem, greater competence, less depression, greater identity development, and more mature moral reasoning. There is some evidence to suggest that when families live in poor and dangerous environments, mothers who undermine their adolescents' independence have better relationships with their teens most likely because limiting autonomy in these contexts is seen as a protective strategy to keep youth safe. Among adolescents living in low-risk environments, however, having a mother who undermines autonomy is associated with poorer relationships with parents.

Research also shows that when parents and adolescents share decision-making authority and make decisions together, adolescents demonstrate better adjustment and are less involved in deviance than when either parents or youth independently make decisions without the other's input. It is particularly advantageous for parents to be involved in and provide some input into adolescents' decision making in early and middle adolescence. However, adolescents typically become more autonomous in their decision making by late adolescence, and increased decision-making autonomy between middle and late adolescence leads to better adjustment, including better self-esteem and less depressed mood, in late adolescence.

Parents and adolescents have both unique and shared views of their family interactions. When adolescents and parents are observed interacting together in laboratory tasks, their perceptions of their family interactions typically diverge from each other and from trained observers' ratings. Parents generally perceive their family interactions as more loving, warm, and cohesive than do outside observers, who in turn view these interactions more positively than do teens. Parents and trained (adult) observers' views of parent-adolescent interactions are more consistent than are observers' and teenagers' perceptions. It is worth noting that these findings differ from the results of research on highly satisfied married couples, which has generally found that spouses share an understanding of their interactions that outside observers do not. In contrast to married couples, parents and adolescents appear to have different stakes in their relationships. Parents may maximize similarities because they want to maintain continuity between generations, whereas adolescents may minimize similarities because they want to differentiate from parents.

Thus, the research reviewed here suggests that conflicts, disagreements, negative moods, closeness, intimacy, and support are all important and developmentally salient aspects of adolescent-parent relationships.

PARENTAL INVESTMENT THEORY

Parental Investment Theory is a biological theory that attempts to explain the dynamic, give-and-take relationships among parents, their offspring, and limited resources. In many species, parents are forced to make a difficult choice between investing in themselves (e.g., survival, mating) and investing in their offspring (e.g., feeding, protection). Although both parents typically have a shared interest in the survival of their offspring, males in most species invest substantially less in their offspring than females, due in part to the fact that females must carry their offspring to term and often provide food, breast milk, and protection. This biologically based sex difference in parental investment has several implications for sexual and familial human relationships. This entry describes the theoretical background of parental investment, summarizes related biological theories such as Inclusive Fitness Theory, and discusses Parental Investment Theory’s implications for attachment patterns, human development, and sexual and familial relationships in humans.

Biological Background

In many species, individuals compete with each other for limited resources such as food and mates. Parenting poses the additional problem of trading off investing in offspring versus investing in oneself or other mates. Creating and rearing offspring is often costly, and this is especially true for female mammals, which are biologically obligated to invest their energy in their offspring during gestation.

This investment often continues following the birth of their offspring to include breastfeeding, caretaking, securing food, and protection from predators. Male mammals are typically not obligated to invest in their offspring once they have contributed their sperm. In many mammalian species, male parental investment is not necessary for offspring survival (e.g., cattle, orangutans). Thus, there is a biologically based cost asymmetry for males and females in terms of parental investment in their offspring; the cost for females is nearly always far greater. Thus, the sex difference in paternal investment in offspring in many species is one of quantity versus quality: Males seek to maximize the number of offspring they can produce by seeking multiple mates, whereas females seek to maximize the survival and viability of the offspring they produce.

There is some evidence that offspring who receive some paternal investment are more likely to survive and reproduce than those who receive less or no paternal support. From an evolutionarily perspective, if offspring require investment to thrive and survive, and if paternal investment gives offspring a survival or reproductive advantage over and above maternal investment, then genes favoring paternal investment may be naturally selected for over evolutionary time. Thus, species that currently exhibit some forms of paternal investment, such as modern humans, owl monkeys, and siamangs (a lesser ape), may have faced selection pressures in the evolutionary past that favored some paternal investment over none (e.g., scarce resources). In humans, the protracted length of defenselessness in infancy and early childhood may have facilitated the natural selection of paternal investment over evolutionary time.

Parental Investment Theory seeks to explain the balancing act among the biological drives of the mother, the father, and their offspring. It is a balancing act because there are inherent cost-benefit trade-offs. Investing in offspring often incurs a substantial cost on the investing parent. Energy that parents could use to promote their own health or to find better or additional mates instead gets channeled into promoting the health and development of their offspring. Although the offspring are the direct beneficiaries of parental investment, the parents may later reap the indirect benefits of having their genes passed on to the next generation should their

offspring survive and reproduce. There is, however, an additional cost-benefit asymmetry: The cost of reproduction for males (e.g., contributing sperm) is far less than the cost of reproduction for females (e.g., months of pregnancy, breastfeeding, caretaking, and protection). Thus, in many mammalian species, males are more likely to spend their energy competing with other males to gain access to additional mates, whereas females are more likely to devote more of their energy to providing nurturance and protection for their offspring.

Parental Investment Theory is partly subsumed by a broader biological principle called Inclusive Fitness Theory. Inclusive Fitness Theory posits that individuals are more likely to help and share resources with kin to whom they are closely genetically related than they are with kin to whom they are distantly genetically related or with unrelated persons (nonkin). For example, all else being equal, a person might be more willing to lend money or donate a kidney to a full sibling than a first cousin. This is due in part to the fact that a person shares one-half of their common genes with a full sibling on average, whereas a person shares only one-eighth of their common genes with their first cousin on average. That is, copies of a person's genes are more likely to be found in their sibling (a first-order relative) than in their cousin (a third-order relative). It is theorized that, over evolutionary time, individuals who acted prosocially toward their relatives—even if it incurred a cost—could potentially reap indirect benefits if the prosocial act promoted the survival and reproductive fitness of those relatives who carried copies of the person's genes. Inclusive fitness theory is important to Parental Investment Theory because it helps explain why parents typically invest more in their own offspring than in others' offspring (e.g., nieces, nephews, or unrelated children).

Parental Investment Theory has broad implications for the biological and social sciences. For example, it has garnered a great deal of empirical support in animal models, particularly among species whose offspring cannot survive without some parental investment. Parental Investment Theory also has important implications for human relationships. Among these are paternal uncertainty, mate preferences in sexual and romantic relationships, timing of sexual maturation in girls, and attachment patterns.

Paternal Uncertainty

Paternal uncertainty is an important concept with regard to parental investment. Because women have concealed ovulation and may engage in extrapair copulations (i.e., having more than one sexual partner in a short period of time), men can rarely be certain that their child is in fact their own (i.e., cuckoldry). In contrast, women can be absolutely certain that the child they are carrying is in fact their own. Thus, there is an asymmetry in relatedness certainty between the sexes. Paternal uncertainty can have important implications for parental investment. For example, men are more likely to experience jealousy at any hint of sexual infidelity in their partner and are less likely to invest in their purported offspring if they believe their partner has been sexually unfaithful.

Sexual and Romantic Relationships

Parental Investment Theory has key implications for understanding human sexual and romantic relationships. Because the cost of bearing and rearing children is higher for women than for men, the two sexes differ somewhat in the emphases they place on preferences for mates. Because women typically seek resources and protection for their children, women especially desire strength, dominance, intelligence, ambition, wealth, and the potential for obtaining wealth in their partners. In contrast, because men typically seek multiple mating opportunities, men especially desire characteristics related to physical beauty and fertility in their partners (e.g., youth, healthy appearance, a low waist-to-hip ratio). These sex differences in mate preferences are especially pronounced among people seeking short-term mates (e.g., casual sexual encounters). When people seek long-term mates (e.g., marriage), they are usually forced to compromise on some of their mate preferences to find a well-rounded partner; as a result, these sex differences in mate preferences are smaller in magnitude, but still persist on average. Research on jealousy and reasons for relationship dissolution show a similar pattern. Men tend to experience more jealousy than women regarding their partner's possible sexual infidelity. In contrast, women are more likely than men to abandon their partner if he loses

status or resources (e.g., being fired from a job). In terms of romantic relationships, Parental Investment Theory may help explain why women may tend to leave their mates for wealthier men and why men tend to leave their mates for younger women. Parental Investment Theory may also help to explain why relationships can become particularly strained when resources are scarce, a new baby is on the way, or both. Thus, due to biologically based differences in parental investment costs, men and women experience different pressures to initiate, maintain, dissolve, and repair sexual and romantic relationships.

It is important to note that there is both individual and cross-culture variation in the extent to which the sex differences in mate preferences are exhibited. Moreover, comparatively little is known about how Parental Investment Theory may affect mate preferences in same-sex couples. Nevertheless, a growing empirical literature of questionnaire, laboratory, and field studies have supported the notion that biological differences in parental investment are responsible for some of the observed variation in sex differences in mating preferences. Both men and women, however, do seek common characteristics in mates (e.g., fidelity, agreeableness) and do have a shared interest in the survival of their offspring.

Parent–Child Relationships

Parental Investment Theory has straightforward implications for parent–child relationships. For example, children who have parents who are warm, attentive, and provide resources are more likely to form secure attachment patterns, whereas children who have parents who are neglectful and provide fewer resources are more likely to form anxious-avoidant or anxious-ambivalent attachment patterns. The fact that anxious-ambivalent children warm to strangers more easily than their secure counterparts may even be an adaptive reaction, in that they are trying secure additional resources from a stranger given that their biological parent has only provided inconsistent support and resources. The sex difference in parental investment may also explain why mother–child attachment is comparatively more central to the psychosocial development of a child than father–child attachment, although it

is also possible that greater attachment leads to greater investment.

Maturation and Menarche

There is some empirical evidence that parental investment (or lack thereof) may be related to accelerated sexual maturation, particularly among girls. For example, some research has suggested that girls who are raised in father-absent homes tend to achieve menarche (first menstrual period) earlier than girls who are raised in homes where their biological father is present. Other research has suggested that lower socioeconomic status (SES), which is more common in father-absent homes, may better explain this relationship. Girls who are raised in low-SES or father-absent homes may have few resources, and this may put them on a developmental trajectory where they mature early so that they can gain resources from potential mates instead of their fathers. Although the precise mechanism of this effect is not entirely clear, it appears that paternal investment may play some role in shifting girls' pubertal timing. Much of this research is currently correlational; there is little definitive research showing a causal relationship between paternal absence or lack of paternal investment and accelerated sexual maturation in girls.

PARENT–CHILD COMMUNICATION ABOUT SEX

Children become aware of issues surrounding sex and reproduction at a much earlier age than their parents typically anticipate. Everyday life is filled with situations and stimuli that could cause young children to be curious about these matters. Parents should recognize that their children's curiosity is normal and that truthful, but age-appropriate responses would be an effective response. Parents need to be aware that information about sexuality can also be conveyed nonverbally and indirectly in the form of uncomfortable body language and silence about particular topics. Parent–child communication about sex is one way to help children learn about sex and develop sexual values that are consistent with those of their parents. This entry examines research on the prevalence, form, and impact of parent–child sexual communication, as well as the characteristics of those parents who are most likely to discuss sex with their children.

Methodology

There are several ways that parent–child communication about sex has been assessed. Researchers have examined the frequency of sexual discussions, the number and types of topics discussed, the perceived quality of communication, the comfort level of the participants, and the nature and pattern of the discussions. Typically, this is done

in the form of a questionnaire administered to the parents and/or the children, but some researchers have videotaped family sexual discussions or have interviewed family members.

There is generally little correspondence between parents' and children's reports of how much family sexual discussion has occurred. In addition, children are often unaware that their parents disapprove of premarital sex, and parents are often unaware that their children have already engaged in sexual activity. This suggests that family members are not necessarily reliable sources of information about each others' behavior.

Predictors of Parent–Child Sexual Communication

There is virtually no research on parent–child communication with children less than 10 years of age about sex. There are, however, many studies of parent–child communication with adolescents, yielding some consistent findings as well as some confusion. It is clear that many parents do not discuss sexuality with their children. Parents are more likely to discuss sex with their daughters than with their sons, and mothers are more likely to engage in such conversations with sons and daughters than are fathers.

Parents are more likely to talk to their children about sex if they have higher levels of general communication with their child, a greater belief that other teens are engaging in sexual activity, and greater concerns about adolescent sexuality. Mothers who report more sexual discussion with their children tend to have more open general family communication, have greater feelings of competence in sexual communication, and are more likely to have had sexual discussions with their own mothers. Fathers who communicate with their children about sex are also more likely to be open in general family communication, to have discussed sexuality with their own fathers, and to have more years of formal education.

There are some cultural differences with regard to the extent of parent–child communication about sexuality. Parents who are White or African American are more likely to discuss sexuality with their adolescent children than are parents who are Hispanic or Asian. African-American families tend to discuss

sexuality at an earlier age and are more likely to discuss “sensitive” topics than White families.

The Nature of Parent–Child Sexual Communication

Parents avoid sexual discussions with their children for a number of reasons, including potential embarrassment, a fear that they have inadequate knowledge to convey, uncertainty as to how and when to begin such conversations, and a sense that children today already know all there is to know about sexuality, would not take the talk seriously, and would view it as prying.

Those parents who talk to their children about sex tend to focus more on biological aspects of reproduction as well as abstinence and contraception. Findings are mixed with regard to discussions of the risks of sexual activity, with some researchers reporting that parents shy away from the topic and others finding that parents tend to stress the dangers of sex. Such family sexual discussions tend to bypass or downplay the pleasurable and positive aspects of sexuality, particularly in talks with daughters. Family discussions about sex typically involve less mutual participation and fewer words than nonsexual conversations.

Potential Impact of Parent–Child Sexual Communication

Some studies suggest that family discussions about sex are related to more responsible sexual behavior on the part of adolescents, with teens who have had more opportunities to discuss sex with their parents being less likely to engage in premarital sexual activity and, if they do have sex, being more likely to use contraception and to have fewer sexual partners. However, just as many studies have failed to find such a correlation.

When researchers take into account factors beyond simple frequency or extent of sexual discussions, there do seem to be some significant correlations with the behavior of the adolescent children. When permissive parents talk to their children about sex, their offspring are somewhat more likely to engage in premarital sex than when conservative parents talk to their children. Specifically discussing contraception is related to a

greater likelihood of safer sex. In addition, family sexual discussions when adolescents are younger and before they have engaged in sexual intercourse tend to be more effective. Finally, if adolescents perceive their parents as being comfortable and open during sexual discussions or when the adolescents are comfortable during the conversations, they are more likely to delay sexual intercourse and use contraception. It is likely that these positive effects are due at least in part to greater closeness and better general family communication in those families in which sexuality is discussed.

There are few studies that support the view that if parents talk to their children about sex, the children will have more knowledge about sexuality. Parent–child sexual communication appears to have more of an effect on the sexual attitudes or values of children than on knowledge or behavior. Studies indicate that parents who have had more communication about sex with their late adolescent children have offspring whose sexual attitudes are much more similar to their own than do parents who have had less communication about sex with their children.

PARENT–CHILD RELATIONSHIPS

One of the most important and earliest relationships is the parent–child relationship. During infancy, this relationship focuses on the parent responding to the infant's basic needs. Over time, an attachment forms between the parent and child in response to these day-to-day interactions. During toddlerhood, parents attempt to shape their children's social behaviors. Parents play various roles for their toddlers, including acting as teachers, nurturers, and providers of guidance and affection. Throughout childhood, children become more interested in peers. However, parents continue to influence their children through their parenting styles. In addition, parents serve as providers of social opportunities, confidants, coaches, and advisors. Although this relationship evolves throughout development, the parent–child relationship still exerts considerable influence over the child.

Theoretical Approaches to Parent–Child Relationships

Several theoretical approaches address the parent–child relationship, including the typological approach, the attachment-theoretical approach, and the social-interaction approach.

The Typological Approach

One of the most influential theories was proposed by Diana Baumrind, who distinguished among three types of parental childrearing approaches. Authoritative parenting is characterized as warm, responsive, and involved, yet unintrusive. Authoritative parents set reasonable limits and expect appropriately mature behavior from their children. Authoritarian parenting is harsh, unresponsive, and rigid. These parents tend to use power-assertive methods of control with their children. Permissive parenting is lax. Permissive parents exercise inconsistent discipline and allow their children to express their impulses freely. Research has found that authoritative but not authoritarian or overly permissive parenting fosters positive emotional, social, and cognitive development in children. Longitudinal studies indicate that authoritative

parenting is associated with positive outcomes for both younger children and adolescents, and that responsive, firm parent–child relationships were especially important in the development of competence in sons. Moreover, authoritarian childrearing had more negative long-term outcomes for boys than for girls. Sons of authoritarian parents were low in both cognitive and social competence. Their academic and intellectual performance was poor. In addition, they were unfriendly and lacking in initiative, leadership, and self-confidence in their relations with peers. Children of permissive or laissez-faire parents were often impulsive, aggressive, and bossy, and they were low in independence and achievement.

Later, a fourth parenting style was recognized—namely, uninvolved parenting, which is parenting that is indifferent and neglectful. Uninvolved parents focus on their own needs rather than the needs of their child. Uninvolved parenting has been associated with disruptions in attachment for infants and impulsivity, aggression, noncompliance, moodiness, and low self-esteem in older children.

More recently, Brian Barber further distinguished types of control that are not fully captured by Baumrind's four-cell typology. He distinguished behavioral control (regulation of the child's behavior through firm but appropriate discipline and monitoring) from psychological control (regulation of the child's activities by modifying his or her emotional state by using guilt or shame induction, love withdrawal, and parental intrusiveness). High levels of psychological control or high use of both behavioral and psychological control is associated with internalizing problems such as anxiety, depression, low self-esteem, loneliness, and self-derogation.

One concern with the typological approach is whether the identified types and their consequences are universal. Recent studies have questioned the generalizability of these styles across SES and ethnic/cultural groups. For example, research has found lower SES parents are more likely to use an authoritarian style, but this style is often an adaptation to the ecological conditions such as increased danger and threat that may characterize the environments of poor families. Moreover, the use of authoritarian strategies under these circumstances has been linked with more positive outcomes for children. A second challenge to the presumed universal advantage of authoritative childrearing styles comes from

cross-ethnic studies. Accumulating evidence underscores the nonuniversality of these stylistic distinctions and suggests the importance of developing concepts that are based on an indigenous appreciation of the culture in question.

Attachment Approach to Parent–Child Relationships

John Bowlby's attachment theory is derived from the evolutionary assumption that both infants and parents are prepared to respond to each other's behaviors in a way that ensures that parents provide their infants with the care and protection that contributes to their survival. Many children form secure attachments, where caregivers serve as sources of nurturance and affection, which gives these children the confidence to explore the world and become more independent. However, when caregivers are less dependable and nurturing, some children form insecure attachments to their caregivers. These children may exhibit resistant, avoidant, or disorganized behaviors toward their caregivers.

Securely and insecurely attached youngsters develop different social and emotional patterns. Research has found that at 4 to 5 years of age, securely attached children were more socially competent, were more socially skilled, and had more friends than other children. Moreover, their classmates considered them more popular than others. At 8 and 12 years of age, securely attached children continued to be more socially competent, peer oriented, and less dependent on adults. Additionally, they were more likely to develop close friendships than their less securely attached peers. At age 19, those adolescents with a history of secure attachment had higher socioemotional functioning, were more likely to have close family relationships, long-term friendships, sustained romantic involvement, higher self-confidence, and greater determination regarding personal goals than peers who had a history of insecure attachment. Attachment has been linked with self-esteem, risk behaviors, and family communication in high schoolers.

The Parent–Child Interactional Approach

Research in this tradition is based on the assumption that face-to-face interaction with parents may provide the opportunity to learn, rehearse,

and refine social skills that are common to successful social interactions with other social partners. This approach overlaps with the attachment approach: Both focus on the importance of examining parent–child interaction patterns in order to understand later development, but they differ in their emphasis on the theoretical centrality of the attachment construct. The parent–child interactional approach focuses more on specific aspects of parent–child exchanges (e.g., positive and negative reciprocity) and assumes that these variables are continuous in contrast to the categorical approach (i.e., attachment classifications) endorsed by attachment theorists. Research in this tradition has yielded several conclusions. First, the nature of the interaction between parent and child is linked to a variety of social outcomes, including aggression and achievement. Parents who are responsive, warm, and engaging are more likely to have children who are more socially competent. In contrast, parents who are hostile and controlling have children who experience more difficulty with peers.

Although there are many similarities in the interactive styles of mothers and fathers, evidence is emerging that mothers and fathers make unique and independent contributions to their children's social development. Quality, rather than quantity, of parent–child interaction is an important predictor of cognitive and social development. Fathers tend to engage in more emotionally arousing interchanges that induce excitement, which has been linked to the development of children's emotional regulation. Mothers, in contrast, are more emotionally modulated in their exchanges with infants and children, but are more didactic and use more toys and materials in their interactions. Both maternal and paternal styles, especially when used in a manner that is sensitive to the child's behavior and emotions, are related to children's success with peers.

Not only are differences in interactive style associated with children's social competence, but the nature of the emotional displays during parent–child interaction is important as well. The affective (emotional) quality of popular children's interactions with their parents differs from that of rejected children and their parents. Consistently higher levels of positive affect have been found in both parents and children in popular dyads than in rejected dyads. Whereas negative parental affect is associated with lower levels of peer

acceptance, children of fathers who tend to respond to their children's negative affect displays with negative affect of their own are less socially skilled (less altruistic, more avoidant, and more aggressive) than their preschool classmates. The influence of the reciprocity of negative affect has been demonstrated only for fathers, which suggests that fathers may play a particularly salient role in children learning how to manage negative emotions in the context of social interactions. Thus, both the nature of parent–child interaction and the affective quality of the relationship are important correlates of children's social development.

Alternative Pathways: Parents as Advisors and Providers of Opportunities

Learning about relationships through interaction with parents can be viewed as an indirect pathway of influence because the goal is often not explicitly to influence children's social relationships with extrafamilial partners. In contrast, parents may influence children's relationships directly in their role as instructor, educator, or advisor. In this role, parents may explicitly aim to educate their children concerning appropriate ways of initiating and maintaining social relationships, as well as learning social and moral rules. Additionally, parents can serve as gatekeepers and regulators of opportunities to have contact with social resources such as peers and social institutions.

Evidence has suggested that the quality of parental advice is related positively to children's social competence with peers among preschool and elementary school children. In adolescence, parents shift their advice-giving strategies and try to keep their children from being influenced by some peers who may be advocating risky or deviant behaviors. This “parental guidance” approach has been associated with selecting friends with low levels of antisocial behavior and higher levels of academic achievement.

Parents can also impact children's social relationships by monitoring their social activities. Poor monitoring is linked to lower academic skills, peer acceptance, and higher rates of delinquency and externalizing behavior. Monitoring has recently been reconceptualized as a process that is jointly

codetermined by the parent and child (both parent and child mutually participate in defining how much information is disclosed by the child and the level of control the parent will exert). Monitoring may be a function of the extent to which children share information about their activities and companion choices with their parents. Prior research on monitoring may be reinterpreted to suggest that children with poorer social adjustment discuss their activities with parents less than well-adjusted children do.

Parents arrange children's contact with peers by designing children's daily informal and formal activities, which promote or discourage children's peer relationships especially when children are young. Investigators have examined children's informal play contacts by describing who arranges the contacts, characteristics of the children's playmates, and the relations between these indicators and children's development. Parents who initiated at least one informal play contact over the past month had children with a larger range of playmates and more companions. Although the role of parents decreases across middle childhood and adolescence, parents and children continue to share responsibility for the initiation and regulation of peer contacts.

Parent–Child Relationship and Other Family Relationships

Although researchers have commonly focused on the parent–child relationship as an independent unit, this dyad is embedded in a variety of other family relationships, including the coparenting relationship. Coparenting refers to the degree to which individual parent–child relationships and styles of interaction are coordinated between parents in their efforts to socialize their children. These patterns can vary in terms of positive/negative affect and degree of coordination and consistency.

Coparenting

Researchers have become increasingly interested in coparenting in recognition that mothers and fathers operate not only as individual parents, but also as a parenting team. A variety of coparenting alliances

can be formed, including antagonistic and adult-centered or hostile-competitive alliances, where there is a significant imbalance or discrepancy in the level of parental engagement with the child. There are also coparenting alliances reflecting cooperation, warmth, cohesion, family harmony, and child-focused. These patterns have been observed across a range of studies with infants, preschoolers, and school-age children and in both European-American and African-American families.

The family unit may include not just a triadic (mother–father–child) unit, but also a larger set of players as other children join the family. Research on coparenting suggests that the coparenting system may undergo radical modification when more than one child is involved. In two-child families, research has found that each parent tends to engage with one child at a time, and that the four members of the family varied in the quality of interactions and amount of unity depending on outside influences such as siblings' gender, age differences, and temperament. In addition, the nuclear family unit is embedded in the extended family, which has unique influences, as does the society and culture in which the family exists.

Determinants of Parent–Child Relationships

In this section, a variety of determinants of the nature of parent–child relationships will be considered. A three-domain model of the determinants of parenting developed by Jay Belsky includes personal resources of the parents, characteristics of the child, and contextual sources of stress and support.

Child Characteristics

The evolutionary approach to child characteristics focuses on tendencies found universally across children. Over the last several decades, evidence has documented that infants are biologically prepared for social, cognitive, and perceptual challenges, and that these prepared responses significantly facilitate children's adaptation to their environment. For example, the ability to recognize human facial features from early in life facilitates recognition of caregivers and fosters attachment. In addition, individual differences between children across a variety

of behavioral characteristics also shape parent–child interactions. A well-researched determinant of parenting behavior is infant and child temperament. Compared with less difficult infants, infants with difficult temperaments elicit more arousal, distress, and coercive parenting behavior from caregivers. In contrast, fearful children may respond optimally to subtle parental socialization strategies such as reasoning or redirection rather than harsh, punitive, or coercive tactics. In general, more active, less responsive, and compliant children elicit more negative parenting and parental affect.

Personal Resources of Parents

Parental resources such as knowledge, ability, and motivation to be a responsible caregiver alter the parent–child relationship. Recent studies show that parental psychopathology, including depression, alters parenting practices. From early infancy onward, interactions between depressed and nondepressed parents and their offspring tend to be less positive, synchronous, and stimulating. (Synchrony refers to a caregiver's ability to adjust his or her behavior to the infant's signals to maintain a social interaction.) This is especially true with long-term parental depression. Infants of depressed mothers may also develop insecure attachments to their caregivers. Other parental problems such as antisocial personality disorder, schizophrenia, limited education, and poverty all contribute to poorer parenting. Positive personal characteristics such as high intelligence, self-control, and selflessness predict better parenting. Recent theorists have argued that some of these individual differences across parents may, in part, be genetically based. Current studies seek to address the interplay of genetically based individual differences among infants and parents and environmental factors that enhance or suppress the influence of these characteristics.

Families, Social Networks, and Social Capital

The concept of social networks includes people, institutions, and community organizations outside the immediate family structure. Social capital is both the flow of information and the sharing of norms and values that serve to facilitate or constrain the actions of people who interact within the

community's social structures (e.g., schools, places of worship, business enterprises). Children benefit when there is a relatively high degree of agreement about social norms and values among members of their family and the wider community. Social network members may facilitate monitoring of children and help socialize children. For example, one study found that adolescent boys had better school attendance and performance, as well as more positive social behavior, when their social networks included large numbers of nonrelated adults.

Ethnicity and Development of Parent–Child Relationships

There has been a marked increase in attention to how ethnicity shapes parent–child relationships. Recent studies of discipline in different ethnic groups suggest that African-American parents are more likely than European-American parents to use physical punishment, even after controlling for SES. However, although the use of physical discipline often predicts higher levels of externalizing (i.e., acting out, aggression, hitting, etc.) for European Americans, this is not true for African Americans. (Abusive levels of physical discipline, however, are detrimental to children irrespective of ethnic or racial background.) Several explanations for these findings have been offered, including the more normative nature of physical punishment in African-American subculture and the need to enforce rules more strictly in the dangerous environments in which African Americans are more likely to reside. Growing up in dangerous neighborhoods brings greater risks for involvement in antisocial behavior. Under these circumstances, strict obedience to parental authority appears to be an adaptive strategy, which parents may endeavor to maintain through physical discipline.

Future Directions

Families are dynamic and are continuously confronted by challenges, changes, and opportunities. A number of society-wide changes have produced shifts in parent–child relationships. Fertility rates and family size have decreased, the percentage of women in the workforce has increased, the timing of onset of parenthood has shifted, divorce rates

have risen, and the number of single-parent families has increased. These social trends provide an opportunity to explore how parent–child relationships adapt and change in response to these shifting circumstances and represent “natural experiments” in coping and adaptation. Moreover, these historical shifts challenge our traditional assumptions that this relationship can be fully understood from studies conducted at a single point in time. The research task is to establish how parent–child processes operate similarly or differently under varying historical circumstances. Illustrative examples of recent trends in parenting research include emerging work on parent–child relationships in gay and lesbian families, the impact of the new reproductive technologies on parent–child relationships, and the effects of parental incarceration on parent–child ties.

PARENTHOOD, TRANSITION TO

Prior to the transition to parenthood, the nuclear family is synonymous with the marital dyad. With the arrival of another individual—a first child—the family system increases in complexity. As one new, relatively helpless individual is added to the preexisting marriage/partnership, the number of interpersonal relationships in the family triples from one (i.e., husband–wife) to three (i.e., mother–child, father–child, and husband–wife). Perhaps the most compelling evidence that such profound change in the family system can affect how partners and families function is to be found in research showing that self-reported depression and distress are more likely to develop in the first year of motherhood than at any other time. Many women, in fact, also manifest increased anxiety about the level of their partner’s love, commitment, and support. The fact that the quality of care that depressed mothers provide their infants is often compromised should make it clear that changes in the family system also have consequences for the development and well-being of the new addition to the family.

In view of the dramatic changes that can take place with the arrival of a first child, investigators have spent decades studying how and why marriages change across the transition to parenthood. The first investigations of this topic were cross-sectional in design, with couples without children simply compared to those with children. Ever since the 1980s, however, longitudinal research has been the norm, with couples followed typically beginning in pregnancy through several years after the first child’s birth. In this entry, not only are changes in marital functioning described across this developmental period, but so are factors and processes that account for why some relationships change—for better and for worse—more so than others.

How Marriages Change

However commonplace the birth of a child, for the two parents involved, especially if married or cohabiting, the transition to parenthood is a major life event. As such, it requires both individuals to adapt to changes brought about by the

responsibility of rearing a child. The challenges faced by men and women during the transition to parenthood are often different generally due to the distinctive changes that they experience in their family roles. It is typically these role changes that have implications for how marital/partner relationships will change.

Although typically viewed as a positive experience, the transition to parenthood can exert major strains on the couple relationship. Indeed, having a baby often creates new problems for a relationship and amplifies existing vulnerabilities. Parenthood thus has the potential to change both men’s and women’s feelings about themselves and their relationships as they assume the important role of nurturing a child from birth into adulthood.

Research that has followed marriages over time—from before to after the arrival of a first child—typically chronicles declines in overall marital quality and self-reported marital satisfaction. Although the average level of decline is not large, its consistency makes it noteworthy. The fact, however, that social scientists cannot run experiments in which they randomly assign some couples to the “have-a-baby” experimental group and others to a “no-baby” control group means that it is difficult to be certain that changes in marriage *associated with* having a first child are truly *caused by* the transition to parenthood. This situation is further complicated by the fact that, in general, marital quality declines over time in most households irrespective of whether they have a child. This situation suggests an alternative interpretation of the well-replicated observation that marital quality deteriorates somewhat following the arrival of the first child: This decline is not really a function of becoming parents, but merely of time taking its toll on the marital relationship. Perhaps the soundest conclusion in light of evidence showing that, in general, overall marital quality and satisfaction decline with time, irrespective of the arrival and rearing of children, is that the transition to parenthood accentuates and accelerates this process.

As it turns out, it is not just positive or negative sentiments about the marital relationship that change from before to after a first child’s birth. Indeed, other changes in marital dynamics probably account for much of the change in sentiment. One of the biggest changes—and one that is typically (although not universally) experienced differently

by men and women—involves the household division of labor. Not only do meals have to be made and homes cleaned, just as before a first child's appearance on the scene, but with the arrival of a helpless, dependent infant, an awful lot of new work is added to households. Feeding the infant, doing his or her laundry, and coping with his or her sleep/wake cycles are disproportionately born by the mother/wife even in putatively egalitarian relationships; this typically means that it is mother/wife who first feels the strain of parenting, and, in consequence, it is wives who first begin to experience increased disenchantment with their partners. Men's dissatisfaction with the marriage often takes more time to emerge. Wives frequently complain about partners "not doing enough" as the household division of labor becomes more traditional in terms of sex roles, with men complaining about wives not appreciating what they do. Deterioration in the frequency and quality of sexual relations is another source of dissension, often experienced by men more than women. Sheer exhaustion resulting from repeated night wakings of the infant makes coping with these changes all the more challenging.

Making the situation even more taxing, perhaps, is that many couples end up with less time to spend together as "just a couple." Some research suggests that time spent in joint leisure activities declines. To the extent that it is just such experiences that engender shared positive emotions, one can see how the transition to parenthood does not just exhaust parents, increase their workload, and give them more opportunities for disagreement (e.g., comfort the crying child vs. let him cry it out), but diminishes the opportunity to nourish the relationship emotionally.

Variation in Marital Change

It would be a serious mistake to infer from all this that there are no satisfactions arising from the arrival and rearing of a first (or later-born) child. Nothing could be further from the truth. Moreover, there is clear indication that the general and perhaps depressing picture just painted, although characteristic of the "average" couple's experience, masks a good deal of diversity in how couple relationships change across the transition to parenthood. Not only is it the case that most relationships only deteriorate in

global marital satisfaction to a modest degree, but work by Jay Belsky following working- and middle-class couples from pregnancy until their first child was 3 years of age revealed three other patterns of marital change. Whereas some couples showed dramatic deterioration and others virtually none at all, a small minority actually showed *increases* in marital quality over time. What remains entirely unclear from the available evidence is the proportion of couples that generally fall into the four patterns of change just described (i.e., severe negative change, modest negative change, no change, and modest positive change). One reason for this is that the kind of longitudinal research needed to address this issue has not been carried out on nationally representative samples of families.

Determinants of Marital Change

The reality of diversity of marital change across the transition to parenthood raises the question of what factors account for why some couples experience more negative change than others and why some couples actually experience positive change. As it turns out, there is no single answer or silver bullet to explain the variation that researchers have detected.

One factor, already noted, concerns the division of labor. The more fathers carry a reasonable share of the traditional female workload (i.e., cooking, cleaning, laundry, child care), the better relationships seem to do.

How well parents coparent also matters. Coparenting refers to the manner in which parents function as a cohesive unit, with partners more or less seeing eye to eye about how the baby should be cared for or, if not, at least respecting the different ways that their partner parents. When one parent believes something strongly and expects the other to conform to that expectation, but the other parent does not, parenting becomes a source of tension in the couple relationship, adversely affecting it. In this way, the transition to parenthood creates new problems for couples and, all too often, amplifies existing weakness in their communication and caring.

Expectations matter more generally, especially when they are violated. Parents-to-be sometimes idealize the experience of becoming parents: "It

will bring us closer; we will do more things together; we will share the workload equally." For such perhaps naïve expectant parents, the transition can be a big surprise as things often do not turn out as expected. Seeing the world through "gray-colored glasses" during pregnancy might be a more strategic way to proceed, anticipating just how challenging, demanding, and exhausting the experience is likely to be. In this way, parents will not be surprised, and even perhaps pleased, when events turn out better than anticipated.

A good time to change metaphorical spectacles is once the infant—and all the work entailed—arrives. Putting on "rose-colored glasses" facilitates seeing things in a positive light. To mix metaphors, this enables parents to see the "glass as half full" rather than "half empty," focusing on and appreciating, for example, what a husband did around the house rather than what he does not do. Although many a wife/mother finds this suggestion unfair, if not unreasonable, a basic fact of life is that rewarding valued behavior (e.g., "Thanks for that assistance; it really lightens my load") is far more effective when it comes to changing behavior than engaging in punishment (e.g., "You never do anything").

Conclusion

Although marital relations typically deteriorate across the transition to parenthood, couples need to appreciate that the change is, on average, modest. It tends to occur in time, but perhaps takes a little longer, even in the case of childless couples. Moreover, this change that couples experience on average masks the fact that, whereas some couples experience substantial negative change, many experience little or no such change, and some even show improvement across the transition to parenthood.

One of the unexpected core challenges that couples confront on becoming parents is that men and women typically view what happens in the family with regard to childrearing from vantage points that rely on different points of comparison. The wife experiencing an increased workload resulting from the transition to parenthood often views her partner as "doing nothing" because she compares him to herself and, relatively speaking, he is not doing much. But the husband often sees

himself as "doing a lot" because, compared with his father, his brother, and perhaps his coworkers, he most certainly *is*, again, relatively speaking. Not appreciating these divergent worldviews can contribute to a kind of culture clash in the form of marital disputes, all of which fuels relationship dissatisfaction.

Relationship difficulties associated with becoming parents have been explored predominantly in modern, Western settings. Isolation from extended families and the absence of transition rituals no doubt exacerbates difficulties. For this reason, the observations made herein based on the study of mostly American and European marriages during the transition to parenthood should not be assumed to reflect what goes on in so much of the rest of the world where research is lacking.

PARENTING

Parenting encompasses a wide range of attitudes and behaviors directed toward meeting the physical, emotional, and social needs of children. As the first relationship formed in life, the parent–child relationship serves as a model for later relationships and is one through which children develop both interpersonal skills and intrapersonal attributes. Not surprisingly, there have been extensive empirical studies over the past 60 years focused on parenting behaviors, particularly those that appear to facilitate children's emotional and psychological development. In the course of the investigations, some factors have emerged as critical dimensions of parenting. In addition to describing these dimensions, this entry presents the field's current understanding of how parenting affects children's well-being, the universality of these effects, alternative ways of conceptualizing parenting, and key predictors of parenting behaviors.

Key Parenting Dimensions

Over the years, three important dimensions of parenting have consistently emerged as central to child development: warmth/involvement, autonomy-supportive versus controlling behavior, and structure. They are linked respectively to three basic human needs: those for relatedness, which refers to closeness and intimacy; autonomy, which refers to self-determination and choicefulness (rather than independence); and competence. Although different terms have been used to describe the three dimensions, these terms have in common a link to a specific need.

Warmth/Involvement

The first dimension has been conceptualized in various ways, including parents' expression of love, their affective response, and their nurturance,

warmth, and involvement. These behaviors facilitate a sense of relatedness in children. Although warmth refers to parents' emotional availability and their willingness to show affection and empathy, involvement refers more specifically to parents' provision of tangible, emotional, and behavioral resources (e.g., time) and implies active participation in the child's life, both emotionally and physically. A warm and involved parent would know about their child's ever-changing interests, attend their games and/or performances, and do so in a caring, positive manner.

Across a wide range of ages, parental warmth and involvement have been linked with a variety of positive child outcomes, including higher academic achievement and lower levels of delinquency and internalizing symptoms. They also predict secure parent–child attachment and later adaptive relationship skills. In addition, warmth/involvement has been shown to facilitate positive outcomes by building adaptive self-related beliefs and motivations such as self-esteem, perceived competence, and perceived control. It is important to note a crucial distinction between being involved and being intrusive. One can take an active interest in one's child without taking over. This leads to discussion of another key dimension of parenting.

Autonomy-Supportive Versus Controlling Behavior

The second parenting dimension is autonomy-supportive versus controlling behavior. Autonomy support involves allowing children to be part of decision-making processes and to have a sense of choice. Children, like all humans, need to feel that they are initiators of their own behavior, rather than forced or pressured to do another's bidding (in this case, their parents'). Thus, autonomy support facilitates fulfillment of the need for autonomy. The opposite end of the autonomy-supportive dimension is control. Controlling parents pressure children into doing specific behaviors using rewards or guilt or by threatening to withdraw their love.

Studies have found that autonomy-supportive parenting is associated with more intrinsic motivation in children—that is, children engaging in activities for interest and enjoyment, rather than as a result of external pressure. It is also associated with greater perceived competence, self-esteem,

and self-regulation in children. These findings indicate that controlling, pressuring parenting results in children doing their activities only because they feel as if they have to, hence undermining their own autonomy in carrying them out. Thus, children of controlling parents tend to have less intrinsic motivation to engage in activities and are less likely to internalize the motivation for less interesting activities. Given that the goal of most parents in trying to get their children to do activities such as cleaning their rooms, sharing their toys, and doing their chores is to do them willingly and develop values for cleanliness, compassion, and responsibility, it is clear that autonomy support is an important parenting dimension.

Structure

The third dimension, structure, refers to parents setting up the environment to facilitate competence. Structure is conceptualized in terms of how parents interact with their children (e.g., the extent to which parents anticipate whether a child can do a task and provide information needed for successful completion of the task) or the way home life is organized (e.g., having clear and consistent rules and expectations). By providing information, rules, and expectations, parents create an environment in which children know what to expect as a consequence of their behavior and thus are able to direct their behavior toward desired outcomes.

Various components of structure have been linked with key child outcomes. For example, clear and consistent guidelines and expectations in the home have been associated with children feeling more in control of and competent with respect to school successes and failures. Similarly, greater predictability in the home has been associated with perceived control and grades in school.

Structure is related to other dimensions that have been studied by researchers, such as behavioral control, monitoring, limit setting, and quality of assistance. Behavioral control and monitoring, measured as parents' knowledge of the whereabouts and actions of their children, has been linked to lower levels of acting-out and delinquent behavior. Quality of assistance and limit setting have both been associated with children's academic competence.

Relations Among the Dimensions

The three dimensions—warmth/involvement, autonomy support, and structure—are largely independent. That is, although they may have low to moderate correlations with one another (e.g., parents who are high in structure also tend to be high in involvement), their shared variance is low so that their interactive effects can be considered. For instance, highly autonomy-supportive parents may provide either high or low levels of structure, and parents with a high level of structure might or might not provide this structure in a manner that supports their child's autonomy. Confusion about the meaning of parental control has led to much controversy about its influence on children's development. The term *control* has been used in reference to pressuring, power assertion, and dominance, as well as in reference to discipline, guidelines, and structure. Consequently, there have been different—sometimes directly opposing—conclusions on how it affects development. Measured as behavior monitoring and discipline, control is associated with positive child outcomes like high academic achievement and low externalizing behavior. When measured as dominance and power assertion, parental control is associated with negative child outcomes like lower self-esteem and motivation. This problem is easily solved if a clear distinction is made between structure, which involves providing rules and guidelines, and control, which involves pressure and power assertion.

The term *autonomy* has also been inappropriately used interchangeably with independence, again leading to confusion about the effects of encouraging autonomy. Research has discovered that joint decision making—characteristic of autonomy-supportive parenting—has positive effects, whereas unilateral adolescent decision making—which characterizes independence—has negative effects. Supporting a child's autonomy does not imply giving him or her free reign. Parents can allow children to have input in decisions and choice, yet still serve as the ultimate authority.

Typological and Dimensional Approaches

Parenting has sometimes been studied in terms of typologies based on a combination of the dimensions. For instance, Diana Baumrind combined

different levels of parents' firm enforcement of rules (which can be conceived of as structure), warmth, and encouragement of individuality to create categories of parenting styles. Parents high in firm enforcement, warmth, and encouragement of individuality were classified as authoritative. This style of parenting was associated with children's social competence and higher self-esteem. Authoritarian parenting, in contrast, characterized by high firm enforcement, low warmth, and low encouragement of individuality, was negatively associated with children's psychological well-being. Permissive parenting, consisting of low firm enforcement, high encouragement of individuality, and high warmth, was also detrimental to children's development. Since Baumrind first published her work in the 1960s, many studies have linked authoritative parenting to a variety of important outcomes, including academic competence, good social skills, and psychological adjustment. In contrast, authoritarian parenting has been linked to low instrumental competence and heightened self-consciousness.

In light of the controversy over the influence of control on children's development, the alternative dimensional approach is advantageous in that it brings to light independent and interactive effects of separate dimensions and helps to sift out the individual effects of each dimension. Thus, researchers can determine, for example, whether providing guidelines and rules is important and whether doing so in an autonomy-supportive manner enhances the effects of such guidelines.

The Universality of the Effects of Parenting

Another advantage of a dimensional approach to parenting over a typological approach is that it affords researchers the opportunity to examine not only the extent to which these effects are the same across cultures, but also points at which variations may emerge and the possible reasons for this divergence. In this way, researchers are able to appreciate the dynamics of parenting practices within societal or cultural contexts.

There has been much discussion about whether warm, autonomy-supportive parenting with provision of structure has positive effects on children's well-being in all societies and cultures. For instance,

it has been argued that in collectivist societies such as China and Turkey, where great value is placed on the interdependence of members of a community, encouraging autonomy might not have positive outcomes. The need for connectedness, autonomy, and competence are theorized to be innate and, thus, cut across cultural boundaries. In both collectivist and individualistic cultures alike, children have these needs and fare best when these needs are met. Indeed, studies among not only North American, but Bulgarian, Russian, Chinese, and Latino populations indicate that fulfillment of these needs is positively associated with psychological health.

However, due to differences in societal or cultural norms, the same parental *practices* may be perceived differently by children, and thus may function differently in how they meet children's needs. For instance, differences in the degree to which emotions are outwardly expressed may result in different snapshots of what a warm and involved parent looks like. In some cultures, warmth and involvement may be outwardly expressed through verbal exclamations of praise and affection, such as a parent telling the child how well he or she did and how proud they are of him or her. In other cultures, it may be expressed in more subtle ways (e.g., with a smile or a nod of approval). When these more subtle expressions of emotion are the norm in that culture, a child may perceive his or her parents as warm and involved. Thus, ultimately, the child's need for relatedness will be fulfilled.

Predictors of Parenting

A key issue of interest is whether parenting styles are characteristics of the parents or the result of factors in the parents' environments. Studies have shown that environmental variables, such as levels of stress and economic adversity, do interfere with parents providing conducive parenting to their children. For example, stress and lack of resources have been linked to lower autonomy support and less involvement and structure. Further, characteristics of children predict parenting, with more difficult children receiving more controlling styles. New research by Wendy Grolnick and her colleagues has shown that not only are contextual

stress and pressure associated with more controlling behavior, but parents' own internal pressure to have their children perform, a characteristic of the parent, is positively related to more controlling styles. The interplay between factors within parents and in contexts in predicting parenting is an important topic for further research.

PEER REPORT METHODS

Peer reports are descriptions of target individuals' thoughts, feelings, motives, or behaviors. A strict definition of the term *peer report* refers to raters who are similar in age, grade, or status to the target individual. However, many researchers use the term more generally to refer to friends, lovers,

coworkers, teachers, or anyone who regularly observes a target in naturally occurring social situations. Peer reports are particularly useful when they are obtained from individuals who are well acquainted with a target and have observed him or her in numerous and varying situations. These sorts of reports are useful in describing a target's behavioral tendencies and predicting future behavior. Peer reports may also be useful when obtained from individuals who possess limited but specific knowledge about a target individual. Peer reports of this type are represented by a professor's evaluation of a prospective graduate student or a boss's performance evaluation of a subordinate.

Researchers use peer reports as a source of data to describe the personality, social, and cognitive characteristics of target individuals. They are a valid alternative to self-reports, which frequently suffer from biases such as self-aggrandizement, self-derogation, or repression. Peer reports may exhibit some limitations of their own, typically due to insufficient information or faulty judgments. However, when they are obtained from individuals for whom accuracy is important, such as lovers, friends, or coworkers, peer reports are a source of information that provide incremental validity beyond self-report measures.

Some researchers argue that the beliefs that peers hold represent more than a simple reflection of targets' behavior. They argue that peer beliefs actually influence the development of targets' personality characteristics. This perspective, commonly referred to as the Looking Glass Self, suggests that target individuals (a) observe how friends and family members respond to their social behavior, (b) internalize these reactions, and (c) develop a sense of self based on these internalized perceptions. Although researchers might debate the importance of this process in the development of the self, it is another indication that peers' perceptions of target individuals play an important role in understanding target characteristics.

Methods

Researchers use several approaches to obtain peer reports. The most common approach involves questionnaires, typically converted self-report measures in which pronouns are changed from

first to third person (e.g., “I am angry” to “She is angry”). Peers respond on a scale ranging from *strongly disagree* to *strongly agree* to statements that may characterize the target individual. The five-factor model of personality consists of five broad trait dimensions—Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness—that many personality psychologists believe form the foundation of adult personality. Popular measures of the five-factor model of personality include both self- and peer-rating versions. These measures were traditionally administered in paper-and-pencil format, but many researchers now present their questionnaires on lab computers or the Internet to eliminate the need for data entry.

The Q-sort approach requires peer raters to sort a deck of cards, each card containing a statement describing a personal attribute, into a fixed number of categories. The goal of the Q-sort approach is to define the characteristics of the target individual that are most and least important. Q-sort decks, just like personality questionnaires, differ depending on the constructs being studied. The California Adult Q-sort, a popular Q-sort deck, consists of 100 statements, each printed on a separate card, that describe a wide range of personality, cognitive, and social attributes (e.g., “Is a talkative person,” “Has a high degree of intellectual capacity,” “Is protective of others”). Raters sort the 100 cards into nine categories ranging from *least characteristic of the subject* (1) to *most characteristic of the subject* (9). The rater is required to place a predetermined number of statements into each category (e.g., 5 in category 1 and 9, 8 in category 2 and 8, 12 in category 3 and 7, etc.). These Q-sort properties help reduce rating biases (e.g., using only ones and fives on a 5-point scale) that are present in typical ratings scales.

Interviews are another approach for obtaining peer information. The interview format may be structured or semistructured, but in both cases the goal is for interviewers to elicit peer evaluations or descriptions about targets. Interviewers might use the information to supplement previously obtained quantitative data, or they might complete a questionnaire or Q-sort to summarize the interview.

These three approaches represent a sampling of possible peer-report methods. These approaches and others are used to assess behavior, personality,

interpersonal relationships, job performance, and more fleeting characteristics such as thoughts and feelings. The validity of peer reports is frequently demonstrated. Furthermore, researchers who obtain multiple peer reports derived from different domains of individuals’ lives (e.g., from an adolescent’s parents, friends, and teachers) are on the path toward capturing the complexity of human behavior.

Research Using Peer Reports

Periodic reviews of current methods inevitably reveal that self-report is the most common method and that the modal psychological study utilizes only self-report. However, despite its frequency, self-report is not the optimal research strategy. Self-reports are limited by a number of well-documented biases. Moreover, there is no single optimal strategy. Rather, an optimal strategy is one in which multiple research methods are utilized. Different methods, such as self-report, peer report, and behavioral observation, each possess unique strengths and weaknesses. When results converge across methods, researchers gain confidence that their results are valid. In each of the research domains described next, peer report methods play an integral role.

Romantic relationships research is a field that, as some have argued, cannot be meaningfully conducted without peer reports. A romantic relationship consists of two people whose thoughts, feelings, and behaviors continuously affect each other. Although it makes sense to collect from each partner how they feel about themselves, it is perhaps even more crucial to collect peer reports indicating how partners perceive each other. Individuals may view themselves as warm and loving, but relationships may perish if their partners view them as aloof and hostile.

In one study of adult aging, self- and spouse ratings on measures of the five-factor model were used to evaluate each participant. Self- and spouse ratings exhibited relatively high levels of agreement on personality traits such as Extraversion and Neuroticism. The couples’ ratings were also used to predict psychological well-being and coping. The self- and spouse ratings did approximately equally well in predicting these important personal characteristics. Although spouse ratings exhibited

statistically significant levels of agreement, they were far from perfect. The researchers interviewed the couples to determine how agreement might be further enhanced. The researchers concluded that several factors influenced agreement, but the easiest way to enhance agreement would be to clarify the wording and meaning of questionnaire items.

Business leaders have come to recognize the high cost associated with replacing members of management teams. As a result, organizational psychologists are often called on to assist in managerial development and to troubleshoot conflict in the workplace. One frequently used approach is called the 360-degree assessment, in which a manager's performance is rated by individuals with differing relationships to the manager. Typically, these raters are the manager's boss, peers, and subordinates. The manager often provides a self-rating, and occasionally family and friends of the manager will also provide ratings. One of the first goals of this approach is to provide a general portrait of the manager. It is also important to determine whether different groups of individuals have the same or different perception of the manager. If perceptions differ, this might suggest that the manager behaves, for example, in a submissive manner around the boss, but is domineering and hostile around subordinates. Self-peer comparisons can also be informative. Large discrepancies might suggest that the manager is unaware of behaviors that are problematic in relations with coworkers. These data are used by organizational psychologists to make recommendations and implement change as needed.

Teacher ratings can be an excellent source of data about children. Elementary school teachers are often with the same group of children for the entire day and have many opportunities to observe each child's intellectual performance and social behavior. Teachers' ratings of children's behavior on questionnaires or checklists can be quite valid. Some researchers are concerned that teacher ratings are biased, particularly when rating children of different ethnic backgrounds. Although rating biases can never be entirely eliminated, a recent large-scale study demonstrated little bias in teacher ratings. In this study, teacher ratings of White and African-American children with ADHD were compared with research staff ratings of the same children. The teachers and research staff (who were presumed to provide accurate assessments) demonstrated a

significant level of agreement. The results suggested that teachers did not evaluate one ethnic group more harshly than the other.

Considerable research has utilized both teacher and parent ratings of children. A recent study found moderate agreement on ratings of hyperactivity, peer problems, and emotional symptoms, which is typical for studies that include both teacher and parent ratings. One reason that higher agreement is not observed may be because certain problem behaviors are more likely to occur in school than home environments. Thus, although parents might acknowledge their child's problem behavior, teachers may have more opportunities in the classroom to directly observe problem behavior.

Historically, the assessment of personality disorders has been accomplished with self-reports. This is not an ideal strategy given that faulty self-perception is characteristic of individuals who have a personality disorder. For example, narcissistic individuals often view themselves as superior to others when there is no objective reason for doing so. Clinical researchers are finding that peers can provide useful information to help in the diagnosis of personality disorders. Research that has examined self- and peer ratings on measures of personality disorders and interpersonal difficulties indicates that individuals do have some insight into their own maladjustment. However, peers appear to be in a better position to report on the interpersonal problems associated with personality disorders. Peers regularly observe the interpersonal limitations manifested in social interactions and provide fairly objective ratings of their experiences, whereas personality-disordered individuals are often unaware how others perceive them.

Self- and Peer Reports Compared

Although most researchers recommend a multi-method strategy, it is helpful to understand how self- and peer reports differ when used in empirical research. It is often stated that a significant weakness of peer reports is that peers do not have access to target individuals' inner thoughts and feelings. Research supports this claim. Researchers found that the experience of positive and negative mood over 8 days was predicted better by self-ratings than peer ratings on Extraversion and Neuroticism. However, in a related study, it was found that

social behavior was predicted better by peer ratings than self-ratings on the five-factor model. Moreover, the average of two peers' ratings generally was a better predictor than a single-peer rating. Altogether, these findings suggest that the self has privileged access to internal characteristics such as thoughts and feelings, whereas peers have a superior vantage point to observe social behavior.

PERSONAL IDIOMS

“Raining cats and dogs,” “Green with envy,” and “Easy as pie”: What these odd expressions share in common is the classification as cultural idioms. They are colloquial expressions that use the English language in creative ways to capture an attitude, image, or feeling. A person who came to America from another country would have to study the sky during a rainstorm for quite awhile to find cats or dogs. In much the same way, friends, lovers, families, and close-knit social networks have idioms that are unique to their interactions. Outsiders would not understand that terms such as *Boo* might refer to a young man's girlfriend or that *jelly beans* is a shorthand way to say, “You're talking too much.” But, in fact, this is exactly the point of personal idioms. They allow persons in close relationships to communicate with a private language that simultaneously unites them while excluding outsiders. The purpose of this entry is to more fully define personal idioms, describe the categories into which they fall, and explain in more detail how they function within relationships.

Defining and Categorizing Personal Idioms

Personal idioms are symbols or codes within the language of close relationships that have special meaning known only to those members. As people share a history, interact in a variety of situations, and come to know each other well, certain terms, phrases, or nonverbal gestures emerge within their conversations. Sometimes these expressions are adaptations of some famous line or scene in a movie, or a childhood nickname, or are simply the lingering phrase from goofy conversation, misspoken words, or word play. For whatever reason, these expressions are noticed and a meaning is assigned to them. From that point on, they become a shorthand way of communicating the meaning beyond the initial context.

One goal of researchers has been to identify the types of personal idioms that characterize close relationships. Perhaps the most widely accepted typology is that proposed by Robert Hopper, Mark Knapp, and Lorel Scott. These researchers collected

545 examples of personal idioms that they sorted into eight categories: (1) *Expressions of Affection* show love, caring, and appreciation (e.g., saying Hunch Nickle or pulling an earlobe to say I love you); (2) *Partner Nicknames* are terms of address for a close other (e.g., Boo, Tooty, Monkey); (3) *Names for Others* are labels for people outside of the relationship (e.g., Lady of the Lakes for a neighbor who flooded the streets when watering her lawn or Queen Kong for a strict high school teacher); (4) *Requests and Routines* are ways to communicate something in the presence of others without their knowledge (e.g., saying “The dog is calling” as a hint that it is time to leave a party); (5) *Teasing Insults* are humorous ways to tell someone that certain behaviors are bothersome without being directly critical (e.g., asking “Are you protesting?” when a partner forgets to lower the toilet seat lid); (6) *Confrontations* are also focused on bothersome behaviors, but without the element of teasing (e.g., a man says “Vickers!” to his wife Vickie when she becomes argumentative stemming from the name of a British machine-gun manufacturer); (7) *Sexual Invitations* are ways of indirectly initiating sexual interactions (e.g., a wife puts on a particular nightgown or a husband says “George is calling”); and (8) *Sexual References and Euphemisms* are terms for sexual intercourse (e.g., ride the merry-go-round) and “pet names” for sexual organs (e.g., Oscar or George for the penis, Jennifer for the vagina, and Sweet Pea for the clitoris). Some couples also have idioms for a woman’s menstrual cycle (e.g., Aunt Bee is in town).

Functions

As indicated, each type of personal idiom serves a specific communicative function, such as expressing affection, criticizing with humor, and negotiating the sometimes embarrassing aspects of sexual intercourse. In addition, however, the presence of personal idioms within a relationship functions to help close relationships achieve three broader goals. First, they allow relational members to create a culture of shared meaning that sets them apart from the larger culture. In doing so, personal idioms constitute part of the relational identity. In this way, they function to create and manifest intimacy. Second, they allow relational

members to avoid conflict over small problems through their teasing expressions and to reaffirm the relationship following conflict. Nicknames and Terms of Affection, for example, remind partners that they value each other and share something special. Using these terms after a conflict reinstates the feelings of specialness and intimacy. Third, they help partners negotiate potentially awkward situations. For example, Requests and Routines enable relationship members to signal needs and desires within larger groups without offending others, and Sexual References and Euphemisms allow romantic partners to negotiate the sometimes embarrassing circumstances of sexual activity. In this regard, the use of personal idioms allows partners to avoid or manage threats to each other’s face.

Summary

Although we smile when we hear examples of personal idioms like Boo and jelly beans, research indicates that couples who have personal idioms are more satisfied than those who do not. However, research also indicates that the line between Teasing Insult and Confrontation is thin and ambiguous. Although these types of personal idioms allow relational partners to avoid serious conflict, they also have the potential to be used as passive-aggressive conflict strategies. Research also indicates that, although personal idioms emerge most actively during early stages of relationships, they are also present in long-term marriages. Indeed, marital therapists have begun exploring a technique of asking couples to create personal idioms, especially Sexual References and Euphemisms, as part of the counseling process. Finally, although we typically associate personal idioms with romantic relationships and friendships, they are also common in families, especially among siblings.

Future Research

Although the study of personal idioms has been a mainstay in interpersonal relationship research, new technologies like text messaging, instant messaging, and social network Web sites (e.g., *Facebook* and *MySpace*) have changed the complexion of

communication, including personal idiom use. New media terms serve as a source for personal idioms much as famous movie lines do. In addition, the constraints of media channels such as text messaging encourage abbreviated expression, which leads to the creation of personal idioms. At present, we know little about this context for the creation and use of personal idioms.

In addition, research should examine idiom use in problematic contexts such as the serious or terminal illness of a partner, friend, or family member. Just as euphemisms help attenuate the awkwardness of communication about sexual activity, personal idioms may help buffer the uncertainty, awkwardness, and emotional pain that is salient to these experiences. Developing a Nickname for a newly bald partner may help calm fears and insecurity from losing hair due to chemotherapy treatment and may enhance a sense of togetherness and affection during such a difficult time. Understanding the use of personal idioms in this context may help therapists, health care professionals, and families find useful ways to communicate about difficult topics.

PERSONALITY TRAITS, EFFECTS ON RELATIONSHIPS

People bring their personalities to relationships. This statement reflects that social relationships are shaped by the personalities of relationship partners and their interactional history. Relationships differ as a function of enduring characteristics of actors and their partners. From an actor's perspective, personality traits considerably determine how one feels, reacts, and behaves in relationships while the partner's personality represents an important part of the actor's environment. Because of this twofold nature, relationships exist at the interface between the individual's personality and his or her environment. This entry provides an overview of relationships from the perspective of personality psychology. Different levels of personality with different meanings for relationships are distinguished. In particular, the effects of enduring personality traits on relationships and relationship functioning are considered by means of three particular mechanisms: selection, evocation, and proactive change. Finally, the entry discusses whether and to what extent social relationships can be considered as an expression of personality.

Personality and Relationships

Personality is the entirety of characteristics in which people differ consistently and meaningfully. The concept of personality has two features: (1) the individual particularities of a person compared with other individuals, and (2) the temporal consistency of this particularity. These features can be conceptualized at three levels. The first level consists of basic dispositions (e.g., the so-called "Big Five" traits—Neuroticism, Extraversion, Agreeableness, Conscientiousness, and Openness). Individual differences in these traits reflect the dispositional signature of personality. For example, people perceive themselves and others regarding their relative position on the Extraversion–Introversion dimension. These basic traits exhibit modest mean-level changes over the life span, yet at the same time show moderate levels of rank-order consistency and substantial individual differences in stability and change. In other words, people change yet remain who they are (compared with others)

because they adapt to age-related developmental tasks and challenges in a way that mirrors their idiosyncratic dispositions. Across adulthood as people grow older, they tend to become more emotionally stable, more agreeable, and more conscientious. These age-related, mean-level changes in personality can be considered normative and are associated with major life transitions in romantic partnership, family, and work. For example, young adults typically become more emotionally stable and more conscientious when they enter into a partner relationship for the first time. However, it is debated among researchers whether this kind of personality change is due to intrinsic maturation or whether relationships set in motion and reinforce processes that create personality change.

The second level of personality consists of so-called characteristic adaptations, such as attitudes, motives and goals, individual abilities, and certain aspects of the self-concept, such as self-esteem and self-worth, all of which are more malleable and sensitive to environmental influences than traits. Characteristic adaptations are flexible, have moderate rank-order stability, and show large individual differences in stability and change. This is because these adaptations are consequences of negotiating environmental demands, coping with challenges of critical life events, and responding to relationship issues such as supportive partnerships. Certain aspects of relationship functioning (not relationships *per se*), such as global perceived social support, can be conceived as characteristic adaptations. For example, global perceived social support indicates the extent to which people believe that they receive emotional or instrumental help from their social network (i.e., family members, spouses, friends, and colleagues). Individual differences in global social support are relatively stable and are more an indicator of the person's personality (level 2) than a characteristic of specific social relationships. For example, more agreeable people tend to perceive their relationships as more supportive in general.

The third level of personality covers the narratives of individual biography. The way people tell stories about their lives reflects how they construct and define their identity, and this is likely influenced by various age-related developmental conditions (e.g., becoming parents, entering work life) and non-normative life experiences (e.g., facing serious

health problems). Life narratives deal substantially with relationship issues because the most meaningful life events involve social relationships (e.g., with a partner or family members). For example, people typically organize their biography along relationship events, such as dating, marrying, parenting, mentoring, leaving the nest, and so on. These relationship events are the foundation of identity.

Although this view of personality organization is common in personality psychology, a comparable taxonomy of relationships and relationship functioning is still missing. Yet relationships can be defined as dyadic interaction patterns between at least two people that continue over time. To the extent that these interaction patterns are unique and at least intermediately stable over time, they represent consistent dyadic differences between relationships. Thus, personality reflects relatively stable differences between people (i.e., individual differences), whereas relationships refer to persistent differences in the connection between two persons (i.e., dyadic differences).

Relationships are interfaces between individual personality and the environment, or, in other words, they are shaped by characteristics of the persons involved and the environment. The question—to what extent characteristics of relationships represent environmental or personality influences—is complex but answerable by empirical research. For example, a dyadic attachment relationship is influenced, among other things, by the attachment styles of both partners and their relationship history. A wife's secure attachment style is part of her personality, whereas her husband's avoidant attachment style is part of her environment, just as his avoidant attachment style is part of his personality and his wife's secure attachment style is part of his environment. The dyadic pattern of attachment-related experiences within their relationship, however, emerges from continuous interplay of her style of seeking proximity and his style of avoiding intimacy. Fortunately, relationship research now has the methodological tools to disentangle these complex associations (e.g., by using longitudinal designs or dyadic and multilevel modeling).

Inasmuch as differences in relationships depend on the personality of actors and partners, including their interaction history, individual and dyadic characteristics of relationships are thought to be

less stable than individual personality traits. Because relationship characteristics are less stable, enduring personality traits are thought to have a greater chance to influence change in relationship characteristics than relationships have to influence personality change. Thus, by and large, many scholars believe that relationship characteristics are more a function of these personality traits than vice versa. For example, Extraversion is an enduring trait with long-term consequences for the development of friendship networks, with highly extraverted people showing increases in social networks over time and more frequent contact with others. At the same time, Extraversion is relatively immune to changes in specific relationships, with highly extraverted people remaining more extraverted than others despite experiences such as social rejection. By contrast, less stable personality characteristics of level 2 or level 3 may be more sensitive to relationship experiences because these are more specifically concerned with social interactions and relationship issues. For example, people adapt their subjective evaluation of global perceived support to their experiences in specific relationships. The ending of a supportive relationship can alter the global perception of social support even though other supportive relationships remain unchanged. In the same manner, people may tell different life stories depending on variable experiences in meaningful relationships. For example, a wife's self-presentation as "happily married" can be altered after divorce into a self-presentation as "happily separated."

The following sections discuss three different ways that personality influences relationships from formation to maintenance and ending: (1) *selection* of relationship partners and experiences, (2) *evocation* of relationships and relationship experiences, and (3) *proactive change* of existing relationships and relationship experiences.

Relationship Selection

People seek out relationship partners and experiences that are consistent with their personality. Relationship selection thus includes two facets: selection of partners and selection of relationship contexts and experiences. The first is shown, for example, in the similarity or dissimilarity of relationship partners'

personalities, whereas the latter is indicated by correlations between individual personality attributes and specific relationship characteristics such as relationship quality.

How well do the personality profiles of relationship partners match? Lay psychology offers two rules, suggesting that either "birds of a feather flock together" or "opposites attract." Whereas the empirical literature clearly supports the first rule, this does not exclude the possibility that there may be some relationships in which the latter works.

Similarities between relationship partners stem from different sources: social homogamy, selection, and convergence. Partners can be similar because they meet similar people due to shared interests and activities they actively seek out similar persons, and they can become similar because they share relationship experiences and influence each other. Evidence for similarity in dispositional personality traits (level 1) tends to be small and rarely exceeds modest levels. Similarities in characteristic adaptations (level 2) are more important, suggesting that people who deliberately enter into new relationships are moderately to strongly similar in attitudes, worldviews, goals, and aspirations. For example, romantic relationship partners tend not to resemble each other much in levels of extraversion, yet they are more likely to share political attitudes and worldviews. Some studies have also shown that relationship partners become more similar over time regarding both traits and characteristic adaptations.

There are substantial dyadic differences in personality similarity and compatibility that covary with relationship satisfaction, relationship duration, and interaction frequency. Although similarities in attitudes, values, or self-esteem, for example, are related to better relationship quality, these correlations do not allow for causal inferences because it is not clear whether similarity affects relationship quality or the reverse. In addition, these associations also can be due to third variables such as selection.

Selection and convergence also refer to general preferences for relationship experiences that contribute to a more or less stable personality-relationship fit. A fit between one's personality and one's relationships is represented by correlations between personality characteristics and relationship attributes. This fit suggests that people

may self-select into relationships or networks of relationships that suit them, irrespective of whether the fit is adaptive or dysfunctional. There is strong empirical evidence for correlations between neuroticism and relationship dissatisfaction, insecure attachment, and maladaptive relationship functioning. Although processes of relationship evocation and proactive relationship change, as explained in the next paragraphs, might contribute to the development of the relationship, selection of the relationship partners is the first step. For example, people with higher levels of neuroticism are more likely than others to enter difficult relationships, or, in other words, neurotic people are generally less satisfied with their partner relationships. Studies conducted at a single point in time cannot disentangle causes from effects because relationship distress may be affected by relationship experiences, neuroticism, or both. Longitudinal studies, however, show that personality–relationship fits result from powerful mechanisms of active screening, seeking, and molding through which relationships become more in line with personality.

Relationship Evocation

People evoke relationship experiences and feedback from others by virtue of their personality traits. It is not surprising that different people receive different reactions from a given person. For example, individuals higher in Extraversion and Agreeableness tend to perceive more support from their social network. More extraverted people know more people, they ask for help if necessary, and more amiable and conflict-avoidant people are confident about receiving help because they would provide it to partners. Existing evidence shows that these personality characteristics influence support received from family members, spouses, and friends differently over time. The dynamic processes of personality–relationship evocation play an important role in personality and relationship development, and there is good reason to believe that personality characteristics (at least at level 1) are an important causal factor. Empirical evidence from longitudinal studies suggests that in the long run Neuroticism is a good predictor of marital dissatisfaction and instability (i.e., divorce). People higher in Neuroticism may

repeatedly provoke negative answers or rejection, which increase disagreement and conflict between marital partners.

Evocative effects tend to grow stronger as people age because individual differences in personality traits become increasingly stable across adulthood, reaching a plateau after the mid-50s. Longitudinal research in adulthood has shown that dispositional traits have strong effects on relationships, but are relatively immune against relationship influences. For example, highly extraverted people show open and outgoing behavior toward people and elicit social support easily. However, the amount of support received from other people is not related to change in Extraversion (or Big Five traits in general). In this way, basic personality traits may exert cumulative effects on relationships.

This does not necessarily apply to characteristic adaptations or to life narratives, which are more sensitive to environmental influences. Consider again the example of social support. There is substantial evidence that received social support from friends predicts change in social self-esteem. Thus, having reliable and helping friends may strengthen the evaluation and appreciation of oneself especially with respect to social relationships (i.e., social self-esteem).

Proactive Relationship Change

Proactive effects on relationship change emerge when people actively manipulate and alter relationships by virtue of their personality. Proactive influences occur in two directions: provoking a desired behavior and stopping an unwanted behavior. The strategies used can differ and depend on individual personality traits. For example, highly extraverted persons are more likely to apply behavioral strategies that are based on social dominance. Thus, they may attempt to draw their relationship partners into new activities that enhance their social life. By contrast, persons higher in Neuroticism may be more inclined to utilize tactics involving emotional withdrawal, conflict, and confrontation, thereby involving relationship partners in a circle of negative interactions with likely unhappy outcomes.

Like evocative effects, proactive relationship change has been shown in longitudinal research,

such as diary studies and longitudinal studies over many years. For example, as mentioned earlier, higher Extraversion predicts an increase in perceived social support over many years. In terms of proactive change, more extraverted people may alter their relationships to become more helpful, such as by frequently asking for support. Other examples refer to the long-term effects of shyness as a joint facet of Neuroticism and Extraversion, with higher levels of shyness predicting slower growth of friendship networks and delayed marriage. These and other findings are noteworthy because the initial associations between personality and relationships were statistically controlled in these analyses, thereby demonstrating the long-term effects of personality on later change in relationships.

Proactive effects on relationship change may also include feedback effects on personality development. Due to selection effects, people seek out relationships and relationship experiences that fit their personality. In a corresponding manner, these relationship experiences may deepen and even accentuate the traits that have initiated them. For example, consistent with high levels of Neuroticism, some people may actively construe relationship experiences in a negative way, which in turn may foster and enhance their neurotic disposition. The so-called corresponive principle is supposedly one of the most powerful principles in the personality-relationship link, illustrating the interplay of personality effects on relationships and its feedback on personality. Describing personality-relationship transactions in this light suggests the question of whether relationships are just expressions of the two partners' personality traits, rather than unique social phenomena in their own right.

Are Relationships Just Expressions of Personality?

Selective, evocative, and proactive personality-relationship effects produce cumulative consequences (i.e., individual reaction patterns are maintained over the life span by the increasing accumulation of their own consequences in relationships) and synchronic consequences (i.e., individual reaction patterns repeatedly produce supporting and validating reactions from relationship partners). Through both consequences, relationships and their characteristics become more and more the reflection of basic

personality traits, rather than the reverse. For example, individuals with high levels of Neuroticism evoke negative experiences that accumulate over subsequent relationship events, thereby reinforcing and escalating the effects of Neuroticism on other life domains, such as well-being and health.

Thus, the nature and significance of relationships may be understood from the perspective of personality psychology. Nevertheless, social relationships are entities in their own right, characterized by complex dynamics and associated with multiple factors, many of which are independent of personality factors. For example, attachment relationships are not only influenced by attachment styles and related personality traits, but also by many other environmental conditions such as physical factors, family background, cultural construction of relationships, historical influences, and, of course, by chance. The study of personality and relationships will continue to present researchers with challenging questions.

PERSONAL RELATIONSHIPS, DEFINING CHARACTERISTICS

Defining *personal relationships* is a tricky business. Countless scholars and philosophers agree that humans are fundamentally *relational* or social creatures, but getting researchers to agree on just what exactly that means is a different story. *Personal relationships* are typically seen as based on personal knowledge, affection, and intimacy, and they are compared to *social relationships*, which are role related and based on someone's societal connection to another (one store clerk relates to one customer in pretty much the same way as any other such pair).

Scholars choose different methods for making their definitions and generally differentiate personal relationships from other types of relationships in one of three ways. The first draws essentially on early philosophical or semantically and religiously inflected views of the nature of relationships. The second approach defines the endpoints of a relationship continuum from minimal contact to close personal relationships, sometimes romantic and sometimes friendly. This approach consequently blurs the lines between the aforementioned philosophical approach and the final approach. This final method of defining relationships may be considered a more “scientific”

approach that distinguishes relationships based on identifiable and quantifiable characteristics or features. This entry addresses each of these approaches.

Philosophical Approach to Defining *Personal Relationships*

The most famous and influential relational philosopher was Martin Buber, who grounded his approach in religion as well as philosophy. Buber argued that humans fundamentally see relationships in two ways. The first way of viewing relationships involves treating others as mere objects instead of as mindful people. Buber called this type of relating “I-It” because in this approach an individual (the “I”) views an Other as a depersonalized “It” and not as a soulful, reflective person. Consequently, Buber explained, the I-It approach to relationships fails to acknowledge the humanity and the personhood of the other person(s). Buber argued that when we engage in an I-It relationship with others, we deny their status as unique thinking creatures created by God, and they become *something* to be experienced as opposed to *someone* with whom to have a relationship. This approach, he felt, leaves out the personality and individuality—indeed, the humanity—of the Other.

One can see examples of this type of relationship in the service industry. People frequently interact with salesclerks, servers at restaurants, individuals who clean houses, and individuals who carry luggage as “Its” (or nonpersons), instead of interacting with them as human beings with unique qualities. In many cases, such people are fulfilling a role or performing a low-level, nonpersonal service and are not engaged in personal conversation except at the end of delivery of their services, when they are thanked personally. Often as they go about their business they are simply ignored as if they were not present at all, as when a hotel server delivers coffee and cookies to a room at an appointed break time during a meeting. The conversation in the meeting continues as if the server were not there, although the server may be thanked at the end of the delivery. It is important that such a person is performing a nonpersonal role in that many people would not even notice if the individuals

who perform these acts of service were replaced with simple robots, provided the robots would still perform the job as efficiently and discreetly as the humans currently doing those jobs. Although the person giving you a massage or teaching a class is also enacting a role, the role is more personal than the previous examples and needs to be considered differently, as in the next section. The impersonal role type of relating stands in contrast to the second way of relating discussed by Buber, which he called "I-Thou."

In the I-Thou manner of relating, Buber saw both individuals treating each other as a mindful, sensitive, and aware human being with whom a personal, even deep, relationship can be created. Buber argued that in the I-It relationship there is a "relationship" only in the sense that there are two differentiated entities, ostensibly but adventitiously, if somewhat artificially, connected as objects. The same would be true if the rock were replaced with a stranger passing by: The stranger attracts attention as a visual object momentarily, but there is no real human connection between the object and the perceiver.

It is only in the I-Thou relationship that any true human *relating* takes place because such relating requires two interconnecting, interdependent, and mutually responsive individuals (not an individual and an object). For example, if a person were sitting on a park bench looking at a rock, one would hardly say that the person has a relationship with the rock other than the fact that the rock holds that person's attention momentarily. However, if a person and his or her lover were sitting on the park bench and engaging one another in conversation, one can see that the two are giving their attention entirely to the other, and thus they can be said to have a relationship. In other words, in the I-Thou relationship, an individual embraces the full humanity and uniqueness of the other, and the I-Thou relationship occurs in the "between" of the two souls coming together. Buber's explanation of the I-Thou relationship is much more difficult to describe than the I-It approach, in part, because Buber argued that the I-Thou relationship was a spiritual, almost metaphysical experience, and in some cases the distinction is less clear than we have tried to draw it here.

For example, the way that a man looks at a woman who is a prostitute is different from the

way a man looks at a woman who is his soul mate. In the former case, the prostitute is simply an *object* of his sexual desire by reason of her fulfilling that role alone, whereas the soul mate may do that and much more, including an intertwining of lives over a lengthy period of time and multiple types of interactions, rather than simply short sexual encounters. The man does not attend to her personhood, but rather sees her merely as a *thing* whose purpose in the interaction is to satisfy his desire. This makes the essence of the connection between the two humans involved in this setting merely an I-It relationship. Alternatively, the man who looks at his soul mate sees differently. Indeed, he does not see a *something*, but rather he sees a *someone*. When he looks at his beloved, he sees a *subject*, another unique individual created by God with whom he has a relationship (as discussed earlier). It is in the act of relating in this way that Buber says we can fully express and fully embrace even our own humanity. In other words, the self can be fully realized only in I-Thou relationships with others. If we are surrounded only by objects, there can be no such relationships. Thus, for Buber, personal relationships are defined as I-Thou relationships, in which the self of each partner can only ever be fully realized through recognition and acceptance of a divinely inspired unique humanity.

One interesting relationship in light of this philosophical approach to defining relationships is the parent-child relationship. Although most people would probably assume that the parent-child relationship is automatically an I-Thou relationship, this may not always be the case. An example of the I-It parent-child relationship that is sometimes portrayed in movies is the cold, distant, authoritative father figure. In cases such as this, the father is rarely present, and when he is it is strictly to play an authoritarian role. Lest it be assumed that this is a one-way street, most of us can probably think of examples of children (either real life or in the media) who also treat their parents as objects rather than people. Thus, although the I-Thou relationship may be the "natural" relationship for either biological or cultural reasons, exceptions certainly do exist.

One can easily see that, although a sort of relationship does exist between a person and a thing (in the broadest sense of the word *relationship*), the I-It type of relationship is not *personal* on any

level. For Buber, it is only in the I-Thou type of relationship that one engages in a personal relationship. Buber added another criterion, an insight since recognized by many other scholars, including those from more scientific and less metaphysical backgrounds: exclusivity. According to Buber, for a relationship to be personal, it must be exclusive in the sense that the two parties become fused exclusively to one another on some level, although other scholars allow a larger leeway and assume that only romantic relationships are entirely exclusive. Put another way, the individuals in an I-Thou relationship are irreplaceable to one another, whereas the two persons are interchangeable in an I-It relationship, as in the previous example of the store clerk and the customer.

Clearly, a sustained I-Thou relationship is exceedingly rare. In fact, it may be helpful to understand the I-Thou relationship as reserved for our closest relationships (e.g., family members, spouses, best friends, significant others, etc.). More important, however, Buber explained that, occasionally, we can have “I-Thou moments” and/or “I-It moments” across a wide variety of relationships. In other words, Buber pointed out that these relationship types are fluid rather than set in stone. Therefore, it is likely that even in our closest relationships, we may sometimes treat the other person as an “It” rather than as a “Thou.” Similarly, there may be times and places when, for some unknown reason, rather than treating a store clerk as an automated checkout system, we are struck by his or her personhood and we suddenly remember that he or she, too, is one of God’s unique creatures.

The Continuum Approach to Defining Relationships

Although Buber’s definition is set up in a dichotomous format, more recent scholars have argued that personal relationships and other types of relationships are best conceptualized as lying on a continuum. According to this group of scholars, there are many gradations of relationships that exist—not only between the poles of the I-It relationships and the I-Thou relationships discussed by Buber, but even within each of them.

Julia Wood identified what she called the “I-You” type of relationship as a distinction relevant within

the I-It category. She argued that the I-You relationship is one in which people are treated as more than mere objects, but the relationships do not have the fullness or richness of the I-Thou relationship discussed by Buber. For example, Wood claimed that most people don’t treat all store clerks as soulless robots, but instead they may engage them in small talk and/or some sort of conversation. In some cases, with repeated interactions over time in the same store (e.g., the local supermarket), the two persons may have such frequent interaction over time that they develop a more familiar style of conversation. They may even learn something about one another’s lives and politely inquire about those topics when they meet. Granted, this conversation is not as deep and rich as in the I-Thou relationship, but Wood maintained that this represented something more than the simple objectification of the I-It relationship. According to Wood, most of our interactions with casual friends, acquaintances, coworkers, and distant relatives are I-You relationships.

Laura Guerrero, Peter Andersen, and Walid Afifi also described relationships along a continuum. Like Buber, these scholars argued that close relationships (i.e., what Buber called the I-Thou relationships) are characterized by irreplaceability, but that there are gradations even within that category (e.g., from casual friendship to deep romantic attachment). They also contended that, for a relationship to be considered “close,” there must be emotional attachment and need fulfillment. Alternatively, role relationships (i.e., the I-It relationships) are functional and/or casual in their nature. These scholars pointed out that casual relationships are often temporary instead of long-lasting. However, like Wood, Guerrero, Andersen, and Afifi also labeled a third category of relationships. These scholars made a distinction between *interpersonal* relationships and *close* relationships. That is, the third category of interpersonal relationships does not require the irreplaceability, emotional attachment, or need fulfillment of the close relationship, but it does require that the individuals involved have some degree of meaningful mutual interdependence, a set of interaction patterns that is unique to the individuals involved (similar to, but not quite the same as, Buber’s concept of exclusivity), and repeated interactions over time.

As mentioned previously, the parent–child relationship seems to provide an interesting example of a relationship that is somewhat hard to categorize. Those who take a continuum approach to defining relationships would probably concede that parent–child relationships are laden with cultural expectations associated with occupying a certain place on the relational continuum. However, most of us probably know of some people whose relationship with their parents would fall into either the I–You or even the I–It definition of relationships. Additionally, the type of relationship that parents and their children have may also fluctuate back and forth along the continuum depending on their respective life stages. For example, one would expect that young adolescents are probably more likely to have an I–Thou (or “closer”) relationship with their parents, whereas teenagers may “drift” away from their parents somewhat.

Obviously, the differentiation of relationships along a continuum as discussed by Wood and Guerrero, Andersen, and Afifi begins to extend beyond the simple dichotomies qualitatively defined in Buber’s philosophical approach and offers a quantitative scientific approach that can more accurately distinguish relationships based on specific characteristics or features.

Scientific Approach to Defining *Personal Relationships*

Some scholars have taken an alternative approach to differentiating relationships based on specific measurable characteristics or features of relationships. Unlike the I–It/I–Thou approach or the continuum of relationship types, these scholars assume that relational characteristics can be quantified. To this end, relationship scholars have developed a large number of different scales to answer questions such as “how much” or “to what degree” an individual feels attached to someone else; how emotionally close they are; the degree of trust, intimacy, or satisfaction that they experience; and even the frequency of meetings and topics of conversation that characterize different relationships. Such assessments are used to differentiate relationships by means of the amount of certain properties that they manifest. Researchers then use these instruments to measure how personal relationships

are quantitatively different from other types of relationships along various dimensions.

Keith Davis and Michael Todd explained that when individuals think about relationships, they think about them in terms of a paradigm case. A paradigm case is essentially a prototype or an exemplar of what a certain type of relationship looks like. They explained that prototypes are composed of a list of attributes that describe a relationship, but they note that this list is not complete or comprehensive enough to actually define the category.

Davis and Todd drew up different scales for characteristics of relationships as a whole and split them into those that applied to close friends and same-sex friends, and then differentiations of best friends, close same-sex friend, close opposite-sex friend, social acquaintance, and former friend. They also examined relationship characteristics as a function of the violations of best, close friend relationships as compared with those that simply drifted apart, finding that all of these variables were implicated in those relationships that ended by a violation. Their basic set of variables was viability, support, intimacy, spontaneity, stability, success, and enjoyment. In a comparison of their own and other kinds of lists, they found that affection and enjoyment, authenticity, conflict management, confiding and intimate disclosure, giving and receiving of assistance, reliability and trust, respect and acceptance, satisfaction, self-respect, shared activity and companionship, similarity, and understanding were some of the basic features that people identified as characteristic of their most personal relationships.

Further attempts to identify the properties that make relationships different in degree of personalness have been continued by a number of scholars in different traditions. Guerrero, Andersen, and Afifi also offered a list of dimensions on which relationships are differentiated. They pointed out that relationships can vary along several levels—voluntariness (i.e., voluntary or involuntary), intimacy (i.e., romantic or platonic), satisfaction (i.e., satisfying or unsatisfying), and length (i.e., short or long term). Such items characterize relationships in terms of the different degrees of key variables, but some scholars have argued that specific types of relationships are uniquely characterized by dimensions not present in other types of personal relationships.

For example, Fitzpatrick argued that marriages are one such relationship—they can be viewed in terms of how traditional or nontraditional they are, how connected or separate the spouses are, and, finally, how likely the partners are to engage in conflict. Other scholars such as Hendrick and Hendrick have developed scales specifically to measure personal relationships that are romantic and to differentiate this category of personal relationships in terms of love types. They have identified six different types of love based on different qualities of desire, playfulness, possessiveness, friendship, practicality, and self-sacrifice. More recently, the Hendricks have pointed to the role of respect for a partner as a property correlating with love and sexual attitudes, relationship satisfaction, commitment, and self-disclosure.

Yet again the parent–child relationship offers an interesting example of relational categorization. Scholars in this tradition of relational definition would most likely categorize parent–child relationships just like they would any other relationship type—along a continuum of various aspects of the relationship. For example, a parent–child relationship could be categorized as varying along almost any of the aforementioned relational dimensions (e.g., closeness, playfulness, friendship, intimacy, satisfaction, etc.).

Clearly the properties of relationships are one of the most fertile and prolific areas of the whole field of research into social and personal relationships.

Conclusion

Scholars have made numerous attempts to define characteristics that make personal relationships “personal.” Such attempts have ranged from the religious, metaphysical, and philosophical to the quantified, empirically based assessment drawn from extensive application of questionnaires and the development of scales for measuring features that are prominent in relationships of different kinds. Although broad distinctions can be made between social and personal relationships, the latter being characterized by the irreplaceability of the partners and the former by their interchangeability, there are many more refined distinctions that can be made. We expect the attempts to obtain even greater precision to be one of the continuing developments of the future of this field

as scholars are more exactly able to differentiate and classify types of personal relationships.

PERSONAL RELATIONSHIPS JOURNALS

Journals are the primary means of publicizing research in science and serve three broad purposes: to communicate the findings of a particular study to other researchers, teachers, and students; to archive research findings for future scholars; and, by virtue of a journal's reputation, to certify the importance and validity of a particular study. Most scholars would agree that journals are the lifeblood of a discipline. This entry provides an overview of the journals that publish research about personal relationships.

What Do Journals Publish?

Most journals in relationship science emphasize empirical articles; that is, papers that report the results of research studies. A large majority of these papers describe quantitative research, although some also include qualitative studies. Some, but not all, journals also publish theoretical reviews, commentaries on studies published in the present or past issues, and book reviews. Manuscripts are selected for publication through a process known as peer review. When a paper is submitted, the editor chooses reviewers to recommend whether the paper is suitable for publication in that journal, and, more important, to raise questions and offer suggestions for improvement. These reviewers are scholars in the field who often have published in that journal and who have expertise about some aspect of the research under consideration. Some journals use "blind review," in which the authors' identities are masked. The reviewers are almost always anonymous to facilitate open and honest comments. Typically, anywhere between two and four outside reviewers are chosen. Virtually all papers that are published go through one or more rounds of revision, some of which can be extensive, in which the authors respond to questions raised during the review process.

Journals vary greatly in the percentage of papers that are accepted or declined; the latter is referred to as the *rejection rate*. A high rejection rate is considered a sign of journal quality. The best journals typically have rejection rates of around 80 to 90 percent. Rejection rates in lesser quality journals tend to be lower.

Interdisciplinary Journals in Relationship Science

Relationships are investigated in nearly all social science and many natural science disciplines, including Psychology, Sociology, Family Studies, Communication, Anthropology, Demography, Economics, Gerontology, Political Science, Biology, Zoology, and Medicine. This means that relationship research is often published in the various journals of each of these disciplines. The advantage of publishing in these journals is that other scholars in one's discipline who do not necessarily

study relationships will be apprised of whatever new advances in knowledge a given study has generated. However, because there are so many outlets that publish research relevant to relationships—certainly hundreds and perhaps more—no individual scholar can hope to keep up with new findings being reported in such a vast array of journals. Indeed, because relationship science is an intrinsically multidisciplinary field, new journals have been established to represent this particular niche. Publishing in these journals has the advantage of exposing one's work to scholars from diverse home disciplines who nevertheless identify as relationship researchers. The disadvantage, of course, is that nonrelationship scholars from one's home discipline are less likely to notice this work. Thus, relationship researchers, like all interdisciplinary scientists, must decide which audience is of higher priority.

Historians of science would probably agree that the establishment of a journal is a key sign that a new area is, or at least is on the path to becoming, an identifiable and accepted area of study. The fact that there are two specialized journals devoted wholly to the topic of personal relationships indicates both that there is a steady and sufficient number of new research papers being generated and that a reasonably large audience wishes to read those papers.

The first personal relationships journal was the *Journal of Social and Personal Relationships (JSPR)*, founded in 1984 by Steve Duck. *JSPR* is home to empirical and theoretical papers on social and personal relationships and currently publishes six issues each year. *JSPR* maintains an informal association with the International Association for Relationship Research (IARR), one of the leading scientific organizations for scholars with an interest in personal relationships (and the only such organization with a broad multidisciplinary focus). The second major journal in the field is *Personal Relationships*, founded in 1994, and owned and operated by the IARR. Patricia Noller was the inaugural editor of this journal. It publishes four issues per year, reporting research on personal relationships conducted from a variety of perspectives and disciplines and with a variety of methods.

Although the study of marriage and family has, to some extent, become an established discipline in its

own right, the fact that contributors to this literature come not only from Family Studies programs, but also from disciplines like Sociology, Psychology, Demography, and Gerontology, suggests that journals in this area should also be considered interdisciplinary. In fact, the first journal to specialize in publishing research on human relationships was the *Journal of Marriage and the Family* (JMF), still considered the leading outlet for research and other scholarly articles on marital and family topics. Founded in 1939, when it was named *Living* (later, *Marriage and Family Living*), with Paul Sayre as the inaugural editor, the first volume included a paper by Pope Pius XII, children's stories, cartoons, and poetry, along with scholarly articles. JMF is owned and operated by the National Council on Family Relations (NCFR), which also publishes *Family Relations*, a more applied journal, founded in 1951.

Disciplinary Journals That Publish Relationship Research

As mentioned earlier, relationship research is conducted in many different disciplines, making impossible a comprehensive list of journals that publish relationship research. Nevertheless, scholars who identify themselves as relationship researchers (and who are members of the IARR) tend to congregate in a few particular traditional disciplines, and these have journals that regularly publish the findings of relationship research. Several of the more popular and highly regarded journals are identified next. These have been chosen according to their "impact factor" scores. Impact is a measure of the degree to which articles appearing in a given journal are cited by others. Scholars generally prefer to publish in high-impact journals because it means that their work is more likely to be noticed, read, respected, and cited, although to be sure there is considerable controversy about the merit of these scores as an index of genuine impact. Journal impact factors and rankings for science and social science journals are reported in *Journal Citation Reports*.

In Social Psychology, relationship research is regularly found in the *Journal of Social and Personality Psychology* and the *Personality and Social Psychology Bulletin*. Developmental Psychology's highest rated journals are *Child*

Development, *Developmental Psychology*, and the *Journal of Family Psychology*, and research relevant to children's relationships is found in all three. The top-ranked Clinical Psychology journal most likely to publish relationship studies is the *Journal of Clinical and Consulting Psychology*. In Sociology, the leading journals publishing relationship research are the *American Sociological Review* and *Social Psychology Quarterly*. For scholars in Communication, the most influential journals regularly featuring relationship research are *Human Communication Research* and the *Communication Monographs*.

If nothing else, the diversity of journals publishing relationship research provides testimony to the importance of the topic and the vigor with which researchers pursue it.

PERSONAL SPACE

Personal space, also described as the *body buffer zone*, is the emotionally tinged zone around the human body that people feel is "their space." Its dimensions are not fixed, but vary according to internal states, culture, gender, and context. Personal space has an hourglass shape: wider in

front and back, and more narrow at the sides. People can tolerate the closer presence of a stranger at the side, as in a bus or elevator, than someone sitting or standing directly across from them. Eye contact plays an important role in personal space regulation. We can approach closer to another person whose eyes are closed than to the same person whose eyes are open. Lovers in an intimate embrace often close their eyes to compensate for excessive closeness.

There are gender and cultural differences in the dimensions of personal space. People from Latin cultures tend to stand closer than people from Anglo-Saxon cultures, and two women interacting will stand closer than will two men. Interaction distance is further influenced by the relationship between people. In an intense relationship, personal space can disappear as two individuals merge into a combined self with frequent touching and body contact. There is no concept of a spatial invasion between two such individuals. Beyond intense intimacy when interindividual spacing breaks down, personal space expresses and reinforces the closeness of a relationship. Friends stand closer together than do acquaintances, who in turn remain physically closer than do strangers. In a similar vein, liked individuals, those of the same status, and those with whom we agree are allowed to be physically closer than those whom we do not like, who are stigmatized in some way, or with whom we disagree.

These well-documented findings can be used by others to estimate the degree of closeness in a relationship. Within the realm of nonverbal communication, people can be taught to “read relationships” by noting the proximity of individuals. This has played a role in lawsuits and court cases in which unwanted physical closeness, especially by a supervisor, is considered harassment. In the obverse situation, an authority figure who allows subordinates to come “too close” can be sanctioned. In one example, a female prison guard who allowed male prisoners to stand “too close” was accused of illicit relationships by her fellow guards. Culture may play a role in such accusations, as in the case of a supervisor accused of, among other things, standing too close to women under his jurisdiction who happened to be of a different ethnicity. This behavior made the women uncomfortable, not only because of the spatial invasion, but also the women’s fear that others would perceive a more

intimate relationship than existed. Corporations and government agencies often offer special training in cultural sensitivity, including information on spatial norms, for employees and families being posted abroad.

A preference for close or distant interaction develops early in life, typically is formed by puberty, and is influenced by modeling. Differences in spatial norms, especially if not recognized or acknowledged, can strain a relationship, with one person feeling that the other is cold and distant while the other resents the partner’s excessive closeness. Shared space can also strain a relationship. This introduces the concept of *territoriality*, the ways in which individuals mark and defend turf. Unlike personal space, which surrounds and moves with the body and expands and contracts according to the presence of others, territory does not move; it has clear markings and fixed boundaries. In shared space, some areas will remain in joint occupancy while other areas will be considered as the private preserve of a particular individual, not to be invaded. For the private space, which can be a side of the room, a closet, or a bookshelf, clear designation or marking of boundaries will reduce conflict.

In the digital age, the emotionally charged zone around one’s body can be invaded virtually. Cell phone and iPod users may act as if public space were private space, converting others nearby into nonpersons. The mobile phone advertisement, “Talk all you want and whenever you want for a flat monthly fee,” is an invitation for auditory invasions in public space, leading to “No Cell Phone” or “Quiet Area” signs in restaurants and other public locations. Posted Webcam images and messages may also invite others into a relationship.

This ubiquitous electronic gadgetry, including iPods and personal digital assistants (PDAs), can be seen as a means of escape, a way by which a person can avoid unwanted encounters. People leave more space between themselves and someone using a cell phone or PDA than someone presumably less occupied. Researchers have found that people on cell phones are less aware of their surroundings, except for the immediate ground area around them. College students who were surveyed reported that a cell phone gave them a sense of control over time and space.

Body size affects the dimensions of personal space and is a factor in perceived invasions. Obese individuals take more room than thin people. Having larger bodies, their boundaries plus personal space zones extend further. The effects of this are particularly evident in public locations with fixed seating, such as airports, trains, and theaters. A larger personal space zone makes it more likely that people may unwittingly intrude, thereby provoking an aggressive response. Jail inmates convicted of assaults had larger personal space zones than inmates convicted of nonviolent offenses.

Early research suggested that personal space was part of a *silent language*, existing for most people below awareness. Since then, the term has become part of popular speech. People not only know what it means, they are more aware when their space has been invaded. If someone on a date stands excessively close to the other person, a salesperson to a reluctant customer, or a police interrogator to a suspect, the person whose space has been invaded usually knows what is happening. Nonverbal indicators of tension such as gaze aversion, hair tugs, and foot taps occasionally give way to verbal responses, expressed most directly when the situation permits, as “Get out of my face.” Despite increased awareness, most people still accept invaded space as a consequence of urban life. They don’t like the intrusion, but resist provoking an uncertain response from someone who has already displayed bad manners.

PERSPECTIVE TAKING

Perspective taking describes a person’s attempt to understand a stimulus from a different point of view. In relationships, perspective taking typically describes one person’s attempt to understand a relationship partner’s mental representations—his or her thoughts, feelings, attitudes, beliefs, preferences, or evaluations. *Perspective taking* is a broad term that is generally used to describe conscious and deliberate attempts to infer other people’s mental states. Perspective taking can lead to empathy, whereby a person directly experiences another’s emotional state or can induce people to experience emotions about another person’s experience, such as pride or sympathy.

Although some evidence exists of perspective taking in higher order primates, there appears to be a dramatic and qualitative difference in both the frequency and elaborate content of perspective taking in humans, making it one mental process that appears to truly distinguish humans from other animals. Accurate perspective taking is a critical feature of successful social interaction, but it is far from invariant. Some situations, some people, and some cultures are more naturally inclined to activate perspective taking than are others. Sometimes the process that enables perspective taking leads to accurate inferences about others’ mental representations, but sometimes it leads to predictable biases in judgment, such as the tendency to overestimate the degree of agreement with another person. Sometimes the attempt to understand another’s perspective has desirable effects on social interactions, such as when it leads to accurate insight about others’ preferences, but it can have negative consequences when biased judgments lead to mistaken inferences about others’ preferences. Understanding the process that enables perspective taking is crucial for understanding the variability in its consequences.

Developing Perspective Taking

Perspective taking is not a skill with which humans are born, but instead must develop over time. Young children, for instance, tend to be profoundly egocentric and do not distinguish between what they know and what others know, do not recognize

the difference between the way an object may appear to them and the way it really is, and do not provide enough contextual information in conversation to identify ambiguous referents. By roughly the age of 5, most children have developed the ability to distinguish between themselves and others, and they have developed the ability to reason about another person's thoughts, feelings, and other mental states as being distinct from their own. Perspective taking develops out of these two abilities. The psychological disorder of autism (and its less severe version, Asperger's Syndrome; proper spelling is Asperger, not Asperger's) represents a breakdown in the development of perspective taking.

Variability in Process and Content

The process by which people adopt another's perspective can include both reflexive (or automatic) and deliberate (or controlled) components. Because people perceive the world through their own senses and interpret it through their own brains, people tend to use their own perspective as a guide for understanding others' beliefs. Although adults have developed the ability to overcome egocentrism when reasoning about others' thoughts to accommodate differences between themselves and others, it does not appear that they entirely outgrow their tendency to begin with an egocentric default. The most common bias observed when people reason about others' thoughts is therefore egocentric bias, whereby people overestimate the extent to which others' perceptions are similar to their own. In communication, for instance, people tend to overestimate the extent to which their intentions are clear to their conversation partner. Because a speaker's intentions are so clear to him or her, it may be difficult to recognize that a listener may easily misinterpret a playful tease, a subtle joke, or a constructive criticism. Such egocentric biases are a frequent cause of discord and conflict in relationships. For instance, those who are personally unsatisfied in a relationship tend to see more hostile intent in a partner's behavior than the partner actually intends. Overcoming one's own egocentric perspective and intuiting another's differing perspective therefore tends to require deliberate effort and attention, and anything that diminishes a person's ability or motivation to

expend effortful thought should generally increase the magnitude of egocentric biases in judgment. Over time, effective perspective takers learn to overcome their own egocentric perspective more readily and consider another's perspective more naturally, but this process does not appear to ever become completely automated.

Not only can perspective taking vary in the extent to which it is activated automatically versus more effortfully, it can also vary in the process by which people try to adopt another's perspective when they are induced or motivated to do so. In particular, individuals can try to adopt another's perspective either by imagining what that other person thinks or feels or by imagining what they would think or feel if they actually were the other person. These two methods of perspective taking produce different physiological and neural responses, and they also differ in their implications for empathic versus self-centered responses to another person. The former is associated with increased empathy, whereas the latter may increase both empathy and personal distress in response to a person in need.

Determinants, Moderators, and Correlates

As with any other skill or ability, possessing a skill and utilizing it appropriately when necessary are two different things. The most important situational, dispositional, and cultural determinants of perspective taking are those that predict when people are likely to try to adopt another's perspective and when they are not.

Because perspective taking is generally an effortful process, the major situational determinants of perspective taking are those that make it easier to imagine oneself in another's position or increase the incentives and motivation for doing so. It is easier to imagine oneself in the position of a person who is similar to the self or who is well liked rather than despised. Both perceived similarity to a target and liking for a target increase the likelihood of adopting that target's perspective. Similarly, prior experience with a situation faced by a target also tends to increase perspective taking. Adopting another's perspective is more difficult when cognitive capacity is limited, such as when one is distracted by some other task that requires attention.

A person has more incentive to adopt the perspective of a person with whom one expects future interaction, and anticipated future interaction therefore increases the likelihood of perspective taking. Individuals who occupy a position of low status or low power within a social organization also have more incentives for adopting the perspective of others and tend to do so more than high-status or high-power individuals. In everyday life, this effect of power and status on perspective taking may also stem partly from the demands and responsibilities that accompany being in a position of power and the diminished cognitive capacity that results from such demands.

Because perspective taking is a mental ability that develops over time through repeated practice, individual differences that index the likelihood of acquiring such practice should predict perspective taking. Chief among these is age: As children get older, they acquire the ability to overcome their own egocentric perspective and reason about others' differing mental states. There is little evidence, however, that such development continues throughout life, and little if any research suggests that older adults are more likely to engage in perspective taking than younger adults. Culture also predicts perspective taking as a function of the frequency and importance of orienting oneself toward another's perspective within that culture. Collectivist cultures (e.g., the majority of Asian and Latin American cultures) place great value on interdependence and define the self in terms of relationships with others, whereas individualistic cultures (e.g., the majority of North American and Western European cultures) tend to value independence and define the self in terms of one's personal accomplishments and status. Members of collectivist cultures, as a result, are more likely to engage in perspective taking than members of individualistic cultures. Finally, self-reported perspective taking is correlated with better social functioning and higher self-esteem, suggesting either that well-adjusted individuals have an enhanced capacity for adopting others' viewpoints or that perspective taking leads to better social function and increased personal well-being.

Relatively less evidence exists for gender differences in perspective taking. Although recent theories suggest the advantage of women versus men in perspective taking is biologically based and that the brain of people with autism—a condition

characterized by deficits in perspective taking—is the extreme form of the masculinized brain, surprisingly few studies support this female advantage. Some research demonstrates that females are more accurate in perspective taking, but only in situations that evoke the expectation that women *should* be better in this capacity. Awareness of the stereotyped concept of “women's intuition” may cause women to work harder at tasks assessing empathic accuracy. These findings suggest that the female advantage in perspective taking may result from differing culturally conscribed expectations for the two genders, rather than from an innate biological sex difference *per se*.

Consequences

Perspective taking produces both obvious as well as nonobvious consequences for social interaction. Because perspective taking involves putting oneself in another's position, adopting another's perspective tends to increase the perceived similarity between oneself and others. This has several interesting consequences. First, perspective taking tends to increase the extent to which people behave charitably toward others. It increases the degree to which people feel empathy for others in positions of need, increases the likelihood of their behaving altruistically, and generally induces more positive evaluations of others. Naturally occurring or experimentally manipulated perspective taking increases the likelihood that people will respond to a request for assistance, donate time and resources to another person, and attempt to provide relief to an individual experiencing pain or suffering. Studies have similarly demonstrated that perspective taking can reduce the likelihood of aggression against another person. Second, perspective taking tends to increase the extent to which people mimic the basic mannerisms of their interaction partner, such as adopting the other person's body posture. Such mimicry tends to increase feelings of social rapport with another person and increases liking for the other person. Third, perspective taking tends to decrease the tendency to stereotype others. Putting oneself in the position of a stereotyped group member means that less attention is paid to the stereotypic features of the group member, which therefore reduces the likelihood that those features are used

when making judgments about these group members. Finally, perspective taking, by its nature, tends to reduce a host of egocentric biases in judgment. People, for instance, tend to overestimate the extent to which others notice and pay attention to them, the amount that they, compared with others, have contributed personally to a group endeavor, and the extent to which a self-serving conflict resolution will be perceived by others as fair. Perspective taking in these interpersonal contexts tends to reduce such egocentric biases and the associated problems that follow. In negotiations between groups, perspective taking tends to increase understanding of an opposing side's preferences and increases attention paid to the opposing side's preferences.

All of these consequences suggest that perspective taking is generally beneficial for social interaction, but there are some negative consequences as well. In particular, adopting another's perspective tends to reduce people's focus on themselves, but people who look into the minds of others do not always do so accurately. Men in abusive relationships who look into the minds of their spouses, for instance, tend to overestimate their wives' hostile intentions. In competitive contexts, people tend to overestimate the extent to which others intend to behave self-interestedly, a tendency that may enhance the consequences of these mistakes. As a result, those who adopt the other side's perspective in a competitive negotiation may overestimate the extent to which others will behave selfishly and therefore behave more selfishly themselves than do people who do not think about the other side's perspective. Whether perspective taking produces desirable consequences for social interaction and relationships depends on what people see when they put themselves in the shoes of another person.

PERSUASION

Persuasion is a communicative act in which messages are conveyed with the intention of changing the attitudes or beliefs of others who retain free choice over their response to the message. Persuasion is usually construed as intentional and is thus a type of, but not synonymous with, social influence, which captures a broader range of means by which people affect one another's attitudes and behavior (e.g., social norms, social learning). In addition, persuasion is noncoercive and is thus dependent on the reactions and choices of the recipient. The importance of the intentions of persuaders (usually called *sources*) and the reactions of recipients highlight the fact that they are in a relationship where both players hold at least some power. This entry describes the basic features of persuasion and how persuasion dynamics operate in relationships with groups, romantic partners, and families.

Factors that affect the efficacy of attempts to change attitudes are typically divided into four types: characteristics of the source (e.g., credibility or expertise), message (e.g., number or quality of arguments), recipient (e.g., motives or personality), and context (e.g., close or distant relationships). Changes in attitudes predict changes in behavior, most strongly when the attitude is at the same level of specificity as the behavior (e.g., attitudes toward a specific candidate predict voting for that candidate more strongly than attitudes toward that

candidate's political party). Most knowledge about persuasion comes from studies of short interactions (e.g., experimenter/participant, participant/participant), rather than in the context of preexisting and presumably more important relationships (e.g., friends, romantic partners, families). As a result, the factors considered to influence persuasion tend to consider individuals separately rather than as part of a relationship dynamic.

Greater persuasion is observed when recipients generate more (both in number and magnitude) positive thoughts in response to persuasive messages. If given sufficient attention, higher quality arguments in persuasive messages are more likely to lead to attitude change. To the extent that individuals have the ability and motivation to process persuasive messages in some depth, they have more positive thoughts in response to and are more persuaded by stronger (i.e., more cogent) arguments than weaker arguments. However, to the extent that messages are not deeply processed, stronger arguments may not be preferred over weaker ones. Variables that affect the level of processing include distraction (decreases), time pressure (decreases), personal involvement with the issue (increases), and need for cognition (increases). When individuals are not processing a message carefully, they become more likely to rely on peripheral cues or heuristic decision rules (i.e., mental short cuts) in determining the worth of an argument (e.g., "experts can be trusted," "I agree with people I like"). However, attitude change occurring as a result of deeper processing is more likely to lead to behavior change and is more resistant to counterarguments.

Relational Motives

Although accurately evaluating the validity of an argument is an important motivation in processing persuasive messages, people possess relationship-relevant goals that can be prioritized over objective accuracy. Recipients in close relationships are at times motivated to hold attitudes that are consistent with their partners' perspectives and/or that serve to sustain the long-term health of the relationship. Individuals in romantic relationships, for instance, often hold biased and overly positive views of the partners and relationship, which

satisfy relationship if not accuracy concerns. Further, the types of persuasive messages employed between close relationship partners differ from the messages used by distant others, advertisers, and experimenters; people in ongoing relationships can draw on their knowledge of one another, as well as the relationship.

Persuasion Through Connection to Groups

Although personal attitudes are a strong predictor of behavior, another important influence is the expectations of a social group (i.e., social norms). For example, during a shared meal, individuals tend to match the amount they eat to the amount eaten by others regardless of their own level of hunger, and people tend to express explicit attitudes toward social groups that are consistent with current social norms (e.g., egalitarianism). Thus, persuasive messages are not only successful when targeting a person's attitudes, but can also produce behavior change by influencing an individual's perceptions of group norms. For example, changing perceptions of the nature of alcohol consumption norms on a college campus has been shown to shift drinking behavior in the direction of those perceived norms. Changing perceptions of group norms is especially likely to lead to behavior change for individuals who identify strongly with the groups in which those norms hold.

Persuasion in Romantic Relationships

In general, feeling identified with the source of a message increases the persuasive power of that message. Recipients exhibit greater attitude change when they like a source, when they perceive a source as similar to themselves, and when they perceive a source as physically attractive. Individuals are especially likely to change their attitudes to agree with their romantic partners, particularly when they are made aware of differences in attitudes and the issue is central to the partner but less important to the self. Although romantic partners tend to be relatively high in similarity, underlying differences in beliefs frequently become salient due to partners' high degree of mutual dependence (e.g., raising children

together brings differing views of parenting to the forefront). Persuasion is a common part of the resolution of conflicting needs during relational conflict. For example, people (especially women) indicate greater use of persuasion with romantic partners than with same- or other-sex friends.

Persuasion during the resolution of disagreements in romantic relationships tends to involve greater use of indirect forms of communication. Relative to strangers, romantic partners discussing a disagreement spend less time directly addressing issues and offer less strong arguments. However, romantic partners do exert more pressure on each other for change than strangers. One common, indirect form of persuasion in romantic relationships is the giving and withdrawal of love. Close relationship partners are more likely than less close partners to refer to the relationship when they construct persuasive messages, noting, for instance, that a particular decision would be good (or bad) for the relationship. Referencing the relationship in this manner is an effective influence strategy and increases attitude change. Nevertheless, more satisfied couples tend to use more direct influence strategies, such as the generation of rational arguments.

The degree of persuasion used in conflict resolution varies as a function of couple type. Validating couples tend to exhibit moderate levels of positive and negative behaviors during conflict. These couples appear to use little persuasion during initial stages of conflict and increase their persuasion use as the conflict builds, with persuasion use receding during the final compromise stage. Volatile couples exhibit high levels of positive and negative behavior during conflict, and they use the highest levels of persuasion throughout the conflict. Avoiding couples demonstrate low levels of positive and negative behaviors, and they use little persuasion throughout all stages of conflict.

Persuasion in Families

Persuasion is ubiquitous in family relationships. This form of influence appears to be particularly important in children's internalization of the values of their family and community. Although both power assertion and love withdrawal are common forms of child discipline, induction (or providing reasons for behavior modification) is most likely

to lead to private acceptance of behavioral standards. In particular, calling attention to the consequences of a child's actions for others may be the best strategy for encouraging internalization. Children also engage in attempts to persuade parents, and children at least as young as age 3 are able to influence their parents' decision making, including the manner in which parents resolve sibling conflicts.

Generally speaking, powerful or authoritative sources are more persuasive than less powerful/authoritative ones. Power in relationships can come from a variety of sources: the ability to give rewards, the ability to exact punishments, a legitimate position of authority, social desirability (referent power), or expertise. In hierarchical relationships (such as parent-child), some types of power (e.g., expertise) may lead to greater attitude change than other types of power (e.g., compulsion) because they enhance internalization.

Persuasion as a Bidirectional Process Across Time

As noted, most knowledge about persuasion comes from research assuming that the persuasive process is unidirectional and time-limited. In reality, relationship partners exist in a continual feedback loop in which each tries to influence the other, altering and adapting their persuasive messages in response to the persuasive messages of the other. For example, distressed romantic couples tend to reciprocate negative acts with other negative acts. This cycle has been described as a "black hole" of negativity because each negative act compounds in a way that makes it increasingly difficult to respond with anything other than negativity.

Only one study has directly examined mutually reciprocal persuasion in real family systems. In a study of persuasion in family car-buying decisions, mothers and fathers were shown to have a unique, relational persuasion dynamic between them beyond their persuasive tendencies as individuals. That is, marital partners' detailed knowledge of each other appeared to allow them to adopt persuasive strategies with each other that they did not use with other individuals (including their own children). Further, persuasion around spending

decisions was shown to be highly reciprocal between mothers and fathers. That is, being open to a marital partner's persuasion increased the effectiveness of one's own persuasive attempts. This research highlights the unique persuasive dynamics that can exist in close relationships, and it suggests that a relational approach is likely to be generative for researchers interested in persuasion and social relationships alike.

PET–HUMAN RELATIONSHIPS

Pets provide a type of close social relationship that may augment or sometimes substitute for relationships with people. In national surveys about pet ownership, the most frequent reasons given for having pets are that they provide friendship, companionship, nonjudgmental social support, and protection from loneliness. The totally nonjudgmental aspect of support is described as an endearing quality unique to pets.

Background

More than half of the households in the English-speaking world have pets. Currently, more American households have a dog than have a child. In the United States, there are more than 70 million pet dogs and at least 75 million pet cats. Americans spend more than \$30 billion annually on their pets, and in national surveys, 90 percent report that their pets are important and cherished members of the family who make them feel calm, happy, and able to handle stress in their lives. Pet owners also emphasize that pets add a much-needed element of nature to their fast-paced and technologically oriented lives. Given that pets require a large investment of time and resources, it is sensible to consider the nature of pet–human relationships and the types of benefits that may result from such relationships.

The idea of animals as significant companions to humans is not new; one of the earliest literary references occurs in Homer's *Odyssey*, in which the otherwise brutal Cyclops, Polyphemus, expresses warm emotion to his favorite ram. What is more recent, however, is the notion that pets are integral members of the family and society, and that they can contribute favorably to the mental and physical health of humans. Although in 1859, Florence Nightingale noted that pets can be excellent companions for people who are ill, it was not until the 1950s that the first journal articles about pets as adjunctive therapists appeared. Over the following decades, hundreds of additional studies have been done by researchers in the fields of psychology, sociology, medicine, nursing, veterinary medicine, ethology, anthropology, physical therapy, and occupational therapy. In these studies, a wide variety of topics have been addressed, including: human–pet relationships and interaction, pets as social support, pets and human blood pressure, pet loss and human grief and mourning, legislation and pets, pets and chronic illness, pets and children, and pets and people who are elderly. Selected findings of recent research are provided next.

Human–Pet Interaction

The most common role that pet animals fulfill is that of companion and friend. Most pet owners form bonds with their animals that are in many

ways similar to relationships they have with other people. For example, pet owners often spend a great deal of time engaged in activities with their pets, they confide intimate feelings and thoughts to their pets, and they express strong feelings of love and affection to pets. In addition, pet owners express the belief that their feelings of love are reciprocated and that their pets help them solve problems by listening.

Marriage and Pets

Research about social interaction has explored how married couples, with and without pets, interact with each other and with their pets. Daily diaries of social interaction were recorded by husbands and wives while at home, work, and social gatherings. Blood pressure and heart rate were recorded during discussions about topics such as finances, relatives, in-laws, and where to spend vacations. Findings include that, relative to couples without pets, pet owners had significantly greater closeness and satisfaction in marriage, more frequent interactions with each other, and lower cardiovascular responses to stress. Among pet owners, those who were more attached to their pets and interacted with them more frequently also reported more frequent and positive interaction with their spouses. No significant differences were found between the responses of men and women or between owners of cats and dogs.

Pets and Elderly People

The relationship between pets and elderly people has been the focus of considerable research. For example, a study of nearly 1,000 Medicare patients found that people with pets were buffered from the impact of stressful life events and made significantly fewer visits to doctors than did people without pets. Similar findings have been reported from the United Kingdom, where it was found that only 1 month after acquiring a dog or cat, there was a 50-percent reduction in reports of minor medical problems. Activities of daily living (ADLs) are often used as measures of ability to live independently. A recent study reported that people with pets had greater self-sufficiency than those without pets. Over the course of a year, the pet owners remained self-sufficient, whereas their

counterparts without pets declined in their ability to care for themselves. Dogs and cats were associated with equal effects. Other research focused on activity among elderly people found that dog owners took twice as many walks as people without dogs, had significantly lower triglyceride levels, and reported significantly less dissatisfaction with their social, physical, and emotional states. Interestingly, it was also found that people without dogs talked only about the past, whereas those who had dogs talked about the present. Increasingly, nursing homes are including resident pets in their environments. Dogs, cats, birds, and fish are most popular, and their presence has been associated with increased social activity as well as decreased use of prescription medications, especially the use of psychotropic drugs to control agitation.

When asked why they have pets, more than 75 percent of elderly people say companionship. The results of many community-based and nursing home studies demonstrate that pets can alleviate a sense of loneliness and isolation and substantially increase social interaction and psychological well-being.

Pets and Children

Surveys reveal that around 70 percent of families acquire some kind of pet when their children are between the ages of 5 and 12. Having a pet fosters sensitivity and responsibility, and it provides companionship. In addition, children who help raise animals are better at empathizing with others. Children have a natural affinity for animals, and the presence of a pet has been shown to have a positive influence on cognitive, social, and motor development. Pets also provide a sense of security for children and always have time to listen. Children form powerful attachments to their pets and consider animals as more comforting than a best friend when they are frightened or ill. Having a pet also has been associated with lower levels of post-traumatic stress among children.

Pets and Social Change

Over the past several decades, relationships between animals and people have changed dramatically. Not only do pet owners consider their pets as close friends, but they buy them special

gifts, take them to daycare and on vacations, purchase veterinary insurance, and refuse to abandon them in times of disasters, such as hurricanes and floods. As an acknowledgment of the importance of pets in the lives of people, many shelters around the United States now have places for pets and owners to remain together. An everyday obstacle that remains is the unwillingness of many landlords to allow pets in apartments. By law, pets are allowed in housing that is federally subsidized, but there is no provision for pets in apartments on privately owned property.

Pets as Social Support: Buffers to Stress

Many laboratory- and community-based studies have considered the role of supportive friends and friendly strangers in buffering responses to stress. In such research, which focuses exclusively on relationships between people, the general conclusion has been that only when friends are perceived as completely nonjudgmental can they buffer stress responses. Although it is difficult to design experiments in which people are nonjudgmental, pets naturally provide total acceptance and never make judgments. Many studies have explored the potential of the nonjudgmental support of pets. In addition, among people with AIDS, pet owners have a lower incidence of depression relative to those without pets. Having a pet, especially a dog, also has been associated with a significantly higher rate of survival 1 year after heart attack, in a manner independent of the physiological severity of the heart attack, demographic characteristics of the patient, and psychosocial factors.

Pets and Blood Pressure

A frequent focus in research about pets and social support is the degree to which the presence of a pet can diminish a person's blood pressure and heart rate responses to a stressful laboratory task such as mental arithmetic. This body of research is based on the idea that people who experience pronounced, frequent, or enduring heart rate and blood pressure responses to stress may be at risk for development of heart disease. Several studies have compared support provided by humans with

that given by pets, and it has been reported that the presence of seemingly supportive human friends has produced dramatic *increases* in blood pressure, whereas the presence of one's own dog or cat has resulted in minimal changes from resting blood pressure. In addition, when pets were present, study participants were significantly better at the difficult mental arithmetic task. When husbands and wives participated in a study, it was found that having a spouse present (regardless of gender) produced the largest of all increases in blood pressure—that is, in terms of blood pressure, it was worse to be with one's spouse than with one's friend while performing mental arithmetic. The best situation for blood pressure response as well as task performance was being with one's pet. This suggests that, regardless of how a spouse tries to be supportive, he or she may be perceived as critical, rather than as nonjudgmental. Interestingly, when pets and spouses were both present during the stressful arithmetic task, blood pressure increases were much smaller, as if the presence of the nonjudgmental pet cancelled part of the effect caused by the spouse perceived as critical.

Work-Related Stress, High Blood Pressure, and Pets

The community-based studies described earlier compared pet owners with people who did not have pets. A valid criticism of such studies is that, because they do not involve random assignment to pet ownership, it is possible that there is no "pet effect" and that pet owners may just be healthier than people who choose not to have a pet. To consider this possibility, a study was conducted in which half of the participants were randomly selected to adopt a pet dog or cat from an animal shelter, while the control group remained without pets. The participants were all stockbrokers who lived alone and described their work as extremely stressful. In addition, they all had high blood pressure and were scheduled to begin taking Lisinopril, a drug that is very effective in reducing resting blood pressure, but not at all useful in blunting responses to stress. The results of this study provide strong evidence for the role of pets in providing a unique type of social support. That is, the drug alone lowered

resting blood pressure, but only when the drug was combined with a pet were blood pressure responses to stress diminished. Interestingly, at the conclusion of the study, when the results of the study were presented to the participants, most of the members of the control group quickly adopted pets as well.

Blood Pressure and Pets: Limitations

Considerable media attention has been given to the “healing power of pets,” and the idea that pets can lower blood pressure has been reported widely. Such reports simplify a complex issue and misrepresent research findings. Although existing research about pets and health demonstrate a significant supportive role for pets, it does not demonstrate that pets can necessarily lower resting blood pressure, but rather that pets can influence the magnitude of blood pressure response to a stressful situation. Consequently, a pet should never be considered a substitute for blood pressure medication.

Future Research

Although research has demonstrated a strong supportive role for pets, a great deal remains to be learned about the relationship between human cardiovascular health and having a pet. For example, it is not known how explanatory mechanisms may be related to or influenced by other physiological factors, such as endocrine function. A recent study has begun to explore this area and has demonstrated that, as blood pressure decreases, levels of the endocrine hormone oxytocin increases, suggesting a relationship between social affiliation and blood pressure responses to stress. A major conclusion of research on the effects of animal companionship is that the degree of attachment to a pet is important. A pet cannot help all lonely or depressed people any more than any other isolated therapeutic intervention can always succeed.

PHYSICAL ATTRACTIVENESS, DEFINING CHARACTERISTICS

The perception of physical attractiveness involves the judgment that a person's overt appearance is cute, beautiful, handsome, sexy, nice, fashionable, or desirable. The diversity of synonyms conveys the fact that perceptions of physical attractiveness are complex and multidimensional. Judgments of physical attractiveness can vary as a function of the nature of the perceptual target (child vs. adult), the current motives (such as lowered self-esteem or ovulation) and demographics of the perceiver (White, Black, Asian, male, female), and the perceiver's culture and historical epoch (Renaissance vs. present, West vs. East). For example, people use different criteria when evaluating the physical attractiveness of a newborn baby boy, compared with that of a 21-year-old man. Furthermore, some criteria can change over time. For example, male beards were popular in

the 1860s through the 1880s, unpopular in the 1920s through the 1950s, popular again in the 1960s and 1970s, and so on.

Physical attractiveness is based on a combination of desirable features and qualities that communicate diverse messages to the perceiver. Physical attractiveness cannot be reduced to a single dimension, such as youthfulness, sexual dimorphism, symmetry, averageness, or fashion, but each can be influential depending on the facet of physical attractiveness under consideration.

Despite such complexity, judgments of physical attractiveness involve an underlying orderliness that can be interpreted. To understand such judgments, it is necessary to analyze the categories of features and qualities that cause someone to be seen as more or less physically attractive. The categories involve neotenous (babyface), sexually mature, expressive, grooming, and senescence (aging) qualities.

Neonate Qualities

Neonate qualities are the babyface characteristics displayed by infants and young children that contribute to perceptions of cuteness. The young of many mammalian species differ in consistent ways from the adults of that species, such as having larger eyes, more rounded forehead, smaller muzzle, and softer, lighter hair. Such features likely evolved through natural selection, when newborn offspring with those features were seen as cuter and given better care by adults. Consequently, they were more likely to survive and reproduce than newborns with other features.

Through random variation, some adults retained cute babyface qualities as they grew up. Those features may have been adaptive by eliciting a portion of the indulgence and care that is usually given to children. Conversely, it may have been adaptive for perceivers to be attuned to cute features because young adulthood is the period of greatest health and fertility. But perceivers can be deceived by adults who retain the overt appearance of youth, but lack the other gifts of youthfulness and emerging adulthood.

Because youthfulness is more closely linked to fertility than virility, neotenous features tend to contribute more to the physical attractiveness of

females than males. However, both genders are rated more positively when they possess the following cute features: larger than average eyes, smaller than average nose, and smooth, clear skin. Females also are seen as more attractive if they have a small chin and no dark facial hair on their lips or jaw. Other babyish features, such as a round head, bulging cheeks, truncated torso, and short stature, are not attractive in adults and are generally superseded by sexually mature qualities.

Sexual Maturity

Sexually mature face qualities are features and qualities that develop during puberty that contribute to judgments of beauty, handsomeness, and sexiness. Such features reflect sexual dimorphism, or the physical differences between the sexes, and may implicitly convey fertility or virility, and the capacity to assume adult roles, some of which tend to be sex-typed.

Female faces lengthen and widen during puberty, but change less overall than do male faces. Young adult female faces are seen as more attractive if they retain neonate features in the center of the face while showing some mature features on the periphery. Adult female faces are more attractive if they possess the sexually mature features of prominent cheekbones and relatively narrow cheeks.

In males, the surge of testosterone and other hormones during puberty causes the bones, skin, and hair to change to a more rugged and angular form. An adult male face is seen as more attractive with a larger chin and jaw, thicker eyebrows, and visible evidence of beard stubble. The facial features that enhance male attractiveness tend to highlight the difference between males and females, but sexual dimorphism is not the essence of attractiveness. Males generally have thicker brow ridges, causing the appearance of smaller eyes, larger noses, and coarser skin with more acne than females, but such qualities do not enhance male attractiveness. Similarly, a thick beard exaggerates the size of the chin and jaw and is evidence of virilization. But a full beard can make a male look a bit too strong and aggressive for many Western females.

In addition, postpubescent faces are more attractive if the features are bilaterally symmetrical and the overall shape of the face is of average proportions,

rather than extremely long or wide. Both symmetry and average proportions indicate stable physical development and resistance to germs and other factors that interfere with smooth growth.

Measurement

Measurement of the characteristics that contribute to attractiveness is based on a variety of research methods. The most straightforward approach is direct physical measurement of people or photographs. The size of specific features, such as eye height and nose length, or deviations from the midline, is measured using recognized anatomical landmarks. To control for variations, the feature measurements are standardized either by using photos taken to be exactly the same size or by calculating the ratio between the size of a feature and the size of the head. The next step is to obtain ratings of the physical attractiveness and other perceived qualities of the target people. Several dozen people must be used in a study to allow independent variation of the features. For example, if the only people with large noses happen to also have large chins, it is impossible to estimate the impact of either noses or chins. For the same reason, it is essential that the sample have some stunningly attractive people, and their opposites, to ensure that the full range of both appearances and attractiveness perceptions are covered.

A second way to evaluate the defining characteristics of physical attractiveness is to create different appearances, either on paper or in a computer. Such appearances can be created by the researcher through drawing, by cutting and pasting together features from different people to create a composite, or by creating composites by merging whole images from different people in a computer. An outcome of the latter approach is that a face created by merging a sample of same-sex faces generally receives a higher physical attractiveness rating than most of the faces that were merged to create it. The computer merging process smoothes out facial imperfections and asymmetries and takes the average of faces that are too long and those that are too short to produce one that is closer to being just right. The merging of faces that are initially rated as highly attractive produces a face that is particularly attractive because each face contributes

similar exceptional features, and the averaging process tends to exclude imperfections.

A third way to evaluate defining characteristics is to allow people to choose the feature that they like, either through a menu of features or by moving a slider that allows selection of a preferred face that is intermediate between extreme faces. Comparable results are obtained through the different methods, which are applied to both faces and bodies.

Sexually Mature Body Qualities

Sexually mature body qualities also develop during puberty and are even more conspicuous than changes in the face. A female's pubic bones grow during puberty to accommodate pregnancy. The waist-to-hip ratio (WHR) is computed based on the measurement of the waist to that of the hips, as in the last two numbers of the 1950s ideal female figure of 36-24-36 inches. Probably because it conveys fertility, a .7 WHR is seen as physically attractive in many cultures. Female breasts also develop as a result of increased hormones during puberty. Noticeable female breasts are seen as attractive. But there is quite a bit of individual and cultural variation in the preference for large female breasts.

Although puberty transforms the female body to prepare it for childbearing, it transforms the male body to increase its effectiveness in competition with other species during hunting, as well as with other males to achieve dominance and status to attract females. Males are seen as more attractive if they have a WHR of 1.0 (hips are not wider than the waist), if they are taller rather than shorter, and if their shoulders are broader rather than narrower. Males who are exceptionally tall or muscular are preferred to males who are short or average in physical development, but extreme height or extreme muscularity is not attractive to most females. Females prefer a somewhat more mature and masculine appearance when they are midpoint in the menstrual cycle, and ovulating, than at other times.

Puberty causes a change in the individual's physical structure, which produces changes in the individual's movement, and voice. Men with deeper voices sound more mature and attractive than

males with higher voices. Puberty also increases the production of pheromones, which are chemicals responsible for the individual's smell. It is not clear whether natural or artificial pheromones can attract a person from a distance. But females can detect males who are symmetrical and better looking, as well as males whose immune system is more compatible with their own, from the pheromones that unseen males leave behind on their t-shirts.

Expressive Qualities

Expressive qualities are characteristics that convey the individual's prosocial attitudes and positive emotions, which contribute to judgments of niceness, friendliness, and engagement. Although neonate and sexually mature qualities are primarily attributable to genes and physical development during childhood and puberty, and are largely fixed (unless there is intervention by a cosmetic surgeon), expressive features are more variable.

Individuals who display large smiles are seen as more attractive than individuals who display small smiles or no smiles at all. The shape of the jaw, and the skill of the orthodontist, determines whether the person can display a full-beam smile that is visible across a crowded room. Although all people are seen as friendlier and more attractive when they are smiling, the effect is stronger when the perceiver is depressed, and in the Western cultures that value expressiveness than in Eastern cultures that limit the facial display of emotion.

A more subtle expressive signal is pupil dilation, or the opening of the colored iris in the front of the eye. Pupil dilation indicates physical arousal and conveys engagement and warmth. Pictures of individuals with dilated pupils are seen as more attractive than pictures of the same people with constricted pupils.

The lips also dilate during arousal. Full, red lips increase female attractiveness, perhaps by conveying positive emotion. But the meaning of lips is not settled. Some commentators have suggested that full lips are characteristic of a babyface, others have suggested that lip size is an indicator of sexually mature female hormones, and still others suggested that, when relaxed, full lips mimic the shape of an expressive smile. Although neonate and mature qualities seem mutually exclusive, natural

selection could have endowed lips with more than one positive attribute.

Similar complexity is evident in the analysis of eyebrows. People's eyebrows tend to rise when they are interested, surprised, or submissive. An individual whose eyebrows are naturally set high above their eyes are seen as more attractive than others perhaps because they convey a consistent look of curiosity and agreeableness. This may be why the eyebrows of infants tend to be set relatively high above their eyes on their rounded foreheads. The eyebrow ridge is reshaped during puberty, which causes the eyebrows to be set lower and conveys dominance rather than interest and submissiveness. This reshaping is more pronounced in males than females. Consequently, highly set eyebrows may simultaneously convey interest, youthfulness, and femininity.

Grooming Qualities

Grooming qualities are characteristics that the individual has cultivated in an effort to enhance neonate, sexually mature, and expressive qualities, plus convey their social affiliations, knowledge, and status. Females employ cosmetics to make their skin look smoother, their eyes larger, their cheekbones higher, and their lips more vivid, all of which tends to increase their attractiveness. Similarly, fuller and sleeker hair conveys self-confidence and health simultaneously, particularly if the hair is cut in a currently fashionable style.

Similar to cosmetics, clothing can be used to send a variety of messages. Through the careful choice of apparel, individuals can make themselves look more youthful and innocent or more sexually mature and available. Different garments, jewelry, tattoos, and accessories can make a person look more happy, casual, and friendly, or more smart, wealthy, dominant, and aloof. Any of those looks can enhance physical attractiveness depending on the needs of the perceiver.

Grooming effects are not limited to perceptions of females. Males are rated as more physically attractive when they are well shaven and wearing a suit and tie, rather than a t-shirt, or the uniform of a fast-food restaurant. Like female clothing, male clothing not only symbolizes status and resources, but also membership in a specific social

group. The clothing of a Wall Street financier, Texas oilman, and Hollywood actor all convey wealth, but also different lifestyles and geographies, which may differ in their attractiveness to different females.

Body weight is also a grooming quality. Ideal body weight is a cultural ideal, but such ideals are influenced by the local ecology. Heavier body weight is generally seen as more desirable in historical periods, areas of the world, or parts of a city where the supply of food is uncertain. Thinner bodies are seen as more desirable when there are ample food supplies. Of course, individuals and groups in the same time and place differ in their access to food and in their body weight preferences. For example, African Americans prefer larger female bodies compared with European-Americans.

Senescence Qualities

Senescence qualities are characteristics that convey aging and contribute to judgments of wise maturity. Just as puberty produces maturational changes that enhance sexual attractiveness, later stages of development bring with it age-related changes, some of which may enhance nonromantic forms of physical attractiveness.

In male pattern baldness, hair on the top of the scalp changes to the short, translucent form that is evident on the front of the forehead, whereas the hair around and behind the ears retains its thicker, darker form. Baldness increases the perception of age and reduces the perception of romantic attractiveness, but that loss brings with it some benefits. Baldness may serve as an appeasement gesture, which tends to reduce competitive aggressiveness by other males, which is replaced by tolerance or respect. Males with a bald scalp are seen as more social, mature, wise, and approachable than the same males with a full head of hair.

Males who are bald and appear to be middle age may be more physically attractive to females who are middle age than males who are 20 years old. Of course, that depends on whether the evaluation is made in terms of attractiveness for a one-night fling or a longer relationship. The converse is not the case; middle-age males tend to prefer

females who are quite a few years younger than themselves for any type of relationship.

Other senescence qualities may also convey a form of physical attractiveness. Gray hair may make a person look distinctive, and lines in the face can convey character. Such qualities may not be as charming as neonate features or alluring as the full bloom of sexual maturity, but the dignity of graceful aging has its own physical attractiveness.

Familiar Qualities

Familiar qualities are aspects of appearance that are seen frequently. If an individual is repeatedly exposed to a stranger's face, especially under pleasant circumstances, that face will begin to seem more physically attractive than if the same face is newly encountered. Similarly, individuals generally rate their friends, with whom they are familiar, as more physically attractive than the friends are rated by other people. In the same way, if an individual's favorite uncle has a prominent nose, then the individual may see that feature as more attractive than do other people. Familiarity also may explain why people see members of their own race as more physically attractive than members of other races.

Social Influence

Social influence refers to the impact of the actions and opinions of other people on what is seen as physically attractive. If an individual observes a peer choose one member of the opposite sex for a date over another, the individual will rate the chosen person as more physically attractive than otherwise would be the case. Guppies and other species show a similar tendency to engage in such mate-choice copying, but there are limits to that tendency. Observers are influenced when the individual who is preferred by a peer is highly or moderately attractive, but not when the preferred individual is objectively unattractive. People's judgments of attractiveness also are influenced by the comments made by peers about photographs of members of the opposite sex, although the rating shift is less than 10 percent. Females are influenced more than males in both contexts perhaps because a male's social standing contributes to his

attractiveness. Such results, combined with research suggesting similarity in the determinants of physical attractiveness across cultures, indicate that physical attractiveness is not simply an arbitrary social construction, but also varies a bit depending on the individual, society, and historical period and other social determinants.

PHYSICAL ATTRACTIVENESS, ROLE IN RELATIONSHIPS

When asked what they find attractive in a potential romantic partner, one of the first features people list is physical appearance. This finding is not surprising given that physical appearance is frequently the first and easiest thing people can learn about one another. We cannot immediately tell whether a stranger is likely to be intelligent or share interests with us, but we can quickly determine whether we like the way that person looks. For this reason, it makes sense that physical

appearance plays a role in attraction. The question is: How much of a role does physical appearance play in early stages of a relationship, and does it continue to play a role in more established, committed relationships? The purpose of this entry is to describe the implications of physical attractiveness for both relationship formation and relationship maintenance over time.

Physical Appearance and Initial Attraction

Perhaps the best documented finding in the literature on physical attractiveness is that attractive people are more popular and sought after than are unattractive people. In a classic study of the factors that predict individuals' initial attraction to potential romantic partners, members of the incoming freshman class at the University of Minnesota were asked to participate in what they believed was a test of a new computer-dating service. Students were asked to complete a number of questionnaires about their personality, background, and interests. In addition, students provided photos of themselves, which the researchers used to rate the physical attractiveness of each student. The researchers then randomly matched students with a date for a Freshman Week mixer; after the mixer, they asked each student whether they wanted to go out with their assigned partner again. The only factor that predicted students' liking for their date and their desire for subsequent dates was physical attractiveness. If students were paired with a physically attractive date, they were more likely to want to go out with them again. However, if students were paired with a less attractive date, they reported less interest in future interactions with that partner. The partner's personality, whether the two people shared interests or came from similar backgrounds, all had no significant influence on the desire for a second date. More recent studies employing a speed-dating format corroborate this general finding. In these studies, participants were asked to interact with several opposite-sex individuals on brief "mini-dates" and then indicate their interest in future interactions with these individuals. Again, physical attractiveness was one of the biggest predictors of participants' liking for their dates. It seems, then, that physical appearance plays a large

role in initial attraction, trumping the effects of many other aspects of the person.

Is physical attractiveness equally desired by men and women? When reporting on the attributes they value in a potential partner, men tend to rate physical appearance as significantly more important to them than do women. This gender difference has been replicated across many cultures, ages, and ethnic groups. Further evidence, however, reveals important qualifications of this effect. For instance, although men report valuing physical attractiveness more than women when considering potential long-term mates, men and women seem to equally prioritize physical attractiveness when contemplating the attributes desired in a short-term romantic partner. Moreover, research suggests that what people say they value in a mate does not always correspond to what people actually seek out when choosing a mate. Several studies suggest that women may underestimate the value they place on physical attractiveness. In one such study, males and females were presented with different kinds of information about potential romantic partners and asked how attracted to each person they were and why. Males reported that physical attractiveness played an important role in determining their interest, whereas females said they were more affected by the person's earning potential and emotional expressiveness. Despite these self-reported explanations, when researchers examined who participants reported an interest in, by far the largest and most potent predictor of interest for both men and women was physical attractiveness. In other words, although women reported that physical attractiveness was less important to them, their behavior revealed that they were just as influenced by physical attractiveness as men.

The Matching Hypothesis

So are people simply looking for the most physically attractive partner they can find? Not necessarily. Rather, people seem to have a reasonably good sense of their own physical attractiveness, and consequently they seek out partners who fall within that same level of attractiveness. Laboratory studies, in which individuals are presented with an array of potential romantic partners and asked to pick which one they most desire to meet, have

revealed that people do not always choose the most attractive option available. Instead, when other aspects are held constant, the most attractive participants often choose significantly more attractive dates than do the least attractive participants. Furthermore, examinations of real-life dating couples reveal that partners tend to be similar to each other in physical attractiveness. This similarity is even more pronounced among married couples, suggesting that perhaps similarity in attractiveness is predictive of courtship success. Together these findings have given rise to the matching hypothesis or the idea that people tend to pair up with partners who are similar to them in appearance.

Several theories have been put forth to explain why people express an interest in partners who match their own level of attractiveness. One such theory involves the fear of rejection. Namely, less attractive individuals may only pursue those partners whom they think might also express an interest in them. As a result, these individuals should avoid the most attractive potential partners because highly attractive partners are perceived as more likely to reject them. A second explanation for why couples match in their appearance draws from equity theory, which argues that relationship partners desire to maintain an equal balance in the rewards each person receives within the relationship. If one partner feels over- or underbenefited in the relationship compared with the other partner, this inequity may lead to relationship tension. Physical attractiveness may be thought of as a rewarding resource that individuals bring to the relationship. An attractive partner not only is aesthetically pleasing to look at, but also may be a source of prestige for the relationship, as having an attractive partner signals to others that one possesses a desired societal commodity. Consequently, if a couple is dissimilar in attractiveness, the more attractive partner may feel underbenefited in the relationship. Moreover, the attractiveness resources of this individual are likely to be valued by romantic rivals, causing the more attractive partner to be less dependent on the relationship and more vulnerable to the advances of other potential suitors. The less attractive partner, then, is under pressure to provide other resources, such as social status or material wealth, to compensate for a lack of attractiveness. Unless this negotiation of resources

proceeds smoothly, the more attractive partner may be less satisfied and more likely to leave the relationship in search of greater rewards elsewhere. Consistent with this notion, studies have shown that dissimilarity in physical attractiveness is associated with lower levels of commitment and a greater likelihood of relationship dissolution. Thus, to avoid the tension of inequity, people may initially seek out relationship partners who are similar in physical attractiveness.

Physical Attractiveness and Relationship Maintenance Over Time

Although a large literature has examined the role of physical attractiveness in relationship formation, less research addresses whether attractiveness continues to be associated with relationship processes and outcomes in established relationships, such as marriage. Yet to the extent that physical attractiveness represents a valuable resource, it may be expected to play an important role in relationships even after those early stages of relationship formation. In fact, research suggests that physical attractiveness is associated with a number of other rewards beneficial for relationships. Physically attractive individuals tend to have higher levels of self-esteem, better employment, higher salaries, and better physical and mental health. Such rewards should make the lives of physically attractive individuals easier, thereby improving attractive individuals' ability to maintain satisfying relationships. Physically attractive individuals also tend to behave more positively in social interactions than less physically attractive individuals. Such positive behavior should generalize to make the relationship interactions of more attractive individuals and their partners proceed more positively as well.

In fact, and in line with the previous discussion of the matching hypothesis and equity theory, some recent research indicates that the discrepancy between partners' levels of attractiveness may influence important marital processes. In one study, married couples were asked to engage in a series of videotaped discussions, in which each spouse was asked to describe a personal goal they desired to achieve. In this way, spouses were given the opportunity to provide

support to their partners during the discussions. Independent observers then rated the attractiveness of each spouse, as well as each spouse's support-giving skills. The discrepancy between husband and wives' levels of physical attractiveness turned out to be a strong predictor of spouses' behavior during the support discussions. When wives were more attractive than their husbands, both spouses were rated as behaving more positively during the interactions. In contrast, when husbands were more attractive than wives, both spouses were rated as behaving more negatively. Why might a discrepancy lead to positive outcomes in one case and negative outcomes in the other? Given that men tend to report valuing attractiveness more than women in long-term relationship partners, a situation in which wives are less attractive than husbands may represent a more salient and important inequity within the relationship, leading to greater relationship tension and worse relationship processes. Conversely, although attractiveness may play a larger role in women's actual mate selection than they recognize, the fact that women do not report valuing attractiveness as much as other potential traits and resources may serve to limit the extent to which couples are bothered by this type of discrepancy.

Relationship Quality and Perceptions of Attractiveness

As a final note, it is important to consider that, although people display a strong liking for those who are physically attractive, the reverse is also true. The quality of people's relationships has been shown to influence their perceptions of their partners' attractiveness, such that being in a satisfying relationship leads individuals to judge their partners as more physically attractive. Thus, the association between physical attractiveness and relationship quality may best be characterized as a reciprocal one. Physical attractiveness predicts who individuals initially pursue for a relationship. Then as the relationship progresses, the quality of that relationship in turn may change the way individuals perceive their partners' attractiveness.

PHYSICAL ATTRACTIVENESS STEREOTYPE

“What does s/he look like?” is often the first question asked about a potential blind date. “S/he has a good personality . . .” is the dreaded reply, although most deny the importance of attractiveness in our relationships. When do people start to care about attractiveness? Is it when they start seeking potential romantic partners? Research shows, perhaps surprisingly, that attractiveness is influential even in infancy. Infants, children, and adults are more likely to choose attractive than unattractive individuals as social partners and to

judge and treat them positively. Most people, even young children, associate positive traits and behaviors with attractive individuals and negative traits and behaviors with unattractive individuals. This entry describes attractiveness preferences and their role in social interaction and interpersonal relationships. Additionally, a discussion of theoretical perspectives is presented.

Preferences, Judgment, and Treatment

Despite common wisdom that beauty is in the eye of the beholder, assessments of facial attractiveness are consistent both within and across cultures. In a review of hundreds of studies, Judith Langlois and colleagues found robust evidence for preferences for attractive compared with unattractive people even among the well acquainted. Even young infants agree with adults about attractiveness and show similar preferences for attractive faces.

Infants

Infants as young as 3 months of age look longer at faces rated by adults as attractive than unattractive regardless of age or race of the faces. By 6 months of age, infants categorize faces based on attractiveness, that is, they perceive attractive and unattractive faces as two distinct types of faces. Categorization into different groups is thought by many social and cognitive psychologists to be a necessary prerequisite before positive and negative traits can become linked to the groups (stereotyping). By 12 months of age, infants associate positive information with attractive faces and negative information with unattractive faces. These early associations may explain why infants treat adult strangers differently depending on the stranger's attractiveness: Infants approach and smile more at attractive strangers, but they avoid and show anxiety toward unattractive strangers.

Not only do infants respond differently to attractive and unattractive people, but they also are treated differently based on their own attractiveness. Adults agree about which infants are attractive and unattractive—not all babies are cute! Adults believe that attractive infants will

become more competent, likable, smarter, and less problematic for their parents than unattractive infants. Premature infants perceived as attractive by nurses thrive and leave the hospital earlier than premature infants perceived as unattractive, possibly because attractive infants receive better care and more attention than unattractive infants. Most important, mothers treat their own infants differently: Mothers of attractive infants behave more positively and focus more attention on their infants than mothers of unattractive infants. Thus, physical attractiveness is important and has mental and physical health consequences even in the earliest social interactions.

Children

Further confirmation of the influence of facial attractiveness on interpersonal relationships comes from research studying children's preferences, judgment, and treatment of peers varying in attractiveness. Karen Dion and others showed that children agreed about who was and was not attractive and were more likely to choose attractive peers as potential friends. When asked to choose which of two children pictured had a positive or negative attribute, children ranging in age from 3 to 6.5 years old chose attractive children for positive traits and unattractive children for negative traits. They judged unfamiliar attractive children as more likable and expected attractive children to behave in a positive, prosocial manner. Children also made similar judgments about their own classmates, with attractive children considered more likable and more prosocial than unattractive children.

Attractive children benefit from positive judgment and treatment by adults, whereas unattractive children suffer negative consequences. Adults judge behavioral transgressions as more negative and antisocial when committed by unattractive children than when committed by attractive children. Adults also suggest harsher punishment for unattractive children. For instance, in a study in which adults judged performance on a cognitive task, women were more lenient toward attractive boys than unattractive boys. These types of judgments and behaviors by adults toward children can have serious implications, especially in educational settings. Teachers have higher expectations for attractive compared with unattractive students. Positive

expectations for attractive children can lead to preferential treatment eventually leading to a self-fulfilling prophecy in which students perform up to expectations, whereas the opposite effect can occur with negative expectations for unattractive children. Studies have shown that students who had teachers with high expectations received better grades and performed better on intelligence tests, whereas students who had teachers with low expectations did not do as well in schoolwork or on intelligence tests at the end of the school year.

Adults

Years of research have focused on how adults judge and treat other adults based on attractiveness. For example, male undergraduates judged an essay more positively if a photograph of an attractive female accompanied the essay than if a photograph of an unattractive female accompanied the essay. Attractive political candidates receive better evaluations than unattractive politicians, especially if little additional information (e.g., political ideology) is available. Multiple studies involving mock juries and job-related outcomes showed that attractive individuals fared better than their unattractive counterparts. Data from studies in which the attractiveness of the defendant in mock trials varied showed that members of the jury found attractive defendants innocent more often than they found unattractive defendants innocent. Additionally, if the jury found attractive defendants guilty, they gave lighter sentences than they gave to unattractive defendants. Regarding job-related outcomes, attractive individuals received more promotions and better pay than unattractive individuals of similar abilities. In fact, attractive people make 5 to 10 percent higher salaries than unattractive people of comparable skill level. Each of these examples indicates that there can be significant consequences associated physical appearance.

Not surprisingly, attractiveness influences romantic and friendship dyads. College students state that physical attractiveness is one of the most important components in choosing whom to date. They believe attractive partners are more popular and likable. Males are especially likely to assume that dating attractive partners increases their own status. In general, romantic couples match on level

of attractiveness, although most people, regardless of their own attractiveness, prefer to date more attractive people than themselves. Although attractiveness is only one of many characteristics that show such a matching effect, it serves as an important initial filter for establishing a romantic relationship. Attractiveness is less predictive for friendships: Male friendship dyads often match in level of attractiveness, but the same is not true for female friendship dyads.

Why Do People Like Attractive People?

Theorists from three approaches offer explanations for why attractive people are preferred. For instance, social theorists assert that attractiveness preferences are culture specific and are learned through socialization, including media exposure; however, studies show that people across cultures and age agree on who is attractive. Furthermore, infants show attractiveness preferences before they have had substantial exposure to media.

The evolutionist perspective suggests that attractiveness preferences evolved as signals of fitness, good health, and reproductive potential. Accordingly, individuals across cultures agree on perceptions of attractiveness because standards of health and fitness have evolved universally. Because humans prefer good health, they prefer and treat targets that represent good health differently than targets that do not. With species propagation as the primary goal, individuals wish to mate with those who are most likely to reproduce successfully and to pass on good genes to descendants. Attractive individuals appear to be healthier than unattractive individuals and are preferred as mates. Along these same lines, parents expect attractive children to be more reproductively successful than unattractive children, thus more likely to perpetuate the parents' genes to future generations. Whether attractiveness is a true indication of health is still under investigation, but studies with hunter-gathering societies have found that attractive women are more fertile than unattractive women of the same age group, whereas studies with modern Western societies have not found relationships between attractiveness and objectively measured health.

Langlois and colleagues have proposed and empirically supported a cognitive explanation for attractiveness preferences. Their model asserts that attractiveness preferences are universal because they derive from cognitive "averaging" resulting in prototype formation. This averaging takes place automatically when people perceive multiple members of a category (e.g., faces). Individuals process stimuli by cognitively comparing and combining them with previous exemplars within the same category. In this way, infants, children, and adults develop and maintain a prototype of that category that represents the mathematical average of experienced category members. Because the prototype is the central tendency of several members of the category, it is treated as the most representative example and is processed more fluently than individual members of the category. Prototypes in general are judged as familiar and attractive, whether the category is birds, furniture, sounds, dot patterns, or faces. Ease of processing results in positive affect toward the prototype. Additionally, examples that closely resemble the prototype are also preferred to examples that are different from the prototype.

Attractive faces are more similar to the prototype than unattractive faces and are thus judged as good examples of the face category. A representation of a face prototype can be computer generated by morphing multiple faces together. Adults judge these computer-generated prototypes as more attractive than most individual faces used in the morph. Infants also perceive computer-generated facial prototypes as attractive. If infants are shown the individual faces repeatedly, infants will then treat the computer-generated facial prototype as familiar even if they have not previously viewed it. Furthermore, research shows that both computer-generated prototypes and attractive faces are processed as faces faster than unattractive faces. Perhaps the ease of processing promotes positive emotional response that influences other judgments of attractive faces, including likability, intelligence, and sociability. Ultimately, such associations may lead to preferential judgment and treatment of attractive people. Although both facial symmetry and youthfulness have been proposed as explanations for attractiveness judgments, neither has shown the robustness of cognitive averaging in explaining attractiveness preferences.

Conclusion

Physical attractiveness is influential in social interactions regardless of the level of familiarity between social partners. We judge attractive people as more likable, popular, sociable, and intelligent than unattractive people. Even from the earliest relationships (e.g., mother–infant, teacher–student), attractive individuals receive preferential treatment and less punishment than unattractive individuals. In adolescence and beyond, attractiveness plays a major role in who we want to date, whereas our own attractiveness influences who we actually date. Preferences likely originate due to automatic information processing, such as cognitive averaging. Preferences resulting from cognitive averaging establish the basis for attractiveness associations and attitudes manifested in interpersonal interactions. Once established, attractiveness preferences and associations may be further maintained and elaborated by socialization processes. Prototype formation is not limited to human faces and appears to be a general mechanism used for comparisons between established knowledge and new stimuli, whether faces, birds, or cars. Perhaps the only way to counteract such a prevalent propensity to judge and treat others based on attractiveness is with knowledge of how influential attractiveness is to interpersonal relationships.

PHYSICAL ENVIRONMENT AND RELATIONSHIPS

Personal and professional relationships are embedded in physical environments—residences, offices, city streets, and so on. Researchers study these settings with respect to how they support or undermine relationship processes and how people use the physical environment as intrinsic aspects of relationships. Research questions include: Is the home designed to support family relationships? Is it decorated and configured to display important meanings in relationships? Does office space allow a balance of individual and communal work? At their core, these questions are about viability: Can the relationship achieve stability as well as growth? Do social relationships support team goals? This entry reviews research on the physical environments of interpersonal relationships in residential, neighborhood, and work settings.

Proximity

Proximity is a well-known prerequisite to many relationships. Relationships are more likely to form among people who come into contact and have opportunities to interact, such as people

whose houses or apartments are close together. People whose apartments are centrally located (e.g., close to mailboxes) are likely to know more fellow residents. Residents of retirement housing are more likely to report socially supportive relationships when they live near the central activity building or near well-used paths in the facility.

Location and Possessions

Locations and objects are integral to relationships. In individualistic societies, partners meet independently of their families. Many couples meet at school, church, neighborhood events, or workplaces. If the courtship progresses, couples often seek out more private places to nurture their relationship. After a wedding, the young couple is expected to live independently, rather than reside with extended family.

Other societies are more communal, and marriage is often viewed as a union of families, rather than a marriage between two individuals. In these cultures, parents exercise more influence over where, how, and when couples meet, including provision of supervised settings where young people can observe or interact with prospective partners. After the marriage, the couple is expected to stay close to either the groom's or the bride's family, even moving in with the extended family. Wedding practices often symbolize the unity of families, such as when both the bride's and groom's families participate in building and furnishing the new dwelling.

Material objects often symbolize the unity of the new relationship, such as wedding gifts that can be enjoyed or used by the couple. In one study, couples were asked to identify objects in their home they liked the most and whether the objects had been acquired by one partner or by the couple. Individuals who were most satisfied with their marriage were more likely to select jointly owned objects as their favorites. A study of polygamous families found that some families provided a separate home for each wife and her children, whereas other families lived communally. Common to both arrangements was the wife's control over the décor. When sharing a home, the wives cooperated in decorating public areas, symbolizing family unity, but each wife had a uniquely decorated bedroom, reflecting her unique dyadic bond with her husband. Thus,

objects and places reflect couple bonding, links to family and friends, and are tangible and visible manifestations of the relationship and their links to larger family and cultural networks.

Privacy Regulation and Relationship Viability

One of the primary ways that people use their environments is to manage interactions with others. Studies of privacy regulation examine how people use environmental and other mechanisms to open themselves to others or to close themselves off. *Privacy regulation* is defined as "selective control over access to the self or group." Individuals and groups decide on their ideal blend of openness and closedness and use regulatory mechanisms to try to attain their privacy goals. Control over access could involve moving close or far from family members, selecting a home with an open or subdivided layout, and so on. A study of space usage in homes found considerable variability in where family members congregated; some used the kitchen and others used a family room depending on the configuration of the home, the family, and their needs.

Residential Environments

Whether one lives in an apartment, duplex, single-family detached house, or other housing form, the privacy gradient of a dwelling can support or undermine relations with others, especially outsiders. Generally, in European-American dwellings, people consider the main entrance to be the most open to outsiders. Outsiders tend to be limited to the front room, often a room not used by the family, but maintained to be presentable to unexpected visitors. The privacy gradient continues toward the back of the home, with semipublic areas (e.g., a guest bathroom), communal areas for close friends and family members (e.g., kitchen, family room), and ends with the most private (e.g., family bathrooms and bedrooms). Some studies indicate that closeness of a relationship is associated with access to different places in homes (e.g., casual acquaintances are restricted to public areas, whereas friends are more welcome in personal areas).

Some groups screen and greet visitors outside the entrance, such as Egyptian Nubians, who build a bench or *mustabah* outside their compound where they visit with neighbors in the evenings.

Effective use of the physical environment can help people manage relationships and maintain orderly lives. Parents can open or close their bedroom doors to signal children when they would or would not be welcome. Children often put up “go away” or “come in” signs to control access to their bedrooms. Some families maintain order by encouraging individuals to sit at the same place around the dinner table, whereas others prefer more spontaneity in seating choices. Similar claims over places can be seen at more microlevels, such as when partners split storage space into “my things” and “your things.” In a study of a senior center, groups of “regulars” begin to think of the center as theirs and tried to block access by “nonregulars,” creating conflicts. Studies of naval recruits underscore the importance of being able to maintain control over one’s things and one’s places. Recruits were housed in pairs to simulate the close quarters of submarine life and then assigned a number of tasks. Those recruits who quickly established territories (“This is my chair and my side of the table”) were more likely to successfully complete the experiment.

Research on crowding in settings such as college dormitories, daycare settings, and homes demonstrates how the physical environment supports privacy regulation. The experience of crowding often relates to the lack of control over contact with others. In large dormitories, with long hallways and undifferentiated spaces, students were overwhelmed by the numbers of other students. They constantly ran into other students, had difficulty finding quiet settings when desired, and eventually began ignoring other residents. In contrast, in dormitories with shorter halls that housed approximately half as many students, there was more socializing among residents and fewer complaints. In another study, the social withdrawal shown by residents living in crowded homes was maintained even when residents were away from home. Other research shows that even in high-density settings, residents can maintain social relationships if the building has interior hallways and small rooms that allow control over interactions.

These and other studies led universities to design dormitories around a “cluster” or “suite system” that provides residents with greater control over privacy regulation. Each suite is designed with common living areas for small groups of residents who have individual or shared private bedrooms. Students visit the common areas when they want to be open to others, and they can go to their individual rooms when they need to be alone. As another benefit, suitemates provide an available and natural group of friends that prevents the social isolation that can occur in large universities.

Community Environments

Social relations with friends and neighbors are also important. Neighborhood physical environments can provide environment supports and cues that keep people away (fences, barriers, “do not disturb” signs) as well as welcoming them (community gardens, holiday decorations). When residents feel that neighbors are trustworthy and/or friendly, they tend to experience many positive outcomes, such as lower levels of crime, less fear of crime, and more positive child outcomes, including good academic performance, less criminal involvement, and less distress. Physical features that may engender neighborly relationships include communities designed to be “walkable.” When communities have many attractive destinations, a dense network of pathways to get there, and enough people to support these facilities, people are more likely to walk and to know their neighbors. Attractive green spaces draw adults and children together, providing more adult-child interaction opportunities, as well as adult oversight of children. Neighborhoods also contain several features that may impair relationship development. For example, children and adults residing on highly trafficked roads tend to have fewer neighborly relationships than those residing on quieter streets.

Neighborly relationships can also be reflected in and supported by the environment. Decorations, upkeep, and landscaping signal residents’ attachment to their home and also convey interest in fitting into a neighborhood and meeting neighbors. In one study, people were asked to look at photographs of homes and decide what kinds of

people lived there. They expected greater friendliness from residents of homes that were well maintained and nicely decorated, suggesting that people can use decorations to communicate openness and elicit interactions with neighbors.

When residents age and have more limited mobility, neighborliness may provide both welcomed social contacts and a sense of well-being. Neighborhood designs that support relationships may be especially important for elderly residents whose friends move away but who themselves are reluctant to move because they are attached to their homes.

Work Settings

Work settings also provide physical environmental supports that foster and impede relationships. Individual offices are usually preferred to open-plan offices because they provide control over interactions. Workplace environments often convey information about status, such as the size and location of a private office, and when one attains the privilege of personalizing the décor. An in-depth examination of culturally diverse work groups indicated that many conflicts occurred because of different beliefs about openness and closedness. Some workers believed an open-plan office meant that other workers should help them with tasks, whereas their coworkers from different cultural backgrounds felt that each individual needed to complete work independently. Some workers enjoyed ethnic symbols in the workplace, whereas others were put off by them and experienced strained relationships. Work settings also need to provide gathering places that support informal interaction. One study found that work rooms that were accessible, allowed surveillance during personal conversations, and were accepted as social settings provided good opportunities for building informal relations at work.

Conclusion

At many levels of scale (couple, kin, community), the physical environment helps people achieve relationship goals. Skilled use of the physical environment helps people make themselves more or less available to others, to signal their desires

for openness or closedness, and to mark the environment with objects that reflect their values, identities, and relationships. These processes are made easier by well-designed environments, as well as skill at delivering and interpreting various messages. These processes are made more difficult when participants come from different backgrounds and cultures, have different relationship expectations, and where meanings of environmental cues are different and easily misunderstood. Good designs and skilled uses of environments will continue to be essential tools for improving development, change, and stability in relationships.

PHYSICIANS, RELATIONSHIPS WITH

In fiction and nonfiction, the patient–physician relationship is depicted as a source of comfort, pain, friendship, shame, love, bad news, good news, fear, hope, disappointment, renewed life, and more. In these interactions, patients and families can help these interpersonal relationships go well, contributing to feeling in control of their health. Conversely, when these relationships do not go well, frustration and disappointment can ensue. This entry addresses patient, family, and physician roles in these relationships, with particular attention to the ways in which patients and families can maintain positive outcomes.

Relationship-Centered Care

Relationship-centered care is a new framework for conceptualizing health care, focusing on the importance of the involved individuals' relationships with each other and with their community, with the goal of providing meaningful relationships in health care. Relationship-centered care is founded on four basic principles according to the Relationship Centered Care Network:

1. Patients and physicians bring their unique experiences and qualities to the relationship. Hence, physicians are advised to remain explicitly aware of their own "personhood" and encouraged to manage their emotions in a way that facilitates connecting with patients. A physician is encouraged not just to act respectfully, but to develop genuine respect for patients.
2. Physician affect and emotion powerfully impact patient care. Physicians are discouraged from excess detachment and encouraged instead to connect through the provision of empathy, incorporating self-awareness.
3. Physicians and patients have a mutual effect on each other. Although the patient's needs take clear precedence, the physician also benefits and grows from the relationship.
4. There is a moral basis to the patient–physician relationship. A caring relationship in which the physician takes his or her role seriously and works to educate and support the patient and relevant family is morally desirable, beyond the fundamental purpose of providing quality medical care.

Patient-Centered Care

Patient-centered care is complementary to relationship-centered care, prioritizing the patient's communication style and biopsychosocial needs in each medical encounter. The physician should express him or herself as if "in the shoes of the other," known as empathy, in response to patient affective and situational cues. Statements such as "I can imagine that would be difficult" or "That sounds scary" have proved beneficial to both parties. Experienced physicians, physicians in training, and medical students who provide empathy to patients are less burned out and more satisfied than their counterparts who do not. Patients who receive empathy from their physician are less anxious and depressed, more satisfied, and more likely to adhere to their physician's recommendations. There is also evidence that these skills are able to be taught. Regrettably, there is evidence that physicians often do not provide adequate empathy in response to patient cues, a phenomenon that has been linked to increased malpractice claims, lower scores in performance evaluations, and decreased patient satisfaction.

Reasons for Inadequate Physician Responses

Medical training can result in emotional numbing and distancing due to such stresses as sleep deprivation, the pressure to succeed in a high-performance environment, role modeling, and coping with the futility of addressing human tragedy and incurable disease. Seven to 10 years of training with 60- to 90-hour work weeks can leave a physician in financial debt, with poor health habits and lack of supportive personal relationships. Continued time stresses in medical practice without much support can tax physicians' emotional resources despite the best intentions. Systems in place throughout training and afterward to address these troubling events include informal and formal support networks, stress management, and educational programs. Fortunately, physicians enter their careers with a desire to help patients, and most learn sustaining coping skills that allow them to work hard to provide high-quality patient care.

Physician Communication Skills

Patient-centered (as opposed to physician-centered) communication skills start with mindfulness of the physician, which includes the physician being centered and self-aware. Being self-aware does not mean, however, that the physician is helpful when sharing these and other personal details about him- or herself. In fact, the physician must focus on the patient and the patient's concern, story, and context, screening out internal and external distractions.

Generally, a visit begins with a greeting, followed by the physician asking about the patient complaint or concern. The physician then asks for all the concerns the patient wishes to address in that meeting, establishes their priority, and, if necessary, limits them to a manageable number. (This organization is important to prevent the patient remembering the most important concern for the day at the end of the visit or in the parking lot.)

Beginning with the most important concern, the physician then elicits the narrative, or story, from the patient about that problem. The physician needs to listen carefully, without interruption. This is a skill that often is not practiced, as evidenced by research showing that physicians interrupt, on average, within 23 seconds of the patient talking. The physician should provide support and empathy, listening for patient and family strengths alongside the health problems. During the patient's story, the physician listens for contextual factors affecting the patient's concern. How do poverty, ethnicity, or family problems affect the presenting concern or the likelihood that a treatment plan will be followed? When family members are present, the description of the problem is deeper and the implementation of the treatment plan is more successful. If they are not present, the physician should ascertain who is relevant to the diagnosis or treatment plan and how their support can be secured.

Negotiating the diagnostic and treatment plan requires that the physician establish a collaborative relationship with the patient and family. Problems that are concrete, primarily biological in nature, and circumscribed are the easiest problems to address. However, frequently, patients arrive with a mixture of biopsychosocial issues that come together and affect each other (e.g., depression and cardiac disease in an immigrant patient). In this context,

biopsychosocial can be defined as an integration of the effects of mind, body, and social environment in a complex fashion. It is the physician's job to elicit the relevant diagnostic information from the patient and relevant others and then formulate a mutually agreeable and realistic treatment plan. Along with other members of the health care team, education about the physical, emotional, and interpersonal aspects of the disease and its treatment are a central part of the physician's job.

Lifestyle issues such as diet, exercise, substance use or abuse, and interpersonal conflict or violence can contribute to the development and deterioration of many chronic illnesses. The physician-patient relationship is a primary vehicle for developing the trust and motivation to address these underlying health problems. For physicians, this means assessing the patient's motivation for change, amplifying patient and family strengths, and avoiding or addressing the blame or criticism that can occur when lifestyle issues affect health.

The Primary Care Physician's Role in the Context of Health Care

Today's health care is provided by a team of health professionals. The primary care (or family) physician and his or her relationship with the patient and family are often at the center of care. Together, the team of professionals seeks to attend to and advocate for the biopsychosocial health of the patient. This means promoting all aspects of health, from the biological to the psychological and sociocultural factors that influence health. The primary care physician and the primary care team provide the medical home for the patient to address concerns about acute, chronic, and terminal diseases. For some patients and insurance carriers, the patient may schedule an "annual physical" with the primary care physician, where health care maintenance will be comprehensively addressed in an age-appropriate manner, including immunizations and blood tests or other evaluations. In some cases, the primary care physician will need to take that initiative when the opportunity arises at problem-oriented visits. The primary care team is the central organizing force in health care; it coordinates and integrates care with specialty physicians and other health care services in order to

provide comprehensive care that meets the patient's needs. This team also tends to the patient's special needs, such as translators and equipment to provide access to people with disabilities.

Physician Knowledge, Judgment, and Ethical Obligations

It is incumbent on the physician to acquire and maintain his or her biomedical knowledge and skills and to develop sound medical judgment to synthesize all of the data. This means that the physician has a moral and ethical responsibility to keep up to date on knowledge in a field so complex that it is impossible to know everything. Hence, he or she must know the limits of that knowledge, when to look up the information, and when to seek consultation. Patients should be able to trust their physicians to meet these obligations.

Numerous ethical issues may arise in the course of medical care, such as end-of-life concerns; medical errors or substance abuse by a member of the team; a physician in educational, financial, or research roles with a patient; and boundary issues in the relationship. Boundaries are defined by the limits placed on the relationship by virtue of the inherent power differences between physician and patient, requiring that the physician consider the patient's dependency on him or her when considering any kind of secondary relationship. Medical boards and associations, such as the American Board of Internal Medicine, universally require that physicians in all of these situations, including medical errors, be honest with the patient and family and prioritize the needs of the patient. If a physician's religion or beliefs mandate against certain treatments, he or she is obligated to refer elsewhere. Additionally, physicians have an obligation to report knowledge of ethical or legal violations committed by other medical professionals to the appropriate board or supervisor.

The Patient's Role in the Doctor–Patient Relationship

With more collaborative, less authoritarian approaches to medicine, the role and responsibility of the patient in the doctor–patient relationship have received more attention. The following

recommendations for patients suggest how one might become an advocate for one's own health and develop a strong and healthy relationship with physicians and other health providers:

- Be realistic (recognizing that no one person can be perfect or meet all of your health care needs).
- Plan ahead and limit your concerns to two or three problems in one visit.
- Announce your agenda at the beginning of the visit and share responsibility for making sure your concerns are addressed.
- Model the respect and caring behavior you hope to receive.
- Ask for help with lifestyle issues (e.g., “Losing weight is a good idea. How can I get help with that?”).
- Ask your primary care physician or nurse practitioner to do preventive testing or immunizations, coordinate care, and communicate with specialty physicians or other providers.
- If the physician becomes angry or defensive, do not escalate, but try to acknowledge his or her time, effort, and frustrations.
- If time runs out, state that you have more questions and request another visit.

The physician–patient relationship is two way; the patient can have an important effect in how it functions. Both members of the relationship have the same goal: a healthy patient. The patient–physician relationship is not an equal relationship because the physician brings professional responsibilities to the patient and family. Yet both sides have important roles in making the relationship a positive one.

PLAY FIGHTING

Play is a common feature of many young mammals, including humans. Although difficult to define objectively, play is readily recognized by observers and has several consistent features: It is engaged in voluntarily, has no obvious utilitarian value, and appears to be enjoyable to the participants. Play can be solitary or social. The most striking form of play seen in both humans and nonhuman animals is “rough-and-tumble play” or “play fighting,” where the participants jostle for some advantage over one another. Unlike serious fighting, play fighting has an organization that ensures that it remains playful, and, remarkably, playful encounters rarely escalate to serious fights.

For play fighting to remain playful, there must be a reciprocal exchange, where enough effort is expended by the participants to ensure that victory does not come too easily, but not so difficult as to make it impossible to attain. By not abusing their advantage once gained, victors ensure that play fights are reciprocal, and, indeed, a common marker of that reciprocity is the presence of frequent role reversals between attackers and defenders. That is, both participants have a chance to gain the advantage. In contrast, in serious fighting, participants do

all that is possible to prevent their opponent from gaining the advantage. The reciprocity inherent in play fighting allows participants to use this experience in functionally beneficial ways.

Although most often associated with the prepubertal period, in many species, play can continue into adolescence and even adulthood. However, play fighting before and after puberty can differ strikingly. Prior to puberty, it is more cooperative. Studies on rats and monkeys provide considerable evidence that the experience of play fighting in this period is important for the development of social skills. An animal that has had the experience of play as a juvenile will have a greater ability to solve novel social problems, be less likely to antagonize its fellows, and not be so stressed by novel social situations. The reciprocity needed to maintain play fighting as playful has the right mixture of competition and cooperation to provide the experience of uncertainty and unpredictability in vigorous social interactions. This experience seems critical for animals to learn to not be flummoxed by the unexpected. The same is likely true for people.

After puberty, play becomes more overtly competitive. When an animal transgresses the bounds of acceptable behavior during play, the partner must determine whether that transgression was intentional. This ambiguity allows an animal to explore the boundaries of its relationships. There are two situations among adolescents and adults in which play fighting is most commonly reported: in social groups between males of differing status and during courtship.

Following puberty, male rats use play fighting to negotiate social relationships with other males and so learn their place in the social hierarchy. A subordinate partner may play in a juvenile-like manner with a dominant animal to ensure that their relationship remains intact. Alternatively, a subordinate can become rougher in its play, thus using it to determine whether its relationship with the dominant can be reversed. Similarly, the dominant partner can increase the roughness of its play, subtly punishing the other animal, thus reinforcing the status quo. Such uses of play fighting seem to be widespread. For example, among adolescent boys, a gentle form of play fighting occurs within the group, which reinforces social bonds. Playing with a boy who is not from the group can be rougher, reinforcing his outsider status.

Among many species, when play is used in courtship, partners use actions typical of play fighting to overcome the reticence of a potential mate in making close bodily contact. There is considerable cross-species variation as to which sex takes the lead in these encounters, but in all cases, the reciprocal exchanges present in play fighting provide a nonaversive means of evaluating the potential partner. For example, playful flirting in humans can be used to determine a potential mate's interest. If one is rebuffed, such an overture can be shrugged off as only playful, which diminishes any loss of face or self-esteem. Females have greater latitude in the force of their actions: They can strike a male more forcefully than would be tolerated if the reverse were the case. These inequalities add to the ambiguity of such play, but also increase its informational value—by exhibiting the appropriate level of restraint, the male can be evaluated for his potential as a mate.

What both the dominance and courtship uses of play fighting have in common is the playful banter that allows participants to assess and manipulate their partners. For nonhuman species, play fighting involves physical contact, but in humans there are also noncontact forms. Verbal joking and its associated laughter, for instance, are human-typical derivations using the essential ingredients of play fighting, and they provide a wider range of options to navigate complex social networks. At school and in the office, boys and men are particularly likely to use jokes as a way of probing and asserting dominance.

Play fighting is competitive, but not too competitive, and jokes can be hurtful, but not too hurtful. Of course, mistakes do happen, and throughout a play fight, participants must continually pass judgment on whether a blow that was delivered too hard was accidental. Similarly, in a work setting, you may wonder, "That's the fifth joke at my expense this week, what's going on?" Contestants can use playful banter to push a little harder than usual, to see what happens, and then, if anyone shows that they are angered, the one that transgressed can back down with "it was only play." Many animals that use play in this manner also have signals that can inform the partner that what is to come or what has just happened was play.

POLITENESS

See FACEWORK

POLYGAMY

Institutionalized mating relationships are found in three primary forms. Monogamy is the marriage of one person with another person of the opposite sex or the same sex. Polygyny consists of the marriage of one man with two or more women, whereas polyandry entails the marriage of one woman with two or more men. Polygamy includes both polyandry and polygyny. Cenogamy is the name given to a group marriage in which any male or female may have sexual relations with any other female or male in the group. Although practiced by a few small experimental communities, such an arrangement has never received institutional status in a culture as a whole. Other polyamorous relationships, such as the union of three or more men, three or more women, and two or more men with two or more women, may occur, but lack names and recognition as social institutions. This entry describes the prevalence of polygamy, determinants of polygyny, the impact of polygyny on women and children, and the determinants of polyandry.

Prevalence of Polygamy

Current Western governments recognize only monogamy, but that is not the case worldwide. Among the 1,231 societies in the *Ethnographic Atlas Codebook*, 186 (15 percent) were monogamous, 453 (37 percent) had occasional polygyny, 588 (48 percent) had more frequent polygyny, and 10 (less than 1 percent) had polyandry.

The foregoing does not mean that 85 percent of the world's population supports polygamy. Many polygamous societies are small, underdeveloped cultures. Nonetheless, polygyny is considered to be a legitimate form of marriage in Algeria, Benin, Chad, Congo, Gabon, Ghana, Kuwait, Nigeria, Saudi Arabia, Togo, and Tanzania, as well as among the Bedouin-Arabs in Israel and Xhosa in South Africa.

The prevalence of polygyny also does not mean that a male may choose any female as an additional wife. In many polygamous societies, the first spouse must consent to the choice of a second spouse. Fifteen percent of societies in which multiple wives were common also emphasized sororal polygyny, limiting the male to his wife's sisters, such as Native American Sioux and the Zulus of Africa. At other times, an additional spouse is obligatory. In 69 percent of polygynous societies, a man was expected to marry the widow of his brother and to raise the nephews and nieces as his own. In 62 percent of polygynous societies, the cowives live in separate dwellings.

The original religious teaching of the Church of Jesus Christ of the Latter Day Saints (LDS) encouraged men to have at least three wives. Polygyny is illegal in the United States, and the LDS church hierarchy banned the practice of plural marriage in 1890 as part of Utah's application for statehood. Nonetheless, polygyny continues to be practiced in some fundamentalist LDS sects, primarily located in Utah, Arizona, New Mexico, and Texas.

Islam permits polygyny with up to four wives. Some Muslim immigrants in the United States from the Middle East, Africa, and Asia bring multiple wives with them during the immigration process, concealing the females' identity as sisters or daughters. Other Muslim men take a second, third, or fourth wife in Islamic religious ceremonies that are not recognized by civil law, leaving the later wives and children in jeopardy in matters of health care, social security, and inheritance.

Determinants of Polygyny

Because polygyny is so widespread, it is difficult to identify variables that consistently predict its acceptance. Among societies that permit polygyny, however, it is practiced more frequently in some cultures than others in terms of the percent of females involved in polygynous unions. More females tend to be involved in polygynous unions and fewer in monogamous unions meaning-wise, but it seems clearer in harsh environmental circumstances, including tropical climates with a higher level of infectious disease and in societies with a lower ratio of eligible males to females, including due to the loss of males in warfare. It also is more frequently practiced in cultures that have greater income inequality, including concentration of a large amount of wealth and arable land in few hands, and delayed age of marriage for males due to the need to accumulate resources in order to marry. Such environmental conditions seem to accentuate the natural selection tendency for the strong and fit to reproduce more than the weak and poorly adapted.

Although some aspects of a harsh environment occur naturally, it should be emphasized that the concentration of wealth and land-holdings occurs only when social norms and structures emphasize individual acquisition rather than communal sharing. The determinants of such norm variations are unclear. Regardless, females in such harsh physical and social environments may be forced to choose between marriage to a healthy and wealthy male who can support multiple wives, a poorer or sicklier male, or no marriage at all. Further suggesting that polygyny is an institution associated with reduced female options are findings that it is practiced more intensely in societies with a low rate of female literacy and little exposure to mass media.

Impact of Polygyny on Women

Information on the impact of polygyny on women is mixed. In polygynous societies, such as among fundamentalist Mormons and Islamic groups, women often have little access to education or careers and may be restricted from owning property or exercising overt political power. Some report jealousy due to their husband sleeping with

other women and resentment when dominated by their husbands' earlier wives. In some polygynous subcultures, girls younger than the age of consent in the larger society have been forced into marriages against their will, providing *de facto* support for rape.

Some women in polygynous societies have expressed dissatisfaction because of their lack of personal funds, transportation, and saleable skills, which creates formidable barriers to divorce. A woman who leaves a polygynous marriage may be ostracized and shunned by the polygynous community, creating strong obstacles to her seeing her children again if she did not retain custody.

Other women in polygynous communities express satisfaction with their lives. They report pride in being linked to a prosperous husband, they enjoy their close relationships with their sister wives, and they benefit from sharing household work and child care. These women also report feeling that they wield considerable influence in the management of domestic activities and in the welfare of the community.

Impact of Polygyny on Children

Children born in a polygynous family may benefit from receiving the genes of successful fathers and in living in the household that such men can provide. The children also may benefit from having multiple role models and receiving the warmth, affection, and care of several mother figures.

At the same time, polygynous marriages are more likely than are monogamous marriages to have spousal conflict, tension, and jealousy. There also is more father absence if the wives live in separate houses, and there may be financial stress if the number of children borne by multiple wives is not paralleled by increased income. There are reports of adolescent males being ejected from polygynous compounds in the United States to reduce competition for the adolescent females. Lacking education or skills for dealing with the outside world, these unfortunates are known as the "lost boys of polygamy."

Some studies have documented the negative effects of polygynous marital structure on the developmental outcomes of children, whereas others have not found evidence that polygyny

places children at risk for adverse cognitive, educational, or mental health consequences compared with children from monogamous families. Disentangling such conflicting results may require knowledge of the religion, economy, and social structure of polygamous cultures, including whether the cowives are sisters or live in separate dwellings. In societies in which polygyny is highly valued in the religion and is a sign of high status, the children of polygynous marriages may thrive. However, when polygyny is stigmatized or an indicator of impoverishment, then children of polygynous marriages may fare less well. Similarly, societies that emphasize communal rather than individual values and involve the extended family in childrearing may buffer the impact of the stressors associated with polygynous marriage, especially on older children who typically spend less time in the home.

Determinants of Polyandry

The marriage of one female with two or more males occurs in less than a dozen cultures, including the Toda of south India, the Nyinba of north-west Tibet, the Pahari of Nepal, the Marquesans of Polynesia, and the Kaingang and the Shirishana of Brazil. The Toda practice fraternal polyandry, in which two brothers marry a woman. Not only are both males related to the offspring, but they have an incentive to work cooperatively on land that stays undivided in the family. Among the Marquesans and Kaingang, by contrast, two males who are not closely related marry one woman.

Polyandry is not an institution in which successful women maintain harems of attractive men. Instead, polyandry tends to occur in cultures with weak economies, in which individual men tend to be poor and have difficulty supporting wives on their own, and women tend to be marginalized and have minimal opportunity to contribute to family subsistence. In such situations, it often takes two men and a woman to make ends meet. The Shirishana are not characterized by poverty, but the society consists of only a few hundred people who live by hunting and horticulture in the more remote regions of Brazil, and they have unstable sex ratios. Because of the relationship between

polyandry and economic and demographic instability, it is difficult to determine the impact of polyandry on women and children, although issues of jealousy and marital conflict have been reported.

To the majority of the world's people, who were brought up within the norm of monogamy, the institution of polygamy may seem exotic and can elicit a reflexive response of ethnocentric disdain. But polygamous institutions appear to have been adaptive in some past and present ecologies and may be so in the future. For example, because of a cultural preference for sons, countries such as China have seen examples of selective abortion and infanticide over the past quarter century used to increase the ratio of males to females. Institutionalization of polyandry could help alleviate the looming wife shortage in such countries.

POPULARITY

Popularity is a term used to describe the social status of an individual. Broadly, popularity refers to high peer acceptability. Popularity indicates that an individual has more social power than other members of a reference group, and this social power may be prosocial or antisocial in nature. Examples of prosocial behaviors include being kind and likable, whereas examples of antisocial behaviors include being aggressive and dominating. The significance of popularity may peak during adolescence, a time during which individuals tend to be particularly concerned about who is popular or unpopular in their peer group. Beyond adolescence, popularity receives relatively little attention in the psychological literature, although popularity in adulthood has been linked to more frequent respiratory infections presumably because popularity leads to increased contact with a greater number of people. This entry describes the phenomenon of popularity, how it is measured, what factors are associated with it, and its role in human relationships.

Conceptualization and Measurement

Historically, *popularity* has been defined in two major ways. Until the 1980s, it was primarily conceptualized and measured using sociometric methods. That is, popularity was measured by examining the position of individuals within groups. More specifically, the sociometric definition of popularity examines the extent to which individuals are rated as likable and socially preferred by their peers. Thus, individuals who are liked and deemed desirable as social partners are viewed as popular. To measure popularity in this way, researchers collected rating scale data to determine whether individuals were liked or disliked by others in their peer group. An individual who received many liked ratings and few disliked ratings by peers was deemed popular.

Other methods of assessing popularity include paired comparisons techniques, in which each participant is presented with the names of two peers and is asked which of the two he or she prefers or likes better. The same participant is then presented with other pairs of peers' names until all individuals

in the group have been contrasted and an overall measure of popularity may be computed for each target. Another common technique is the nominations method, in which each individual is instructed to list a number of peers (typically three) who are best liked and a list of peers who are least liked. These assessment methods are useful across the life span (even preschool children are able to provide meaningful sociometric data), are correlated with teacher reports of peer acceptability, and are related to the quality of peer interactions, including initiation of play and friendships.

In the 1980s, researchers began to theorize that popularity involved more than a single rating of likability. Instead, it was proposed that popularity was composed of two dimensions: (1) social preference, the extent to which an individual was liked; and (2) social impact, the extent to which an individual was perceived to have social power. More in line with a sociological approach, this two-dimensional theory measured popularity in terms of the individual's characteristics (e.g., friendly or unfriendly) and status in the social group (e.g., high status or low status). Popularity was defined in terms of social centrality, and individuals with a reputation of social power and impact were perceived as popular.

Early on in this tradition, popularity continued to be measured using liking and disliking nominations by peers. Individuals were asked to rate their peers as liked or disliked. In addition, researchers measured social preference (liked minus disliked) and social impact (liked plus disliked). Using this model, five sociometric types were derived: popular, rejected, neglected, controversial, and average. Popular individuals receive many liking ratings and few disliking ratings; thus, they are high in both social preference and social impact, and they are liked and desirable as friends. Rejected individuals are similarly high in social impact, but differ from popular children because they may or may not be liked. Neglected individuals are low in social impact and moderate in social preference, receiving few positive or negative peer nominations. Like popular individuals, controversial children are high in social impact, but unlike popular children, they receive many positive and negative nominations by their peers. Interestingly, it is possible to be simultaneously liked and disliked by peer group members. Research findings show that

high numbers of liked and disliked nominations are indicative of high social status, albeit a controversial one. Further, research suggests that children classified as controversial make up only a small proportion of the group and that they do not remain in that category for long. The remaining third of children are classified as average: They receive moderate numbers of positive and negative nominations by their peers.

When researchers found that popularity was not linked solely to an individual's likability, they began to study popularity in terms of two distinct, measurable phenomena: sociometric popularity and perceived popularity. *Sociometric popularity* was defined in terms of likability. Perceived popularity was defined in terms of social power or status. To measure sociometric popularity, individuals were asked to name peers with whom they would like to be friends. To measure perceived popularity, individuals were asked to name peers whom they perceive to be popular. Sociometric popularity and perceived popularity do not always overlap. That is, an individual may have substantial social power, but may not be well liked by peers or vice versa. Interestingly, using measures of both sociometric popularity and perceived popularity led to a heterogeneous group of individuals who are considered popular.

Individuals who were rated high on perceived popularity and low on sociometric popularity were seen as dominant and aggressive. Individuals who were rated low on perceived popularity and high on sociometric popularity were viewed as friendly and trustworthy. Finally, individuals who were rated high on both perceived and sociometric popularity were perceived to have all these characteristics.

Popularity in Childhood and Adolescence

Popularity as a phenomenon is most apparent in middle childhood and adolescence. By the fourth grade, perceived popularity is well established, and children are able to identify characteristics of popular and unpopular peers. These characteristics range from positive, prosocial behaviors to negative, dominating behaviors. Some positive descriptors that are associated with being popular include being cool, athletic, smart, and friendly. Negative descriptors include being stuck-up and relationally or overtly aggressive toward peers.

Relational aggression refers to acts that intentionally manipulate or damage social relationships via behaviors such as teasing, spreading rumors, or exclusion. There is evidence that highly aggressive boys may be some of the most popular children in school. Other characteristics that are commonly associated with popularity are attractiveness and having many material possessions. Studies have found that girls may be more aware of the characteristics associated with popularity than boys.

As discussed earlier, although high social status is typically viewed as desirable, not all popular individuals are liked. Many popular children are not prosocial. Indeed, children and adolescents who are perceived as popular can be some of the most aggressive (relationally and overtly) members of the peer group. Some potential reasons are that, once students achieve high social status, they may feel a need to continue to engage in aggressive behaviors to maintain their status.

Factors That Affect Popularity in Childhood and Adolescence

Role of Family

Another factor that has been found to influence popularity is the quality of family relations. Research indicates that family cohesion, adaptability, and marital satisfaction predict children's popularity over time. Possible reasons for these findings are that parents who are emotionally positive and who model prosocial behavior tend to raise children who emulate these behaviors in their peer relationships. Birth order has also been related to popularity: Children who have older siblings tend to be more popular than first-born children presumably because they have more interpersonal experiences with other children within their homes. Further, parenting styles have been linked to children's popularity. Authoritative caregivers who provide a combination of warmth and articulated limit-setting tend to parent children who are well liked by peers and adults.

Other Correlates

Research has linked popularity to a number of positive attributes. Generally, high peer acceptance

is related to short- and long-term psychological well-being. For example, popular individuals tend to be more intelligent, socially skilled, and physically attractive. Behaviorally, popular children are viewed as friendly, cooperative, extraverted, and competent in initiating, maintaining, and resolving conflict within relationships. Popularity has also been linked to better emotion regulation. Popular children tend to perform well academically relative to their rejected peers, who tend to perform poorly in school. Additionally, popular children tend to be more engaged in school. Children with common names also are more likely to be popular than their peers with more atypical names.

Gender Differences

There may be gender differences associated with changes in an individual's perceived popularity and likability over time. Research indicates that boys who are well liked tend to be perceived as more popular over time, whereas girls who are perceived as popular tend to become less liked over time. One possible explanation for this finding is that girls may increase relationally aggressive behaviors after they achieve popular status in an effort to maintain it. Another potential reason for this trend is that less popular girls tend to be envious of girls who are perceived as popular and therefore rate them as less likable.

Risks Associated with Popularity

Popularity may be a risk factor for some individuals. Children and adolescents who are popular tend to be more influenced than their less popular peers by broad social reference groups. Once popular, individuals have a significant amount of social power within their peer group, but they must actively work to maintain their status in their social hierarchy. Popular children and adolescents are likely to emulate positive and negative behaviors they observe in society at large. These behaviors are perceived as useful for maintaining their social status. As one example, prosocial behavior is favored over serious deviant behavior such as hostility and aggression in society at large, and there is evidence that hostility and aggression decrease with popularity. As another example, sexual

activity and alcohol and substance use are largely acceptable behaviors in society, and there is evidence that popular adolescents are at greater risk of engaging in these activities relative to their peers.

It is important to note that individuals who are not popular also may emulate the risky behaviors of popular peers in an effort to increase their own social status; however, these individuals have fewer of the protective factors that popular individuals have, putting them at increased risk. Although specific protective factors have not been identified, it appears that engaging in risky behaviors during adolescence has less potential for long-term consequences when these behaviors occur within the context of other, more positive cognitive, emotional, familial, and social factors.

PORNOGRAPHY, EFFECTS ON RELATIONSHIPS

Researchers over the past three decades have been investigating how pornography and erotica affect viewers' attitudes toward women, appraisals of their romantic relationships, and tendencies toward aggressive behavior. More recently, they have begun investigating the impact of pornography use on both the viewer and on his or her romantic partner. With the explosion of personal computers and Internet connections in the home, as well as the number of pornography sites on the Internet, ease of access to pornography is unprecedented. Yet at present, relatively little is known about the effects of pornography on romantic relationships. According to a recent report in *Time* magazine, the American Academy of Matrimonial Lawyers stated that pornography use has been implicated in more than half of recent divorces in the United States. Studies have primarily examined such use in Western cultures, although research in Eastern cultures is beginning to emerge. A number of important findings have appeared consistently and are described in this entry.

To begin with, there are qualitative and meaningful differences between sexually explicit materials that are pornographic and materials that are erotic. Pornographic materials combine sexual explicitness with degradation and/or violence in a manner that appears to condone the degradation or violence. Degrading elements commonly include depicting women in subordinate positions and roles or portraying them as degraded persons. Violent elements can include slapping, punching, gagging, and other physical contact that would likely result in discomfort or pain. Of note, perpetrators of aggression are rarely punished for such acts, and targets of aggression appear to thoroughly

enjoy such degrading or violent treatment. In contrast, erotic materials present egalitarian and consensual depictions of sexuality, in which the pleasure of both partners is the focus.

Researchers have found differences between the effects of pornographic and erotic materials. Generally, men report feeling positively about both types of sexually explicit materials and report that such materials enhance their sexual knowledge and attitudes toward women and sex. However, after viewing pornographic (but not erotic) movies, they are (a) more likely to feel that a female victim is at least partially responsible for sexual assault, (b) more likely to endorse sexist attitudes, (c) less likely to report being in love with their romantic partner, and (d) less likely to find their romantic partner attractive. Women see pornographic and erotic materials differently. In general, erotic materials are seen positively, whereas pornographic materials are seen as disgusting and/or disturbing. However, there appears to be a trend toward more accepting attitudes toward pornographic materials on the part of women.

When examining relationships between sexually explicit material use and couple satisfaction, studies to date have been unable to accurately differentiate between pornographic and erotic materials. However, interesting findings have emerged from research that focuses on sexually explicit materials as a whole. Generally speaking, the majority of people who view or whose partners view explicit materials do not report their own or their partner's use of such materials as problematic for the relationship. Notwithstanding, studies have shown that between 20 and 35 percent of women whose male partners view sexually explicit materials do report distress over such use. (In contrast, fewer than 10 percent of men report similar distress over their female partner's use of such materials.) This distress often takes the form of women stating that their partner's use feels just like an affair. Distressed women report that a partner's heavy use of sexually explicit materials compromises their sense of intimacy and closeness to the partner, makes them feel like sexual objects rather than true partners during sexual relations, and leaves them feeling physically inadequate as they compare themselves unfavorably to the women portrayed in the pornographic materials. Married women and those whose partners use sexual materials frequently are

more likely to express distress than women who are just dating their partner or whose partners report less frequent usage.

How use of sexually explicit materials relates to couple satisfaction and sexual satisfaction depends on who is viewing the materials and the purposes for which they are viewing it. Research has found that women's use of sexually explicit materials is associated with an increased sense of sexual satisfaction for both her and her male partner, as well as increased relationship satisfaction for her male partner. In contrast, men's use of sexually explicit materials relates to *decreased* sexual satisfaction for both him and his female partner. Expressed differently, the more women report using such materials, the more sexually satisfied they and their partners are; but the more men report using such materials, the less sexually satisfied they and their partners are. Other studies have confirmed a relationship between men's use of sexually explicit material and lower relationship satisfaction with a romantic partner.

Why would satisfaction ratings differ depending on whether it is men or women who are viewing sexually explicit materials? The answer to this question appears to lie in the reasons for such usage. An overwhelmingly consistent finding dating back for more than 30 years, across multiple studies, and in various countries is that men view sexually explicit materials significantly more often than women. Recently, researchers have investigated the reasons for such use. What this research suggests is that the primary reason that men use sexually explicit materials is to aid in solitary masturbation. In contrast, the primary reason that women report using these materials is as part of and an aid to lovemaking with their romantic partners. In other words, most of the time they use sexually explicit materials, men use them in a relationship-*distracting* activity, whereas women commonly use such materials in what can be called a relationship-*enhancing* activity. (Although men also see explicit materials with their partners, more often they report using such materials alone.) Therefore, when the primary reasons for such use are considered, it makes sense that higher use of sexually explicit materials by women results in greater sexual satisfaction for couples, whereas higher use by men results in lower satisfaction.

Although future studies need to better discriminate the different effects of pornography versus erotica on romantic relationships, it is encouraging that researchers are beginning to examine how such materials affect not only individuals, but also couples. Given how accessible such materials are, an increased understanding can help couples better manage such use for their long-term relationship happiness and success.

POSITIVE AFFECTIVITY

Conventional wisdom holds that happy people have stronger social relationships than their less happy peers, and empirical research supports this popular belief. In this chapter, we examine how social relationships are influenced by positive affect (PA)—the feelings reflecting one's level of pleasurable engagement with the environment. High PA is characterized by excitement, alertness, and enthusiasm. High negative affect (NA), by contrast, is a

state of subjective distress and encompasses a number of unpleasant moods, such as anger, disgust, fear, and nervousness. Both PA and NA play important roles in interpersonal relationships; however, this entry is limited to discussing PA.

Assessing PA

PA Measures

PA is commonly measured using self-report questionnaires that require participants to rate various mood descriptors. Disagreement exists, however, regarding the subcomponents of PA, and this is evident in the discrepancies in content among PA measures. Consider, for example, the widely used Positive and Negative Affect Schedule (PANAS). Its PA scale contains 10 descriptors (e.g., *enthusiastic*, *confident*, and *alert*) that assess the PA subcomponents of Joviality, Self-Assurance, and Attentiveness. In contrast, the Profile of Mood States scale only assesses the Vigor subcomponent of PA (e.g., *active*, *lively*, and *energetic*). The Center for Epidemiological Studies Depression Scale contains four items measuring enjoyment, happiness, optimism, and self-esteem. The Multiple Affect Adjective Checklist–Revised divides positive mood into two subscales—Positive Affect (e.g., *friendly*, *happy*, and *satisfied*) and Sensation Seeking (e.g., *active*, *daring*, and *enthusiastic*).

In addition to self-report questionnaires, PA is also assessed using a number of other methods, including observer ratings, counts of positive emotional words in narratives or essays, and the coding of facial expressions (i.e., sincere or so-called “Duchenne” smiles).

Despite the diverse approaches in PA assessment, both self-report and non-self-report measures of PA evidence high convergent validity, suggesting that they are tapping the same construct. Nevertheless, it remains unknown how different PA assessment tools might impact studies of interpersonal relationships.

Related Constructs

PA is closely related to other positive psychology constructs and is sometimes considered equivalent to them. The most common of these is the Extraversion personality factor, which is strongly

correlated ($r = .46$) with the PANAS PA scale. Measures of subjective well-being and self-esteem are also closely related to PA. However, these measures do not directly assess pure PA, and they often contain a low NA component in addition to a high PA component.

Stability

Trait PA has been found to be remarkably stable across time, suggesting that people typically return to their individual baseline affect levels soon after the occurrence of significant life events. However, although PA is often studied as an enduring trait, it also can be measured and manipulated as a short-term state.

PA and Relationships

Frequency of Social Interactions

What are the implications of individual differences in trait PA for social relations? Anecdotal evidence suggests that people who experience frequent positive moods are viewed more favorably by others and are more likely to engage in social interactions than those with rare positive moods. This association between level of PA and frequency of social activity has, in fact, been demonstrated in several studies. For example, in one study, researchers tracked participants' daily moods and social activities over a 6- to 7-week period and found a significant correlation between PA and socializing.

Sociability

High- and low-PA individuals appear to differ in their temperaments. As mentioned earlier, those high in trait PA are likely to have extraverted personalities—that is, they are warm, energetic, and seek to affiliate with others. Their sociable, pleasant natures may lead them to actively search for opportunities for interpersonal contact; likewise, others enjoy interacting with them. For example, one study examined the influence of affect on social interactions between unacquainted dyads. The results showed that participants who interacted with high-PA partners rated their experiences as more enjoyable than those paired with low-PA partners. Additionally, independent observers

judged the videotaped interactions involving high-PA partners to be of relatively better quality.

Social Networks

One of the most robust findings in the literature on PA is that happy people have relatively stronger interpersonal relationships. Indeed, given that high-PA individuals are generally sociable, it is not surprising that they are more likely to be involved in a romantic relationship than their low-PA peers. In a longitudinal study, women whose facial expressions showed high levels of genuine PA in their college photos were relatively more likely to be married 6 years later and less likely to have remained single 22 years later. PA is also significantly associated with the number of friends one has, as well as one's amount of social support and perceived companionship.

Satisfaction and Quality of Relationships

Studies further suggest a link between PA and satisfaction with social relationships. In the context of romantic relationships, this effect has been found among both married and dating samples. High-PA individuals rate themselves as relatively more committed to their intimate relationships, and they evaluate their relationships as being of higher quality. Those high in PA are also more likely than their low-PA counterparts to feel close to a friend, to experience few friendship conflicts, to report having high-quality friendships, and to be rated by their peers as having high-quality relationships. Furthermore, high-PA individuals are not the only ones who benefit from their abundance of positive emotion: The spouses of high-PA individuals are relatively more likely to experience increases in marital well-being across time.

Conclusion

Throughout much of the history of psychology, researchers have emphasized negative affect. This entry reflects newfound attention to PA and its role in interpersonal relationships. Studies conducted in recent decades have reliably demonstrated that PA is correlated with numerous indicators of social bonds, including social activity, sociability, size of

social network, and satisfaction and quality of relationships. However, the direction of causality remains unclear. In particular, researchers do not yet know which is the stronger influence—namely, whether PA promotes these social indicators or whether these social indicators foster PA. Currently, empirical evidence points to both paths. For example, longitudinal studies have shown that happier individuals are relatively more likely to attract friends and marriage partners, and laboratory experiments have demonstrated that those induced to feel happy are more likely to socialize, self-disclose, and show interest in social activities than those induced to feel neutral or sad. Conversely, high-quality relationships and frequent social engagement are associated with positive emotions and overall well-being, both cross-sectionally and across time. This growing evidence supports the folk belief that happy people have better relationships than unhappy people.

rates remain near 50 percent, and marital dissolution is now an accepted feature of our social landscape. Indeed, the recent advent of “divorce announcement” stationary appears to signal a new level of public acceptance of postdivorce life as a normative life transition. Popular media, for example, are increasingly likely to represent postdivorce adults and single-parent and stepfamilies as valid and functional examples of family. Such trends reflect evolving social norms and expectations of marriage and divorce across the life span, and they represent the larger context in which individuals shape their own personal expectations of postdivorce relationships. This entry focuses on the postdivorce relationship between former spouses in particular, with the understanding that divorce affects the entire family and social network of a couple.

The postdivorce relationship between former spouses builds, by definition, on prior marital dissolution. Divorce is nearly always a disruptive and disturbing experience for the former spouses and their family members. Postdivorce couples often face diminished financial resources and a reduced standard of living, particularly among women. Former spouses must often relocate to new home(s). When children are involved, the postdivorce relationship between former spouses is likely to be much more complicated, but ultimately more significant, given parental responsibilities to provide continuity and care for children experiencing a reconfiguration of their family. Researchers and mental health clinicians (therapists) who study the long-term effects of divorce on adults and children have sought to explain those factors that contribute to positive and negative outcomes of postdivorce relationships. This entry summarizes relevant constructs and highlights significant findings regarding postdivorce relationships between former spouses. Suggestions for future directions in research and interventions are considered.

Concepts Relevant to Postdivorce Relationships

Despite a greater acceptance of divorce in American culture, individuals who divorce generally experience a profound sense of loss, sadness, and even failure. Although the end of a difficult marriage can be a relief and opportunity for growth, divorce

POSTDIVORCE RELATIONSHIPS

Americans continue to favor marriage as a desired and normative adult life transition, but divorce

most often signifies a loss of an intimate other, an extended family and social network, as well as an imagined future.

For many former spouses and their family members, divorce and the postdivorce relationship can evoke a form of *ambiguous loss*. Such losses are marked by uncertainty regarding the presence or absence of a loved person, place, or state of being. Certainly, one or both members of a divorced couple can experience a lack of clarity or agreement about the nature of one's former spouse role or place in one's life. The former spouse is still there but not there. Such ambiguity also can complicate the resolution of former social and familial identities and roles for both the individual and the larger family and social network. For example, a noncustodial parent is still a mother or father, but may have more limited opportunities to fulfill his or her parenting role. Similarly, former in-law relatives may still feel like family even when they are no longer legally or socially viewed as such. Pauline Boss, who first identified ambiguous loss as a distinct concept in family stress research, reports that such boundary ambiguity can be particularly difficult to negotiate and can threaten psychological well-being of both the individual and the larger family system if left unresolved.

Similarly, postdivorce relationships must address other coexisting aspects that can be challenging to resolve. For example, a postdivorce relationship is premised on a life event (i.e., divorce) that is both deeply personal and openly public. It is a relational event, but one that has its own ongoing process dynamics, such as for former couples with children, who must negotiate their parental roles separately and together. For divorced adults who remarry, they are both divorced from one partner and married to another. In these ways, postdivorce relationships require some level of disengagement and dislocation even while it presents opportunities for rediscovery and reconnection.

Such dualities reflect the inherently layered and complex state of postdivorce relationships that can contribute to a heightened sense of *boundary ambiguity*. Boundary ambiguity is a family systems concept that reflects a lack of clear or shared understanding of who is in and out of one's family. Unresolved boundary ambiguity can significantly intensify personal and relational stress between former spouses and can add considerable confusion

for involved children. It is, therefore, important for researchers and clinicians alike to consider and assess the levels of loss and unclear relational boundaries experienced by former partners and family members in order to support their respective well-being and facilitate optimally adaptive postdivorce relationships.

Relational Antecedents as Predictors of Postdivorce Relationships

Researchers have increasingly sought to detect which particular spousal relationship factors predict postdivorce outcomes, such as continued contact, contact quality, and individual well-being. For example, the duration of a marriage prior to divorce, the presence of children, shared economic ties such as a joint business, and time since divorce all contribute to the quality and nature of postdivorce relationships between former spouses. Marriages of shorter duration generally result in less postdivorce interaction between former spouses compared with couples who were married for longer durations, whereas former spouses without children have less contact over time postdivorce compared with former spouses with children. Former couples that had close extended families and/or intertwined social networks prior to divorce often face additional emotional challenges in the early postdivorce periods.

Relationship quality prior to divorce is another critical aspect to consider when examining postdivorce relationships. Researchers have found that former spouses who struggled with serious behavioral conflicts prior to divorce are likely to have far more antagonistic postdivorce relationships compared with those couples that did not report serious or chronic conflicts. Similarly, those who divorce amicably are much more likely to have more positive postdivorce relationships than those individuals who become engaged in antagonistic or contested divorce proceedings. It must be noted that most divorce research has been based on middle-age adults and has focused on issues particularly relevant to midlife, such as coparenting. To date, later-life marital dissolution and repartnering have largely been overlooked in the divorce and step-family literatures despite increasing rates of divorce and remarriage among adults more than 65 years

of age. As our society continues to age, it will be critical for more empirical and policy research to document the content and nature of divorce and postdivorce relationships among later-life adults and their intergenerational family members.

It is also worth noting that a great deal of this research has relied on divorced individuals seeking mental health intervention or support. The use of such populations that are distressed enough to seek out a therapist, as opposed to more representative samples, necessarily limits the predictive quality and generalizability of research findings.

In the past, traditional therapy treatment of divorced adults typically encouraged a complete dissolution of any emotional connection between former spouses. It was assumed that divorce terminated any form of relationship between former spouses, and that continued contact and feelings for the former spouse signified poor adjustment to the divorce. Studies examined the role of *negative attachment*, as defined by ongoing hostility toward, or preoccupation with, a former spouse. Such research determined that preoccupation with a former spouse or the failed marriage, in particular, represented postdivorce attachment distress and bereavement and negatively impacts well-being.

Mounting evidence on the negative effects of divorce on children, however, highlighted the potential value and need for continued contact and collaboration, at least between former spouses with children. Research reporting that divorce often resulted in the loss of father-child contact and persistent parent conflict led researchers to recognize that the end of a marriage should not always or necessarily be the end of the former spouses' relationship in most cases. Recently, researchers have interpreted the presence of more positive forms of attachment between former spouses as natural and even beneficial, especially for those with ongoing parental contact and responsibilities. Family researchers and therapists, including Constance Ahrons, have asserted the existence and importance of *the good divorce* and have stressed that a more collaborative, mutually supportive postdivorce relationship is both possible and desirable for former spouses. This line of research has acknowledged and affirmed that the lives of former spouses, especially those with joint children, continue to intersect in important ways over time and throughout the life course. Given

this, divorced couples may benefit significantly from well-timed support from social networks, counselors, and institutions to successfully negotiate the challenges of postdivorce coparenting. Inclusive communication and policies in school and other family settings, for example, can go a long way to optimize divorced parents' ongoing involvement in the important developmental transitions in their children's lives across the life span.

Conclusion

No two divorces are exactly alike. Therefore, it should come as no surprise that postdivorce relationships reflect great heterogeneity as well. Increased attention to issues of diversity is needed in research and development of clinical interventions. Concerns relevant to couples that divorce in later life need to be explored and documented. Late-life illness and caregiving issues, as well as financial issues regarding inheritance and long-term care support, will present significant challenges to postdivorce former spouses and their family members. In addition, the current postdivorce relationship research literature focuses exclusively on heterosexual couples and their families. As homosexual couples increasingly seek access to legal marriage and choose to have or adopt their own children, it is critical to incorporate these families into ongoing research, therapeutic, and policy efforts.

Given significant demographic shifts in ethnic, racial, and age occurring in the United States, it will be increasingly important to expand research efforts directed at charting those factors that predict better or worse outcomes for former spouses, their children, and other family members. Such research will continue to benefit those most directly involved and inform those concerned and actively engaged with promoting family well-being across the life span.

POWER, PREDICTORS OF

Power is typically defined as the ability to shape, influence, or control the behavior of another. Although power is often described as something that people possess, power is actually a dynamic of social relationships. That is, the exercise of power is rooted in the interaction of specific individuals, with specific characteristics, in specific contexts. Being able to predict power dynamics, or an individual's ability to exercise power, means knowing something about the social location (or social status) of each actor, the relationship of the actors to each other, and the context in which the interaction takes place. This entry examines the power bases (tools or resources) that individuals bring to a particular situation and the power processes (interactional dynamics) of that situation to understand (and predict) power outcomes.

Resources as Predictors of Power

Most discussions of power are rooted in resource-exchange theory understandings of human behavior. According to these perspectives, people give and receive benefits (or exchange resources) as part of normal interaction. Resources can be anything of value—tangible or intangible—that individuals desire, and they serve as the bases for exercising power. The most obvious resources include money,

material goods, and status/prestige, but there are others as well: love, affection, sexual favors, specialized knowledge, social approval, time, attention, and other services (including everything from cooking and cleaning to giving backrubs). In any relationship, these resources are exchanged on an ongoing basis. Sometimes like is exchanged for like, as in a romantic relationship, where both partners give and receive love, affection, and attention. In other circumstances, partners exchange different or even complementary resources. For example, in conventional marriages in Western cultures, men have traded the income they earn as sole (or major) breadwinner for the homemaking and child-care services of their wives.

Relationships develop and continue because each partner has something to offer the other, meaning that, over time, stable and harmonious relationships depend on the continual exchange of resources. Further, there is an implicit pressure toward equitable exchange. It is uncomfortable for participants if one person is giving more (or taking more) than the other; each partner wants to feel that she or he is both giving and receiving something of value and that, on balance, the exchange of resources in the relationship is “fair.”

Achieving this balance depends on a number of factors: specifically, the needs and alternatives of both individuals. The value of the resources exchanged in any relationship depends on the appetite, desire, or need one has for a particular resource, as well as the opportunities one has for satisfying that desire or need elsewhere. For example, if Person A needs monetary resources, she or he will appreciate Person B for providing them. If Person A can provide something of equal value, harmony and stability are achieved. However, if Person A's need for money continues and if she or he cannot find anyone else to provide it, Person B's money becomes even more important. If the resources that Person A has to offer in return are not as attractive or can easily be found elsewhere, an imbalance creeps into the relationship.

This imbalance in resources is critical because an imbalance in power could develop from it (i.e., an imbalance in resources exchanged in a relationship is a predictor of an imbalance of power). In the prior example, if Person B knows that Person A needs money and also knows that Person A has

few options to obtain it elsewhere, Person B could ask a higher “price” for this resource (e.g., by demanding more services or even deference). The only counterbalance that Person A has to these increasing demands would be to withdraw from the relationship. But if Person A’s needs for money continue to be high and few alternatives are available, Person B will continue to enjoy a power advantage in the relationship.

This means that possession/control of resources that are highly valued in a particular context is predictive of higher power in a relationship. The previous example draws on a popular and widely valued resource: money. However, the same dynamics could hold true for other resources, such as love or attention. Individuals who possess or control these resources can potentially exert a great deal of power over the behavior of another. Parents, for example, can withhold love or attention as a means of controlling the behavior of their children. Individuals may withhold affection or sex in an attempt to control the behavior of their intimate partners. However, children can decide that pursuing their parent’s approval is fruitless or not worth the effort; lovers can leave to build healthier relationships with others, rather than give in to sexual or emotional blackmail.

Although love can be used in these destructive ways to attempt to gain control, love or affection can also act as a temper on the potential power embedded in the control over resources. Within close friendships, love relationships, or relations among family members, the calculations of fairness and equity will also be shaped by cultural norms of selflessness and altruism. Friends, lovers, and parents accept that giving more than the other, without thought of personal benefit or gain, is often part of their role and is seen as evidence of their love and commitment, rather than an indicator of power. Context, then, is key. Resources per se are not predictive of power, but they can be used to one’s power advantage under specific circumstances.

Power and Social Location

Although relative resources and access to resources can serve as predictors of power, this is not always the case. The value of the resource can also depend on the social location or social status of the giver. In

other words, power exercised on the interpersonal level is linked to patterns of domination and power on the social structural level. Inequalities along the axes of gender, race, social class, sexual orientation, and so on shape the value of the resources available to and controlled by individuals. Those in subordinated statuses (all women, men of color, the poor, gays/lesbians/bisexuals, etc.) often see the value of their resources diminished in their attempts to negotiate power in their relationships.

For example, for generations, men have been sole (or major) breadwinners in most households, and contributing this important resource has been a source of power for them. First, men have been able to secure the homemaking and childrearing services of their women partners and wives. (One might be tempted to argue that women hold equal power to force men to provide in order to continue receiving women’s services. However, the asymmetry of this argument lies in the fact that men can leave families and do well—perhaps better—economically, whereas wives who leave—or attempt to force husbands to leave—would find themselves in substantially reduced circumstances.) Second, because the family’s economic survival has depended on the man’s ability to perform (often physically demanding) labor, men have been able to lay claim to greater leisure time and a larger share of food at the family table. Finally, and perhaps most important, men have controlled family finances and reserved the right to make any and all household decisions. Of course, the specific practices vary. Some husbands have controlled all financial and household decisions directly. Others have delegated financial management of the household to their wives (after taking the funds they required for their own use and leaving wives to worry about how to cover family expenses) or allowed women to make some everyday household decisions while reserving the right to control important matters (by “putting their foot down”). Whatever the practice in any particular family, these arrangements have largely reflected *men’s* preferences. This sweeping power that men enjoy has long been justified through resource-exchange theory logic: Men get more in their relationships because they are contributing the most important resource in that context.

However, as women have moved into the workforce in large numbers and become equal financial

providers in many instances, and primary or sole providers in others, their incomes have not been as highly valued and, therefore, have not conferred the same kind of power that men have historically enjoyed. Wives are not able to ensure the equal participation of their husbands in household responsibilities (although a substantial majority explicitly state this as a goal). Wives also tend to have much less control over family finances and household decisions than men in similar circumstances have had even when they earn more than their husbands. This means that the value of resources is “gendered”: Money is used as a power base more directly and efficiently by men than by women. Put another way, the value of money contributed by men is higher and, therefore, a better predictor of power.

Power Processes

Although two people may share goals or desires and work cooperatively toward reaching them, the focus on power processes highlights circumstances where two individuals desire different ends or outcomes and examines how these individuals negotiate a final outcome or decision. It is useful to think of power processes as an array of strategies that each person can draw on in an effort to prevail. These strategies include nagging, withdrawing, bargaining, persuading, compromising, and commanding (or issuing ultimatums). At the end of these negotiations, a final outcome is reached. To the extent that the outcome is more closely aligned with the initial preference of one individual (rather than the other), that person is assumed to have exercised greater power in the process.

Throughout the negotiation process, individuals may draw on various resources in their attempts to prevail. Those with money may be able to sway the negotiations by arguing that it is *their* cash that will be spent. Those with greater knowledge of a particular topic may convince their partners that they know best in this area. Those with greater personal or social charm may simply be more skilled at getting others to go along with their desires. For immediate results, the ability to issue orders is perhaps the most effective exercise of power; however, this ability may come at a cost. The other person may come to resent not having a say in what happens in the relationship and, over time, may find the relationship unattractive.

Theoretically, each of these strategies should be available to both participants in the process. However, some individuals in particular social locations will have greater access to (or success with) certain strategies. For instance, it is easier and more effective for parents to issue ultimatums to their children than the reverse. Parents' status gives them the “right” (legitimate authority) or power to make decisions regardless of their children's preferences. Unilateral decision making in other contexts must draw on some socially recognized position or authority to be effective.

Returning to the earlier example of married couples further demonstrates how one's ability to affect the power process will be linked to social location or status. The money that husbands and wives bring to the table is valued differently. Similarly, spouses also draw on different strategies in the decision-making process; many husbands still exercise veto power, whereas wives more often report using logic and persuasion as they attempt to make their points or try to change their husbands' minds. This gendered difference in strategies in the power process reflects larger differences in gender expectations for men and women. Despite changes in behavior on the part of many men and women over the last several decades, there remain some strong, underlying cultural norms that encourage men to be forceful and aggressive and encourage women to be nice and compliant—anything but domineering. These cultural pressures limit women's options in the power processes and diminish their ability to influence final outcomes in their relationships.

Predicting power outcomes, then, requires understanding the nuances of a given situation. It requires knowing something about the resources and strategies on which each participant can draw because these represent potential tools for exercising power. However, these tools are not neutral because what works for one individual in a specific setting may not work for another. Predicting power dynamics and outcomes requires understanding how larger cultural demands impinge on individuals' behavior and shape their options in the interactional context, as well as how these options enhance or limit their power.

POWER DISTRIBUTION IN RELATIONSHIPS

The *power distribution in a relationship* refers to who has greater ability to influence or exert control over others in the relationship despite resistance. Power is fundamental to all human relationships no matter how close or distant. Further, all relationships—heterosexual, homosexual, romantic, family, coworkers, and friends—can be characterized as power relationships regardless of whether power is an obvious component of the relationships. The distribution of power also affects a wide range of other relationship matters, including feelings of trust, satisfaction, violence, leisure, and longevity.

Power is not an individual trait such as physical appearance. There are no inherently powerful (or powerless) people; certain people are powerful because they possess more resources or other qualities than others. In this sense, power distributions are relative in nature. Another way in which power can be thought of as relative is that a person's power must be understood in the context of a particular relationship. Thus, an individual may have a high-status job or prestige in the community, but this does not necessarily translate into higher power within his or her marriage or other intimate relationships. Whether one's social power contributes to greater power within intimate relationships is

dependent, in large part, on how much power one's partner has. A woman manager, for instance, may be capable of exerting considerable power within the workplace, but may not be able to do so within her romantic relationship, especially if the partner is of equal or higher status. Cultural traditions and norms, especially gender expectations, also dictate the distribution of power within relationships.

Power may be manifested in various ways, such as having greater say in making important decisions, veto power (having the ability to veto the less powerful member's decision), dominating conversations, and so on. Power can also be overt (exercised outwardly) or latent (hidden); verbal, psychological, or physical; or spoken or unspoken. Indeed, it is not necessary for power to be exercised at all in order to have it. Take the case of a child who "walks on eggshells" around his father, trying hard not to upset his father. The child's fear may be rooted in previous violence, but it might also stem from knowing that the father simply has the ability to punish. Researchers also make a distinction between *orchestrative* power (making decisions about what gets done) and *implementation* power (deciding how it will get done).

Generally speaking, power can be distributed unequally or equally. When power is unequally distributed in a relationship, one person or group has greater influence over the course and definition of the relationship. In cross-sexed relationships, an unequal distribution of power can be characterized as either male-dominant (men hold most of the power) or female-dominant (women have more power). When power is equally distributed, no one person or persons dominates the relationship and interactions. This doesn't mean that they share power across all areas or domains of the relationship; rather, on balance, everyone is recognized as being equally powerful. When individuals exercise power in different domains, but essentially have equal power, the relationship is said to be *autonomic*. When individuals share power across domains, they are said to be *syncratic*.

Determining whether a relationship is equal or unequal is not an easy task for a number of reasons. For one thing, what goes on in the privacy of individuals' lives is usually hidden from outside observers. Even the individuals involved in the

relationship may not agree on whether and who among them has more power. Research has shown that individuals tend to underestimate their own power in relationships.

Another reason it is difficult to determine whether a relationship is equal or unequal is that there are so many areas in which power can and is exercised—or potentially can be exercised—that it is difficult to gain a clear sense of its balance in a relationship. Suppose it was within your power to make the important decisions for your family, such as whether to have another child, whether to move the family to another town for your job, whether to initiate a divorce, and so on. The fact is, these decisions affect everyone profoundly, but are made infrequently; thus, it might be easy to lose sight of how much power you really have in the family. Suppose you do not have control over the big decisions, but can affect many small decisions, such as what the family will eat for dinner, whether the children will go to after-school care this week, or whether to invite friends over for dinner this weekend. It may appear and feel like you have most of the power in the family because these decisions are so much more immediate, but the reality is more complicated than that.

This scenario leads to another important factor with respect to determining the distribution of power in relationships. Suppose a couple has a traditional, autonomic relationship: Her primary roles involve taking care of the house and children and she has nearly complete control over issues such as decorating the house, what to feed the family, whether to home school the children, and so on, whereas his responsibilities center on supporting the family financially. On the surface, it would appear that the couple's arrangement is egalitarian (autonomic). But what if her husband is thrilled that she is taking on domestic and child-care responsibilities because he has no interest in such matters and even considers them to be "below" him? In such cases, it could be argued that power is not equally distributed and that in an autonomic relationship the respective domains must be valued equally by all in order for it to be egalitarian.

Research has shown that couples commonly engage in "myth making" in order to convince themselves (and others) that their relationships are consistent with what they value.

Who Has the Power in Relationships?

Research has shown that power is usually not distributed equally in relationships. The earliest studies on marital power revealed that husbands had slightly more power than their wives. For instance, with respect to decision making, most couples were "autonomic," although husbands had more say than their wives; in conflicts, husbands were more likely to get their way; and when it came to making major changes for one's partner (such as relocating for one's spouse), wives tended to make such sacrifices more than their husbands. Studies of dating relationships revealed similar patterns.

As families and relationships change over time, expectations concerning power within these relationships also change. Prior to the mid-20th century, most marriages in the United States were considered patriarchal or autonomic. It was generally assumed that men made the important decisions and had final say. The Women's Movement challenged men's presumed privilege, and women entered the labor force in record numbers, giving them more equal standing in their relationships. However, even in contemporary intimate heterosexual relationships, men are likely to have slightly more power than women. Such power is likely to stem from two major sources: persistent gender inequality within society that grants greater privilege and status to men and values masculine traits and skills over feminine ones, and the fact that power is based in part on resources (e.g., expertise, money, education) and men tend to be older, more educated, and earn more money than their partners.

What happens when gender is taken out of the equation? Research has shown that in same-sex relationships, power continues to shape the relationships. Lesbian couples tend to be more egalitarian than either gay or heterosexual couples, whereas gay couples tend to be less egalitarian than heterosexual couples. Similar to heterosexual couples, power in same-sex relationships largely depend on who brings what to the relationship in terms of status and resources, and what the couple values.

In recent decades, parents' power over children has also been challenged. Whereas parents were once assumed to have nearly complete control over their children's lives, cultural influences in children's lives such as media and consumerism have

instilled a greater sense of power among children and has led, to some extent, to a redistribution of power between parents and children. Research shows, for instance, that most parents today consult their children before buying clothes for them or give them the money to purchase their own clothes, whereas parents in past generations were more likely to buy children's clothing with little or no input from the children. As children's dependence on parents declines, parents' power also declines.

The Egalitarian Myth

In some relationships, power is a clear and fundamental aspect of the relationship, and it is clear to everyone who should have the power. In employer–employee or parent–child relationships, for instance, everyone expects the employer and parent to be more powerful (although the reality is not always so clear). Other types of relationships, such as friendships, however, are expected to be more egalitarian. In the United States, power in romantic partnerships is also largely expected to be relatively balanced. To acknowledge to others or even oneself that the relationship is unequal is to go against strong cultural norms about how relationships should work.

When cultural expectations dictate that relationships should be egalitarian, individuals may work hard to hide signs of inequality from critical outsiders and even to convince themselves that the relationship is balanced. Sociologist Arlie Russell Hochschild studied how couples manage the housework within busy families and negotiate rules for doing so. She found that most couples want to share equally in the housework, but that usually didn't happen. To obscure that unpleasant reality, they might develop myths to convince themselves that everything was fair. For instance, one couple that had fought continuously over who did the housework finally "resolved" the issue by symbolically dividing the house into the "upstairs" and the "downstairs." The upstairs, which the wife handled, was most of the house; the downstairs, which was basically the garage, was the husband's domain. On the surface, things appeared fair, and the tensions that had evolved around doing housework had been quelled. The problem was that there were

many more tasks associated with the upstairs than with the downstairs.

The Changing Nature of Power

Power is a fluid concept—a person's having power at one point in time does not necessarily mean that he or she will be powerful throughout the relationship. Consider what can happen over the course of a marriage—the couple may break up and reunite, marry, divorce, bear children, change or resign from jobs, and so on. Friendships often experience periods of intense intimacy and times of greater estrangement. Children begin their lives completely dependent on parents and others, usually gain independence in young adulthood, and finally may be responsible for the well-being of their aging parents. All of these factors influence the distribution of power.

PREDICTING SUCCESS OR FAILURE OF MARITAL RELATIONSHIPS

Intimate relationships usually begin as a great source of satisfaction; however, many relationships show declines in satisfaction over time and ultimately end. This phenomenon has generated a vast research literature attempting to delineate the critical differences between relationships that succeed and those that fail. This entry first addresses the definition and measurement of relationship outcomes, followed by a discussion regarding the importance of, and methodological issues related to, this domain of research. It concludes with a review of variables shown to predict relationship outcomes.

Defining and Measuring Relationship Success and Failure

One measure of relationship success is whether the relationship persists over time or ends. *Relationship dissolution* refers to a relationship ending in separation or divorce; it is measured by assessing relationship status (intact or terminated). Assessing dissolution alone does not enable researchers to examine the process by which some relationships change from initially satisfying relationships to unions that dissolve. Thus, relationship success or failure is also defined in terms of how satisfied or dissatisfied each partner is with the relationship. *Relationship satisfaction* encompasses an individual's evaluations of and feelings about his or her relationship or partner. It is measured using *self-report questionnaires* in which individuals rate their level of satisfaction. Dissatisfying relationships are certainly at greater risk for dissolution; however, the association between relationship satisfaction and dissolution is not as strong as one might intuit. Dissatisfying relationships endure for many reasons, and satisfying relationships may dissolve in certain circumstances. Although couples vary widely, on average, the longer relationships persist, the more stable and less satisfying they become, reducing the correlation of satisfaction and stability as relationships develop. This suggests that relationship dissolution and satisfaction are distinct outcomes that should be investigated

separately to fully understand the variables that predict relationship outcomes.

Importance of Predicting Relationship Outcomes

Gaining a better understanding of the factors that predict relationship outcomes is critical because relationship distress and divorce have negative consequences for children and adults. Divorced individuals experience higher rates of stress, depression, and other health problems than their married counterparts. Furthermore, children raised in families experiencing high levels of conflict suffer more conduct, psychological, social, and academic problems. As adults, offspring of divorced parents have more mental and physical health problems, as well as greater relationship distress and instability. The best interventions designed to prevent and treat relationship distress are those based on research identifying the factors that lead to relationship dysfunction.

Methodological Issues in the Prediction of Relationship Outcomes

The best way to predict relationship outcomes relies on *longitudinal research designs*, in which a sample of engaged or newlywed couples is tracked and assessed prospectively over time to measure changes in relationship satisfaction and status. Longitudinal designs are generally favored over *retrospective designs*, in which participants rely on their memory to report on past events, and *cross-sectional designs*, in which data are collected at only one point in time. The prospective nature of longitudinal designs largely solves memory problems associated with retrospective designs and enables a better understanding of developmental change, which is at the heart of predicting relationship outcomes. In other words, longitudinal designs provide an answer to the question, "Why do some relationships that start out so well fail?"

Variables That Predict Relationship Success or Failure

Hundreds of variables have been studied to answer this question. The following sections summarize a

vast body of research regarding the prediction of relationship outcomes. For the sake of brevity, only those variables found to predict relationship outcomes consistently across several studies are described. It should be noted that researchers do not make specific predictions for individual couples regarding relationship outcomes and then follow up to see whether predictions were accurate. Rather, these studies use statistical methods to examine the extent to which certain variables of interest are associated with later outcomes across a sample of many couples. Although some research has identified sets of variables that account for close to 90 percent of relationship outcomes (e.g., occurrence of divorce) in particular samples of couples, these same sets of variables have not been subsequently shown to predict outcomes for different samples of couples with the same accuracy rate. This occurs because the specific statistical equations used to predict outcomes in a particular sample of couples may not generalize well to samples of different couples. Taken together, marital research highlights variables that generally increase or decrease the likelihood of divorce or distress, but assertions that one can reliably predict relationship outcomes for particular couples are as yet not supported by available research.

This entry uses Karney and Bradbury's Vulnerability-Stress-Adaptation (VSA) Model to organize description of the factors that predict marital outcomes. This model posits that three broad, interrelated constructs account for relationship outcomes. *Enduring vulnerabilities* refer to stable demographic and individual difference variables. *Stressful events* refer to the stressors and transitions that a couple experiences. Finally, *adaptive processes* refer to the ways in which a couple manages the conflicts that inevitably arise as a result of enduring vulnerabilities and stressful events. The following sections describe each predictor in turn.

Enduring Vulnerabilities

Each partner brings to the relationship a set of experiences and relatively stable personal characteristics that influence how partners respond to and behave toward each other. Family-of-origin experiences constitute one class of enduring vulnerabilities. Coined the *intergenerational transmission of*

divorce, parental divorce increases the likelihood that offspring will experience relationship distress and divorce as adults. Adults whose parents divorced report higher levels of aggression and negative affect (e.g., anger, contempt) in their own marriages. This suggests that negative behaviors (or the lack of adaptive behaviors such as problem-solving skills) observed in one's family during childhood may influence adult behaviors with romantic partners.

Early childhood experiences also influence one's *attachment style* or working model of close relationships. Individuals with a secure attachment style feel worthy of love and expect loved ones to be responsive to their needs. In contrast, anxiously attached individuals feel unworthy of love and experience anxiety about potential rejection and abandonment. More securely attached individuals maintain more stable relationships and report higher levels of relationship satisfaction than their insecurely attached counterparts perhaps because they utilize more adaptive communication and conflict-resolution skills (e.g., attentiveness, compromise).

Neuroticism, or *negative affectivity*, is a stable personality trait marked by the tendency to experience and express *negative affect* (e.g., anxiety or irritability). Although various dimensions of personality affect relationship functioning, neuroticism is one of the strongest and most consistent predictors of relationship dissatisfaction. Negative affectivity is associated with higher rates of destructive communication behaviors during relationship conflicts. Conversely, individuals with higher levels of *positive affectivity*, or the tendency to experience positive emotions, report more satisfying and committed relationships.

The influence of psychopathology has also been investigated, with depression being the most extensively researched psychological disorder. Stress-generation theory suggests that depressive symptoms create relationship stress. Studies indicate that depressed spouses are more apt to seek negative feedback and excessive reassurance from their partners. Depressed individuals with low self-esteem may seek negative feedback in an effort to verify that their own negative self-views are consistent with how others view them. These behaviors create interpersonal stress that, along with increased negativity during conflict, maintains depressive symptoms in a cyclical manner.

Evidence also reveals a longitudinal association between substance abuse and relationship distress. Alcohol abuse predicts increases in relationship distress and the likelihood of divorce or separation. In fact, individuals with alcohol problems are more likely to divorce than individuals with any other psychological disorder. Rates of divorce among problem drinkers range up to seven times rates among the general population. An associated danger of alcohol abuse is its tendency to increase the likelihood of aggression, which predicts relationship dissatisfaction and dissolution and is discussed later in this entry (see “Adaptive Processes”).

Premarital cohabitation, or the decision to live together before marriage, is also associated with relationship dissatisfaction and dissolution. Recent research suggests that couples who cohabit before engagement to marry are at the greatest risk for poor relationship outcomes, with slightly lower levels of risk for couples that cohabit after formal engagement. Recent and ongoing studies are attempting to identify the mechanisms behind this association, but initial results suggest there is no simple explanation.

Finally, various demographic variables represent enduring vulnerabilities to relationship dissatisfaction and dissolution. Greater *age* at the time of marriage predicts increased relationship satisfaction and stability. Relationships in which husbands report higher *income* and *employment* levels are less likely to dissolve. Relationship dissolution is more likely when women report greater income and employment levels than their partners for reasons that remain unclear. Divorce rates decline somewhat with increased *educational attainment*; however, people who graduate from high school or college have lower divorce rates than people who complete only some college. Greater *religiosity* is associated with lower tolerance for divorce and greater commitment. Evidence is mixed, however, as to whether more religious couples are actually less likely to divorce. Previous marital status predicts relationship dissolution because *remarriages* are slightly more likely to end in divorce than first marriages. This is notable because approximately half of all first marriages in the United States end in divorce, and close to 85 percent of divorced individuals remarry.

Stressful Events

Stressful events (e.g., unemployment, illness) may generate new sources of conflict between partners or exacerbate existing conflict, rendering couples more vulnerable to relationship dissatisfaction and dissolution. Furthermore, enduring vulnerabilities, such as neuroticism, may create stressful life circumstances or cause partners to experience events as more stressful. In general, stressful events predict relationship dissatisfaction and dissolution.

One exception to this general finding is stress associated with the transition to parenthood. Becoming a parent is associated with declines in relationship satisfaction; however, having a child makes couples less likely to dissolve their relationships. This may reflect the tendency for couples to stay married for the sake of their children, or it may occur because parenthood is considered a normal, positive event, whereas other stressors are not. Couples that engage in adaptive problem-solving and supportive behaviors during stressful events are less vulnerable to dissatisfaction or dissolution.

Adaptive Processes

Adaptive processes refer to the ways in which a couple manages the conflicts that inevitably arise as a result of enduring vulnerabilities and stressful events or from issues associated with the increased interdependence that follows marriage, such as sharing finances or raising children. When conflict between partners is not well managed, the accumulation of negative interactions erodes relationship satisfaction. Accordingly, the behaviors enacted by partners during relationship conflicts have been extensively investigated as predictors of relationship outcomes.

Studies have generally demonstrated that negative behaviors predict relationship dissatisfaction and dissolution. Negative behaviors include *negative affective behaviors* and *negative communication skills*. Negative affective behaviors refer to nonverbal displays of negative emotional states, such as anger or hostility. Negative communication skills are defined as verbal expressions that impede adaptive communication, such as generalized criticism or defensiveness. Couples that become less satisfied over time also exhibit two

particular patterns of negative behavior. A pattern called *negative reciprocity* occurs when one partner responds to the other's negative behavior with more negative behavior, thus perpetuating and escalating the cycle of negativity. *Demand-withdrawal patterns* develop when one partner becomes demanding and critical and the other partner withdraws from the negative interaction. Engaging in physically aggressive behavior is a particularly maladaptive way of handling relationship conflict. However, it is not uncommon: It occurs in approximately half of all newlywed couples. Although less severe acts of aggression (e.g., pushing) are initiated by men and women with comparable frequency, the effects of these behaviors on relationships differ as a function of the perpetrator's gender. Specifically, husbands' physical aggression early in marriage predicts declines in satisfaction, whereas wives' physical aggression early in marriage predicts relationship dissolution.

Alternatively, positive behaviors during conflict have also been investigated. Positive behaviors are categorized as *positive affective behaviors* and *positive communication skills*. Positive affective behaviors refer to nonverbal indicators of positive emotional states, such as affection or humor. Positive communication skills refer to verbal expressions that facilitate communication, such as the use of paraphrasing or compromise. In general, lower levels of both types of positive behaviors predict relationship dissatisfaction and dissolution, whereas higher levels enhance relationship satisfaction. More important, positive affect weakens the harmful effects of negativity on satisfaction, suggesting that the impact of negativity may depend on the larger interpersonal context in which it occurs. For example, negativity in a generally affectionate relationship may be experienced less negatively or viewed more benignly.

Partner behaviors outside the context of conflict also predict relationship outcomes. For example, declines in love and affection over time are associated with relationship disillusionment and subsequently relationship dissolution. Similarly, partner behaviors observed during discussions of problems outside the relationship (i.e., individual problems) also influence relationship outcomes. Engaging in more negative behaviors (e.g., negative affect, critical remarks, disinterest) and less positive

behaviors (e.g., reassurance) during the provision of support predicts relationship dissatisfaction. This association holds even when accounting for the detrimental effects of negativity during conflict.

Partners in satisfying relationships also engage in *relationship-maintenance behaviors* that promote relationship persistence. *Accommodative behaviors* indicate a partner's willingness to respond to negative behavior in a relatively constructive manner and are more likely to occur when partners report a strong sense of commitment to the relationship. *Commitment* is comprised of an intention to persist in the relationship, coupled with a sense of attachment to and dependence on one's partner. Satisfied, committed partners also demonstrate a *willingness to sacrifice* their own self-interests to enhance the well-being of their partner and the relationship. They are also more likely to exhibit *forgiveness* in response to perceived partner transgressions.

Partners' *cognitions*, or thoughts about and interpretations of each other's behavior and the relationship, consistently predict relationship outcomes. Maladaptive *attributions* are explanations for perceived transgressions that identify one's partner to be the cause of the transgression and assign blame. Maladaptive attributions predict declines in relationship satisfaction, as do unrealistic *relationship beliefs*, such as the belief that any disagreement with one's partner is destructive.

Conversely, certain cognitions promote relationship satisfaction and persistence. Adaptive attributions positing mitigating situational factors as the cause for negative relationship events predict positive outcomes. Satisfied individuals also attribute positive relationship events to their partners and develop idealized beliefs about their partners and relationships that maintain relationship satisfaction. Idealized beliefs are formed not only by reconceptualizing negative partner qualities as positive ones, but also by believing one's own relationship to be superior to other relationships and by actively minimizing the positive qualities of potential alternative partners.

Whether adaptive or maladaptive, the aforementioned behavioral and cognitive processes are influenced by enduring vulnerabilities and stressful events. Stress affects several aspects of adaptation, such as the likelihood of engaging in, and making

maladaptive attributions for negative behaviors, as well as the capacity to provide partner support. Enduring vulnerabilities also impact the degree to which couples experience and successfully adapt to stressful circumstances. Thus, stressful events and enduring vulnerabilities affect relationship outcomes via their influence on adaptive processes. Adaptive processes influence relationship outcomes, such that adaptive behaviors and cognitions enhance relationship satisfaction and persistence, whereas maladaptive behaviors and cognitions render relationships less satisfying and more vulnerable to dissolution.

Summary

Specific enduring vulnerabilities, stressful events, and adaptive processes predict relationship satisfaction and dissolution to varying degrees. Understanding the strength, nature, and moderators of these predictors enables the development of interventions to prevent or treat relationship discord. Enduring vulnerabilities and stressful events are difficult to modify, so most of the empirically supported interventions developed to date have focused on adaptive processes. Increased understanding of the factors that predict relationship outcomes will allow these interventions to be more effective. Given the numerous negative consequences associated with relationship dissatisfaction and dissolution, understanding their predictors has the potential to have a tremendous impact on the psychological and physical well-being of adults and children.

PREGNANCY AND RELATIONSHIPS

Pregnancy is an event experienced by most women. Normal pregnancy lasts 40 weeks. During this period, women experience changes in their appearance and size, physical condition, family and work roles, and interpersonal relationships. As explained in this entry, pregnancy affects many human relationships, including those with spouses or partners,

other family members, and female friends, and it even affects interactions with strangers. This entry also discusses how relationships affect pregnant women and can influence aspects of the birth and the health of the child.

Impact of Pregnancy on Human Relationships

Women often express concerns about the changes that may occur in their relationships during pregnancy. Women pregnant for the first time tend to be particularly concerned that their relationship with their husband or other committed partner may decline as a result of the changes that they are undergoing. However, studies find that husbands typically feel closer to their wives during pregnancy and that both partners experience an increase in marital satisfaction *prenatally* (during pregnancy). This changes after birth, however, especially after the birth of a first child, when marital satisfaction usually declines. Relationship satisfaction may also be associated with sexual interest and activity: Many women report that they experience enhanced sexual pleasure during pregnancy compared with other times in their life. Although there is much individual variability in sexuality, studies find that women on average experience decreased sexual interest and activity in the first trimester of pregnancy, increases in the second trimester, and a decrease in the third trimester and after birth.

Pregnant women who are already mothers typically express concern about the impact of being pregnant on their other children. There is little research examining this type of impact, nor on how pregnancy affects a woman's relationship with her other family members. Some nonscientific sources have suggested that being pregnant leads a woman to desire a closer relationship with her mother and to resolve any existing relationship difficulties with her.

Pregnant women often seek out other women for information and inspiration to help them adjust to the changes they are experiencing, particularly women who have just had babies. Pregnancy also affects pregnant women's interactions with strangers. Some studies find that strangers, especially men, react to a pregnant woman by staring or avoidance. However, other research

indicates that a pregnant woman is more likely than a nonpregnant woman to receive assistance in daily life, such as having a door held open for her. Pregnant women also report that strangers frequently offer unsolicited advice, touch their pregnant bellies, and make comments about their physical size. Such experiences, which pregnant women widely report as aversive, may help explain why they tend to stand at greater distances from other people than do nonpregnant women, a phenomenon that is often attributed to pregnant women's distorted body image, but that also may reflect an attempt to avoid some interactions.

Impact of Human Relationships on Pregnancy

Supportive human relationships provide a variety of benefits to pregnant women. The term *social support* is used to describe these beneficial provisions of relationships. As it is typically defined, social support includes emotional concern, affirmation, material or tangible assistance, and the provision of information.

Over the last few decades, there has been increasing evidence that these types of social support are associated with better physical health and psychological well-being in pregnant women and a reduced likelihood of adverse birth outcomes such as low birth weight or preterm delivery. Babies born preterm (before 37 weeks of pregnancy) usually have not completed normal development and growth. Preterm delivery and low birth weight (less than 2,500 grams, which is approximately 5.5 pounds) contribute to serious cognitive, medical, and other problems in infancy, childhood, and adulthood.

Supportive relationships are believed to benefit pregnant women in part because supporters can provide information that leads women to take better care of themselves or to get needed medical assistance, and supporters can help with tasks that might otherwise be difficult for pregnant women. Women who receive more social support during pregnancy are more productive at work and report that they function better in their roles at home. Supporters can also provide comfort or affection that helps reduce the stressfulness of pregnancy, resulting in what is known as a stress-buffering effect. This is important because stress in pregnancy

has been shown to elevate women's risk of delivering a preterm or low-birth-weight baby.

Various dimensions of social support have been examined in pregnancy, including quality of support, satisfaction with support, perceived availability of support, and actual receipt of support. Some studies find that particular dimensions of social support are associated with different outcomes in pregnancy. For example, one study found that women who were more *satisfied* with the support they were receiving from the baby's father and from their health care providers delivered babies with better Apgar scores (a measure of the newborn's physical condition); those who reported *receiving* more social support during pregnancy were less likely to experience problems during childbirth, and their newborns also had higher Apgar scores. Finally, women who had at least one relative or close friend living nearby and who lived with the baby's father during pregnancy were least likely to deliver a low-birth-weight baby.

There is also evidence that the benefits of social support to pregnant women are influenced by who provides the support. Support from the baby's father appears to be of particular value to most pregnant women; support from other family and from friends is especially beneficial to pregnant women who do not have a committed or stable relationship with the baby's father.

Most studies of social support during pregnancy have been *correlational*. That is, they examine existing interpersonal relationships and social support and measure their associations with variables such as a woman's emotional status, her health, and the outcome of her pregnancy. However, some *experiments* have been conducted in which women with little existing social support receive assistance or companionship during pregnancy from people provided by the researchers. Most of these experiments find that the women who are randomly assigned to receive this support experience better psychological and emotional states, fewer physical complications during pregnancy and childbirth, and healthier birth outcomes than those who do not receive the support.

PREJUDICE

Prejudice is a negative evaluation of a social group or an individual that is based on the individual's group membership. Prejudice is the negative affective component in attitudes, and it can set the stage for discrimination—differential treatment toward members of groups that are the targets of prejudice. Prejudice can be overt and conscious and is widely recognized in this form. But it can also be subtle, and people can be mostly unaware that they harbor negativity toward some groups.

Prejudice can affect close relationships at every stage of their development, whether it is prejudice by race, gender, status, weight, religion, ethnicity, accent, political attitude, hobby, or even zip code. Most of the research in this area has focused on race, religion, and gender, and these are the prejudices that are most likely to be important in relationships. Prejudice affects attraction between potential partners, relationship formation and maintenance, and the type and length of relationships. It can lead to stress, conflict, and even relationship dissolution. Close relationships, in contrast, can reduce or even eliminate prejudice.

This entry defines *prejudice* and traces its effects on close relationships. It begins with relationship formation, follows the course of relationships, and ends with the role that relationships can play in the reduction of prejudice.

Initial Contact

Prejudice can prevent people from forming friendships and romantic relationships. When these prejudices are overt, their effects on relationships are straightforward: People neither initiate nor prolong relationships with people they hate. But prejudice often affects people's behavior without their awareness, and unconscious prejudice can even prevent relationships from developing. Because these effects are subtle and outside of awareness, they might be harder to detect, are often expressed in a way that people don't perceive as prejudice, and might be more resistant to change.

Relationships begin with an initial contact, often face to face. Proximity and similarity are two major factors in attraction and relationship formation. As a result, within-group contacts are more likely to occur than between-group contacts. The foundation of within-group relationships is based on segregation. Similar people meet each other because they find themselves in the same places: neighborhoods, schools, universities, sporting events, e-mail listservs, Internet chat rooms, or social networks like *Facebook*. This lowers the initial chances of people from different groups interacting and forming a relationship. There are other reasons that people tend to have less interaction and form fewer relationships with minority and stigmatized groups members, including: (a) the smaller number of minority members leads to a lower likelihood of initial contact, (b) the geographical distribution of minority members and physical segregation, (c) language and cultural differences can make interaction between members of different groups cumbersome, (d) exposure to peers' prejudice, and (e) anxiety based on unfamiliarity with outgroup members.

Anxiety is an especially influential obstacle to the initiation of new relationships. Because members of one group are often anxious about interactions with members of other groups (e.g., they lack knowledge of how to act in such an encounter,

they may have different cultural expectations, or they may anticipate hostility from the outgroup), such relationships are less likely to be initiated. Anxiety makes people less willing to form close relationships across racial, religious, linguistic, or other cultural boundaries. Anxiety may also lead to awkwardness and avoidance—even in the absence of prejudice—which in turn may lead to the perception that someone is motivated by prejudice. With a realistic concern about encountering prejudice, one might interpret awkwardness and discomfort as signs of prejudice, leading him or her to withdraw.

Prejudice not only serves as a motive for maintaining separateness and frowning on across-group relationships, it may also contribute to the motivation to maintain ingroup-only relationships. Across-group relationships may be seen as threatening; small ethnic groups might slowly disappear through across-group marriages, and many times such groups try to discourage their members from relationships (especially long-term and serious ones) outside the group. For example, in Hebrew, the word *Hitbolelut* means assimilation, but carries the negative connotation of a Jew marrying a non-Jew.

People may still have reasons to initiate a relationship with an outgroup member, including curiosity, preference, previous experiences, values, rebellion against one's group, and simply liking people for who they are. People who choose to overcome or ignore the difficulties often make an extra effort to overcome the effects of segregation or prejudice.

Relationship Maintenance

People who overcome obstacles to initiate a close relationship may still face difficulties maintaining it. One reason is that couples from different racial groups are less likely to share views and values about family and childrearing. For instance, research has shown that sex-role ideology and housework-sharing attitudes differ between same-race White couples and same-race African-American couples; this can make coordination of day-to-day activities harder. Second, although some conflict is normal and healthy in relationships, across-group relationships have been shown to have more sources of conflict than within-group

relationships. One reason for this is the extra stress to which people in these relationships are exposed. Across-group relationships (especially intra-ethnic couples) are subject to more discrimination and criticism in public from strangers and in private from close friends and family members (e.g., in the United States, marriages between African Americans and Whites are still less likely to be accepted than same-race marriages). Criticism is likely to add stress, which in turn incubates more conflicts.

One critical asset that people in relationships have is social support. Support from peers and family provide emotional and practical resources that help partners repair relationships. Not having this support—or, worse, experiencing anger or disdain instead—may increase tension in one's life and can undermine relationships. This may be one reason that adolescents involved in interracial romance tend not to reveal their relationships to their families and friends and why they are less likely to meet their partners' parents. Studies show that when interracial or across-group relationships do go public, peers and family members tend to exhibit explicit prejudice toward the relationship partner, and they tend to be less willing to give practical or emotional support to the couple. The failure to obtain encouragement and support can, in turn, worsen relationship quality, speeding dissolution.

Various factors affect the amount of prejudice that couples experience. Some communities are more tolerant than others, which substantially affects the rate of interracial marriage. National norms in the United States and Europe are changing; interracial marriages are increasingly more common today than they were 50 years ago (0.4 percent of U.S. marital partners had a mixed racial makeup in 1960, compared with 5.4 percent in 1999), and younger generations report fewer such challenges than their older, intermarried peers. As communities diversify through migration and intermarriage, familiarity is likely to reduce prejudice against interracial couples.

However, most U.S. marriages at the beginning of the 21st century are still between members of the same racial ethnic and religious groups. To some extent, this "assortment by group" is caused by factors other than prejudice. Demographic and social factors such as differential geographic distribution

of racial and ethnic groups, or attraction to people with similar attitudes, beliefs, or religious observances, issues of language, socioeconomic status, and other customs, all contribute to staying within one's group. But the underlying mechanisms of these variables at a structural level (e.g., segregation, group inequality) are closely intertwined with prejudice and discrimination at the psychological level. Segregation may lead to few intergroup friendships and marriages *because* of prejudice, rather than as an independent contributor.

Relationship Dissolution

Differences between partners (e.g., language barrier, cultural gaps, social norms) can make across-group relationships more prone to failure. Adolescents involved in interracial romantic or friendship relationships are more likely to terminate their relationships than those in same-race relationships even after adjusting for individual, relationship, and social network factors. Although the literature about the length of interracial marriages is not entirely settled, evidence seems to suggest that interracial marriages are more likely to dissolve than intraracial marriages (especially in the first 10 years of marriage) due to factors that are either directly or indirectly related to prejudice and discrimination.

Despite their difficulties, interracial couples show equal if not greater levels of commitment than intraracial couples. Research suggests that people in interracial or interethnic relationships tend to bolster the strength of their relationships not by perceiving themselves as satisfied, but rather by reducing their sense that they have alternatives to the current relationship. Still, findings suggest that, whereas among the general population 50 percent of marriages are likely to end up with a divorce, 66 percent of interracial marriages in the United States end in divorce.

Relationships and Prejudice Reduction

Although there are barriers to across-group and interracial relationships, acceptance of interracial relationships has been increasing for decades. In the 1967 decision *Loving v. Virginia*, the U.S. Supreme Court struck down all laws that prohibited

interracial marriage, and since then interracial marriages have increased. Acceptance of these couples has increased along with this and is highest in younger generations. More and more across-group relationships are likely to succeed, and partners in interracial relationships are likely to approach the same level of relationship satisfaction as those in intraracial relationships. Whether it is overcoming adversity that improves the relationship or whether only the strongest interracial relationships survive, success in these relationships is possible. Such success, in turn, is likely to lead to a decrease in prejudice not only toward one's partner, but toward the partner's group as well.

One of the most common and reliable ways of reducing prejudice is through intergroup contact. Romantic relationships and friendships both provide motivation to keep in contact, which in turn reduces prejudice. Reviews of the research on "the contact hypothesis" (nonconflictual contact between groups reduces prejudice) have concluded that indeed contact is a powerful influence for reducing prejudice. The more intimate the contact (i.e., more open communication, self-disclosure, and sharing of activities), the stronger the effect. In other words, the closer the relationship between members of different groups, the more likely contact is to reduce prejudice.

Even indirect contact can reduce prejudice. The more close relationships that a person's friends and family have with outgroup members and the closer these relationships are, the less prejudice a person is likely to report. This "extended contact hypothesis" can reduce the acceptability of prejudice, reduce the anxiety people might feel about making friends, increase the information available about different groups, and provide a social network that facilitates new contacts. This reduction in prejudice can be as large as the reductions that come from having a relationship with an outgroup member. The extended contact principle also works when people read books or are exposed to media about across-group relationships.

Evidence for the positive effects of close relationships also comes from experiments on attachment security. People who perceive themselves as worthy of being loved and perceive other people as trustworthy and supportive—people who have a secure attachment style—show less prejudice toward members of outgroups. When people's

sense of attachment security is temporarily increased in laboratory experiments, their prejudice is reduced in the short term, even in the face of perceived threats from outgroup members.

Conclusions

Prejudice affects relationships at every stage. Whether open and acknowledged or largely unconscious, it inhibits opportunities and the desire to meet, it interferes with the smooth operation of such a meeting, and it tends to slow the growth of intimacy. Once relationships are formed, prejudice may increase conflict within the relationship, reduce obtained and perceived social support, and increase the probability of relationship dissolution. However, overcoming these obstacles and remaining in an across-group relationship, especially close friendship and romance, turn out to be the most effective ways of reducing prejudice.

PREVENTION AND ENRICHMENT PROGRAMS FOR COUPLES

Although individualized face-to-face therapy is designed to remediate couple problems or distress, a growing array of structured programs target couples that are experiencing little or no distress with the goal of improving or maintaining the couple's relational harmony. These programs have been variously labeled "marriage enrichment," "marriage education," "premarital preparation," "relationship enhancement," "psychoeducation for couples," or simply "relationship education." Although relationship education may be delivered through books, pamphlets, media campaigns, Web sites, and fact sheets, most programs involve structured, face-to-face workshops or classes in community settings such as churches, schools, universities, hospitals, or family resource centers. These structured programs are delivered by clinicians, counselors, clergy, peers, teachers, and trained lay leaders to couples or individuals at various stages of the relationship life cycle (e.g., dating, engaged, married, transition to parenthood, divorced, remarried).

The umbrella term *couple relationship education* (CRE) is used here to encompass this diverse array of approaches and programs designed to strengthen couple relationships before problems become entrenched, overwhelming, and destructive. *Couple relationship* rather than *marriage* is used as the umbrella term to be inclusive of other forms of couple bonding and to limit the focus of this entry to programs that address relational as opposed to institutional, legal, or other aspects of a couple union. This entry provides an overview of the history, current status, efficacy, and typical features of CRE programs.

History and Development

Across cultures and time, wide variations exist in the degree to which marriage and close relationships are an arena open to public scrutiny and expert advice. In the United States, until recently, there was strong resistance to research and education on the seemingly intangible, natural if not spiritual, and exceptionally private processes of love, mate selection, and matrimonial functioning. However, events in the second half of the 20th century heralded an unprecedented call for societal attention to strengthening couple relationships. Social scientists began in earnest to study not just individuals, but relationships, and thus relationship science was born. Research revealed that close, intimate relationships were not simply nice, but essential for human thriving and constituted the core context for human development. Science was able and ready to explore the nature and functioning of these critical relationships with the hope of improving the quality of human lives.

During this era, researchers were documenting the skyrocketing divorce rate and the increasingly unhealthy state of Americans' relationships: Extramarital affairs occurred in as many as one third of marriages, more than 50 percent of marital relationships dissolved, and in at least one half of intact marriages partners experienced significant relational strain and unhappiness. A host of negative consequences for both parents and children were identified—from reductions in work productivity, to conflict and stress, and ultimately compromises in physical and emotional functioning. In contrast, couple relationships characterized by effective communication, closeness, and flexibility were found to be associated with a positive quality of life.

Against this backdrop, at least three separate developments entwined to support the current popularity and proliferation of CRE programs: research on marital and family interaction processes, grassroots marriage enrichment, encounter and related "growth" movements, and federal and state support for family life education.

Marital Interaction Research

In the 1970s, clinical psychologists such as John Gottman and Robert Weiss began conducting

observational studies of the interactions of married partners to identify behavioral differences between happily and unhappily married couples. By illuminating relational processes associated with successful marriages, this pioneering research provided an empirical basis for skills-based educational programs for couples. What was found to be critical to a healthy conjugal bond was not whether partners have differences and disagreements, but how partners handled those relational differences. Previous research on the predictors of marital success focused on static variables such as family-of-origin issues, demographics, or personality—variables not easily amenable to change. Attention to behavioral interactions reoriented the field to factors that empirically were shown to make a difference and were, at least in principle, amenable to change. A path breaker in this area, Howard Markman, one of Gottman's students, translated the insights derived from this new research tradition to a prevention program for couples (initially designed for couples at the transition to marriage), creating one of the first evidenced-based CRE programs. Based on the research findings, Markman's Prevention and Relationship Enhancement Program (PREP) focuses heavily on teaching effective communication skills related to managing conflict. However, PREP and other research-based programs were offered to couples primarily through university clinics and departments, and little or no dissemination resulted from this work during the early stages of its development.

Grassroots Support for Marital Enrichment

Although developments related to remedial interventions for couples have always been the province of professional therapists, prevention and enrichment programs for couples began as popular grassroots movements and continue to be fueled by them. The early roots of CRE can be traced to the inception of the Roman Catholic Marriage Encounter program in 1962 in Spain and to similar faith-based and secular programs in the United States. Despite different formats and approaches, these early CRE programs shared a foundation in a humanistic philosophy, encouraging growth in personal and relational domains. From this perspective, relationships, and marriage in particular, were seen as a primary arena for actualizing human

potential. Like CRE programs today, the emphasis in these early programs was on the betterment of family life through improved communication. Through grassroots support and coordination among numerous faith-based as well as secular organizations, premarital preparation and marriage enrichment programs became widely disseminated in the United States, Australia, and other Western countries. For example, the Catholic Church began requiring an educational premarital counseling program of any couple marrying in the Church. By the early 1990s, about 30 percent of couples were receiving some form of CRE prior to marriage, primarily through programs developed outside the university and with little or no research basis.

State and Federal Support for Family Life Education

As a public institution, marriage is in the direct eye of the government; despite some pockets of public indignation related to interference with such a private affair as a romantic and sexual relationship, both state and federal government entities have exerted direct and indirect influence on the nature of romantic, marital, and family relationships. Although a range of government policies have shaped the character of marriage and family life in the United States, the discussion here is limited to government support for family life education, an important stream of influence for present-day CRE programs.

In 1914, Congress established the Cooperative Extension Service (CES) as a partnership among the U.S. Department of Agriculture, the state land-grant universities, and county governments. CES was explicitly designed to help citizens use research-based knowledge to improve their lives in selected areas, including family life. CES offices are located in almost all of the 3,077 counties in the nation and are staffed by county extension faculty who bring research knowledge from the university out to their constituencies. The outreach efforts of Extension have brought Family Life Education to the nation's families for decades in the form of workshops, pamphlets, fact sheets, newsletters, and other educational materials. The National Council on Family Relations provides credentialing for family life educators, ensuring a qualified and professional workforce.

In the late 1990s, the federal government began to take a more active role in supporting CRE as part of a major “Healthy Marriage Initiative” spawned by societal trends suggesting erosion in the institution of marriage and by the rise of a popular “Marriage Movement” calling for a return to more traditional marital arrangements in U.S. society. Although the government initiative is much broader in scope than the prevention of relationship distress, a cornerstone of the new initiative is an emphasis on the quality or health of marital relationships, and relationship and marital education were identified as part of the solution. Under current federal policy, states are allowed to use Temporary Assistance for Needy Families funds to support marriage education programs for disadvantaged families. Some states have mandated basic marriage and relationship skills training in public high schools or reduced the cost of a marriage license if the couple enrolls in a premarital education program. Other states have supported training in CRE programs to help disseminate marriage education within their borders. Within CES, the National Extension Marriage and Relationship Education Network was formed to provide research-based resources and catalyze new partnerships to advance knowledge and practice of CRE.

The Face of CRE Today: A Convergence of Streams Brings a New Tide

At the dawn of the 21st century, not only is there an acceptance of research on topics such as intimacy, infidelity, and infatuation, but there is also a hunger for expert guidance on the steps needed to achieve a satisfying and stable couple relationship. The landscape of CRE initiatives and programs today is diverse and complex precisely because it represents the convergence of a number of separately developing fields and movements, including the three prominent ones described in some detail before.

At one time, there was a clear distinction between prevention and enrichment in CRE, owing at least in part to their respective champions: Prevention efforts were primarily emanating from the professional and academic communities, whereas enrichment efforts were being promoted by lay secular and faith-based organizations.

However, the distinction between the prevention of distress and the promotion of healthy functioning has effectively disappeared in current CRE programs; both goals are embraced and articulated together in the common theme of “strengthening” relationships. Similarly, there has been a breakdown in the gulf between professionals (therapists, psychologists, counselors) and nonprofessional, lay, or paraprofessional helpers. Because no national, state, or organizational credentialing or licensing is required of CRE leaders, the field currently is open to professional and nonprofessionals alike. In the earlier phases of development, professionals were not providing much dissemination, whereas lay leaders were not relying on evidence-based approaches. Each group is now borrowing from the insights of the other, and pockets of convergence are evident. Government involvement lends further support for both of these objectives; recent government initiatives are consistent with the desire for widespread dissemination, and government funding generally requires solid and continuing empirical evaluation to establish effectiveness.

Importantly, the government’s role in supporting CRE has added to the new tide an emphasis on cost-effectiveness and a broadening of the reach to disadvantaged and traditionally underserved populations. Both the grassroots marriage enrichment movement and the academically based prevention effort have touched the lives of primarily White, urban, middle-class, educated couples. In contrast, government involvement, including extension services, has played the important role of stretching the reach of CRE to more disadvantaged and underserved populations. Recent federal initiatives have spurred the development of new curricula or adaptations of existing curricula that are more sensitive to the unique challenges of disadvantaged groups. In addition, the federal government has funded several large-scale CRE demonstration projects, which will provide evaluation data greater in scope than any previous research study. Both public and private funding for CRE programming and evaluation have increased significantly in the past decade.

The traditional distinctions between remediation and prevention, or therapy and education, have become increasingly blurred in this new landscape. This is a trend seen not only in the area of

CRE, but in the medical and mental health areas more generally. With pressure to achieve cost-effectiveness—and to reach more couples while spending less—and with the success of brief intervention and psychoeducational models in medical and mental health settings, individualized face-to-face therapeutic intervention models are being reserved for only the most serious or extreme cases. In the couples area, the move to educational models has been welcomed given that couples therapy generally shows only a moderate success rate, and few actually seek it out—the vast majority of those who divorce do not report having seen a therapist or counselor.

In further testimony to the merging of remedial and preventive approaches, many couple therapies now have a codified set of parallel strategies that can be delivered as CRE, rather than in a traditional face-to-face therapy session. Signs of a merger flowing in the opposite direction include the fact that insights from therapeutic processes are continuing to influence and shape CRE programs. Some of the most respected CRE programs are based on the clinical experiences of their therapist authors or the research of clinical psychologists.

This new tide brings greater attention to the “how tos” of relationships than perhaps ever before, and CRE programs are proliferating rapidly. CRE is beginning to become institutionalized and organized under an umbrella organization, the Coalition for Marriage, Family, and Couples Education, which sponsors an annual conference. However, with the new demand for relational education, significant commercialization of CRE products is taking place, and choosing an educational program can be daunting for both couples and practitioners. Unfortunately, many programs are based on personal observations rather than scientific or clinical wisdom (e.g., John Grey’s popular *Mars and Venus* books), and the vast majority of programs are unevaluated.

The Effects of Couple Relationship Education

With rapid proliferation of new programs, it is perhaps not surprising that few have been evaluated. Unfortunately, evidence of long-term effects from rigorous and replicated controlled outcome

studies is generally lacking even for well-established programs. As preventive interventions, these long-term gains are particularly important to document. It is generally only the skills-based programs that have been evaluated in controlled trials, and PREP is currently the only program that has been evaluated for long-term effects. Nonetheless, evaluation results are generally encouraging. Couples report high satisfaction with the programs, and a number of meta-analyses have confirmed an overall positive effect for CRE programs on short-term outcomes. Skills-based programs have been found to lead to increased marital satisfaction and improved communication skills, and, at least in the case of PREP, these gains hold up over years. Bernard Guerney’s Relationship Enhancement (RE) program is another established program with a strong evaluative base. Numerous studies of RE find that couples generally make significant improvements in the targeted areas: communication, empathy, self-disclosure, and relationship satisfaction.

Although the potential for CRE programs to prevent marital discord and divorce and improve relational harmony over time may be more promise than established reality at this point, the recent influx of funds, the systematic calls for additional and long-term outcome evaluations, and the large-scale federal evaluation and demonstration projects underway promise to provide important new insights on the efficacy of CRE in the coming decade.

Features of Typical CRE Programs

Although the content and delivery formats of CRE programs vary widely, most programs incorporate a similar set of educational messages and employ similar “teaching” strategies. The goals of a typical CRE program can be summarized as follows: motivate partners to nurture their relationship and take responsibility for their own behavior; teach effective communication skills; provide strategies for managing conflict, problem solving, and dyadic coping; prepare couples for common relationship issues; encourage empathy, intimacy, and responsive caregiving; and enhance fun and togetherness.

Consistent with the educational goals, programs are usually delivered in a group format or classroom setting, with anywhere from a handful of couples to 50 or more present. Some programs

have adapted a more individualized counseling or coaching format where couples meet individually with an instructor. This is more common in programs that use an inventory approach, and a personal session is used for feedback. Most group programs are taught by a single instructor, although married or unmarried partners often work together to allow modeling of the target behaviors. Programs use other formats as well. PREP, for example, although usually delivered in group sessions, has used a variety of alternative formats, including self-directed learning guides, telephone-based consultation, and eLearning via Internet delivery.

Programs vary in duration and intensity from a single, brief workshop to a day- or weekend-long event, to multiple 2-hour sessions provided over a period generally ranging from 5 to 12 weeks. Some programs are formal and structured, whereas others are informal and idiosyncratic. Evidenced-based programs are often formally structured, “trademarked,” and steps are taken to achieve fidelity and restrict delivery of the program to trained and certified facilitators. Teaching involves a mix of experiential exercises and didactic material, interspersed with audiovisual supports, including movie clips or illustrative clips from couple interaction studies. To achieve optimal benefits, there is growing appreciation of the importance of regular and sustained “practice” of the lessons delivered in a program, including “booster sessions” delivered at regular intervals following the initial session. Workbooks and homework assignments are often used to encourage activities outside of the classroom setting.

Conclusion

The potential for CRE programs to significantly improve the quality of couple relationships will depend on the extent to which the programs are effective in the long-term and the extent to which programs with documented efficacy can be disseminated widely within the population. Widespread dissemination of CRE programs requires surmounting what have been called in the clinical literature “barriers to treatment,” such as cost, inconvenience, and social stigma. Although CRE has distinct advantages over therapy in each of these areas, the barriers have not been eradicated. Most individuals feel they

need driver’s education before taking to the highway and are therefore willing to pay a fee for driver’s education, but a similar view has not generally taken hold among engaged couples with respect to navigating the new terrain of marriage. Even nominal fees for premarital education may drive couples to launch their marriage without training. Practical issues such as finding a time when both partners are free, finding child care, getting to the place where the program is offered, and so on can present formidable barriers. Without a prevailing assumption that relationship training is necessary, these relatively minor inconveniences are likely to keep partners at home. Further, couples may feel the need for training signals a deficiency. Despite positive labeling such as *premarital preparation* and *marital enrichment*, public exposure of participation in CRE activities may carry a “social stigma” for some couples.

Parents have accepted and relied on parent education for decades now—there is no assumption that parents are born with an accurate internal map for parenting. A similar attitude may slowly begin to take root for the navigation of close, romantic relationships. CRE proponents believe a map is essential—for most people, education is needed to become a good partner or spouse and a thriving couple. Although the development, evaluation, and dissemination of effective educational programs may be costly, ignoring the health of couple relationships may be more costly. The growth and popularity of CRE programs and the investment in large-scale evaluations are signs that the relational foundation of human life is being taken seriously.

PREVENTION AND RELATIONSHIP ENHANCEMENT PROGRAMS (PREP)

PREP include several research-based and research-tested curricula that teach skills and principles for helping people increase chances for a happy and healthy relationship. A unique feature of PREP is that the information, skills, and strategies taught in PREP are based on research on how relationships work. Moreover, the content of the program is continually refined and updated based on new research findings and experiences in disseminating the program. This entry provides a brief historical overview of PREP, summarizes five versions of this program, presents findings from studies evaluating its effectiveness, and highlights directions for further research.

Historical Overview

Based on studies examining behaviors and perceptions of both distressed and nondistressed couples, as well as studies that identify factors associated with relationship success, PREP started in 1980 as a premarital intervention program designed to enhance relationship functioning and prevent divorce. Key research findings at the time were summarized by George Levinger, who noted that

the disagreements couples had did not matter as much as how they were handled. Therefore, early versions of PREP focused on teaching communication and conflict-resolution skills. In addition to being based on available research on marital success, PREP built on the work of Sherod Miller and associates' Couples Communication Program, Bernard Guerney's Relationship Enhancement Program, as well as Virginia Satir's and Salvador Minuchin's versions of family system theory.

The first use of PREP outside of a research context occurred in 1991, when the Navy decided to train Navy and Marine chaplains and social workers in PREP to help military couples. In 1995, the U.S. Army started using a version of PREP called Building Strong and Ready Families, which was geared toward the challenges faced by military couples. Today, nearly all Army chaplains are trained in PREP.

In 1999, the state of Oklahoma started the Oklahoma Marriage Initiative and chose PREP as the curriculum to use to improve marriages in the state. Spearheaded by these initial dissemination efforts, interventions founded in whole or in part on PREP are now being used in a variety of settings (e.g., U.S. Head Start programs, high schools, prisons, youth services diversion programs, Job Corps, religious organizations, and the military), leading to the provision of services to increasingly diverse and high-risk populations.

Evaluation Studies

Early studies of the effectiveness of PREP in university laboratories showed promise for teaching couples communication and conflict management skills, and it led to refinements of the program and large-scale tests of the model in community-based studies. Refinements over the years included focusing on protecting and preserving positive connections (e.g., fun, friendship, sensuality), as well as understanding the deeper meanings underlying successful relationships, such as commitment and forgiveness.

Larger scale outcome studies of PREP and other programs have also been promising. For example, reviews of the effectiveness of premarital intervention programs (including PREP) tend to find that couples receiving such training have significant

immediate gains in communication processes, conflict management skills, and overall relationship quality, and that these gains appear to hold for at least 6 months to 3 years. There is also evidence that premarital education of various types is generally effective for people of varying racial backgrounds and income levels, although such services are much less available to those with lower income levels. Recent efforts have focused on evaluating the extent to which PREP can be disseminated in community settings by training other providers (e.g., clergy) to deliver the program, and results of this service-delivery model have been promising.

In contrast to research on therapy approaches, prevention approaches like PREP have not typically provided data on the percentage of individuals showing significant improvement or deterioration over specific time periods, data on what predicts who does or does not benefit, nor data on relapse. One of the major reasons is that most participants in prevention programs are already happy with their relationship, and the overarching goal is to keep those couples happy. Nevertheless, future research needs to provide these data. There are preliminary data suggesting that there may be an attenuation of effects over time, highlighting the need for booster sessions for couples.

There are now five distinct curricula available based on PREP:

1. Classic PREP, a 12-hour program for couples;
2. Within Our Reach, a 30-hour program developed for couples with low income levels that includes more group activities, a strong experiential teaching style, and new information on stress and coping;
3. Within My Reach, a 16-hour program developed for individuals (rather than couples) that covers skills for relationship success, information on partner choices, and discussions of how relationships affect children;
4. PREP for Strong Bonds, a 16-hour program for Army couples; and
5. Airman to Airman, a program for men and women in the Air Force (see PREPinc.com for details about these programs)

There is also an Internet version of Classic PREP for foster and adoptive couples.

New Directions for PREP

Two challenges confront the prevention and education field: (1) getting partners to attend a class or program together, and (2) tailoring programs to serve the needs of diverse populations, such as those with low incomes or recent immigrants to the United States.

Services to Individuals

One of the biggest challenges for couple therapy or education is getting both members of the couple to attend. Preliminary data from a national evaluation of marriage education showed that more than 40 percent of couples did not attend even one session of a scheduled intervention. Although getting one member of a couple to attend seems easier, little research has been done on whether both members of the couple need to participate in a program for it to be beneficial. A related and equally important question is whether the gender of the participating member is important for transmission of skills and information to the nonattending partner. Research on PREP is now underway that addresses the question of how services delivered to individuals can generalize to couples and if there are differences in couple outcomes if services are delivered to males versus females.

Low-Income and Diverse Populations

Another major issue in the field is extending the research base of programs like PREP to low-income, ethnically diverse populations. With the exception of several recent studies, most evaluations of PREP and related programs have used samples that are predominantly White and middle class. Guided by findings that economic strain is linked to marital conflict via emotional distress, new versions of PREP include more activities and use culturally sensitive techniques designed to help couples cope with economic stressors to create safer, more stable environments for their relationship and their children.

Future directions for PREP and the relationship education field include conducting long-term research on prediction of marital distress and divorce and assessing long-term preventive effects

of interventions, particularly with diverse populations; developing and evaluating Internet-based delivery platforms; reaching younger people and higher risk populations; and training a wide range of service providers to deliver research-based interventions.

PRIVACY

Privacy is considered a cultural value, and legal scholars have grappled with the parameters setting the standard for privacy issues. However, in the context of human relationships, privacy is more dynamic and increasingly relevant as technological advances change the fabric of how people interact. In general, *privacy* in the United States is defined as information, territory, space, or possessions that people believe they have the right to own and over which they exercise control.

Broadly, privacy may be further conceptualized as instances when people restrict access to others and safeguard autonomy. However, within human

relationships, privacy refers not only to restricting access, but also to conditions under which others are granted access to private information, space, and possessions. An easy way to conceptualize this process is to consider all that people hold private as being housed within a boundary. When wishing to grant access, individuals open that boundary allowing others admittance to space, private possessions, or private information. When individuals opt to retain privacy, they close boundaries and keep others out. This entry discusses the conditions of privacy, privacy management apparatus, privacy invasions, and current privacy trends.

State and Conditions of Privacy

Several conditions represent the state of retaining privacy. For example, people may seek solitude achieving freedom from observation by others. Alternatively, people may strive for a privacy that affords liberty to act in public without concern for being identified, thus achieving a state of anonymity. Finally, privacy is attained through limiting disclosure to others. In addition to conditions of privacy, there are also privacy functions that represent reasons for limiting privacy access. Thus, privacy grants personal sovereignty by avoiding the possibility of being dominated by others. Privacy allows an emotional release from role demands. Privacy provides opportunities for evaluation by temporary separation from human relationships allowing time to process information. Privacy additionally offers protected communication to share personal information with trusted others. Finally, privacy protects potential vulnerabilities from exposure of information that might compromise reputations of individuals. Thus, people limit access to privacy boundaries to achieve one or more of these goals.

Privacy Management Apparatus

Human relationships require both privacy and granting access to others. Individuals cannot sustain relationships if they do not allow others to become privy to their personal moments, information, or space. At the same time, people need to preserve autonomy through managing privacy. To have an optimal relationship with others, people

require both privateness and publicness. Because these are concomitant needs, individuals develop strategies to manage them simultaneously. People control their privacy boundaries by regulating access through the development of privacy rules. People develop those rules by using decision criteria, such as motivations for access, cultural expectations, personality needs, and risk-benefit assessments that impact levels of access.

Privacy Invasion, Violations, and Dilemmas

When others encroach on an individual's space, misuse information, or treat possessions in unacceptable ways, that person feels violated. In U.S. society, some violations are considered to be legal matters. For example, although people typically trust medical professionals, with new health care technologies such as electronic medical records, patients have voiced uncertainties about the likelihood their privacy is protected throughout the health care system. Laws such as the U.S. Health Insurance Portability and Accountability Act of 1996 were crafted to protect patient privacy. Beyond legalities, people have emotional reactions to invasions of privacy because the act of invasion compromises an individual's sense of control.

People often find it difficult to rectify privacy violations that occur among individuals considered friends or with whom individuals have ongoing relationships. Relationship partners typically negotiate parameters for when and how privacy boundaries are drawn to include or exclude others. If people explicitly identify these boundaries and friends or intimates intentionally violate them, there is great potential for conflict because not only is privacy violated, but people also may feel that relational trust is breached.

More often than privacy violations or intrusions, individuals find themselves involved in privacy dilemmas with friends and families. Many times it is difficult to satisfactorily solve privacy dilemmas because sometimes the way people handle the problem complicates the issues. For example, suppose a teenage girl tells her older sister that she is pregnant, begging the sister not to tell their parents about the pregnancy. If the older sister keeps the secret, she may feel that she is betraying her parents. If she tells her parents, she betrays the younger sister's trust, likely creating emotional difficulties

with her sister that would need to be addressed. Thus, selecting an apparent solution to a privacy dilemma may necessitate complex strategies of managing relationship conflicts as a result.

There are two kinds of privacy dilemmas. First, accidental privacy dilemmas occur when people inadvertently discover something hidden, for example, where keeping the discovery concealed can cause problems, but acting on the discovery may also cause difficulties. Second, there are confidant privacy dilemmas where people are told volatile information that might be difficult or impossible to keep confidential. For example, a woman learns she has a genetic predisposition to contracting breast cancer. To cope with the information, she confides in her sister-in-law, but makes the sister-in-law promise not to tell her husband, the confidant's brother. The sister-in-law finds herself in a quandary because she has loyalties to her brother as much as she feels committed to the trust given by her sister-in-law. In all, invasions, violations, and privacy dilemmas may challenge the way people are able to sustain their privacy needs.

Current Privacy Trends

Privacy is at the forefront of many contemporary human relationship matters. Two such issues are the ways in which modern technology affects the privacy of human interactions and privacy within families and other personal relationships.

Impact of Modern Technology on Privacy

The Internet has exploded with multiple avenues by which people manage relationships and communicate with each other. New technologies that facilitate social networking on the Internet have positive aspects in that they allow people to form and sustain relationships, but there is also the possibility that relationships can be undermined or exploited through these technologies. One of the struggles in using these technologies to initiate and manage relationships is the issue of privacy. For example, it is problematic for users of a site such as *Facebook* to assume that information is protected. Although there is sufficient evidence to show that information on these Web sites is far from secure—for example, prospective employers,

family members, and others can access the information—some people act as if the information is secure and may post suggestive pictures from parties or highly disclosive information on their sites.

In addition to social networking through the Internet, the use and abuse of other technologies also challenge people's sense of privacy. For example, the handy supermarket or drugstore cards that give discounts also track buying habits. There has been talk of providing these records to physicians and insurance companies so that they can monitor purchases and determine whether dietary restrictions are being followed. Likewise, the U.S. REAL ID Act of 2005 imposes new security, authentication, and issuance standards for information on state driver's licenses and state ID cards. These cards carry significant personal information on a magnetic strip that some privacy advocates argue allow for tracking the individual. Personal choices and preferences weigh the costs of losing privacy against the benefits of the technology.

Privacy, Families, and Personal Relationships

Privacy is integral in many ways to family life and personal relationships. Families teach children how to manage privacy by providing implicit or explicit rules that help them navigate choices about disclosing family information both internally and to outsiders. For example, parents illustrate their expectations for privacy when they caution their children not to talk about family finances outside of the home. At times, families are so private that they may be considered secretive. Secrets represent information that has a thick boundary around it with limited or no access to others. However, privacy is a more general term that represents degrees of protection of or access to information people believe they own and have the right to control. Some families have developed privacy rules granting more or less open access for disclosing both internally among members and externally to people outside the family, whereas other families may be more secretive and deny access. Adolescents test what privacy means to them, how much privacy they need, conditions for trusting others, and how to regulate access with others, including parents and siblings. Adolescents tend to gain a sense of emotional autonomy when they are able to choose which information they tell their parents and

which they keep private. When parents allow their adolescents to have the choice of revealing or concealing, the parent-child relationship improves, adolescents are able to grow more confident in their sense of self, and they feel less desire to be secretive with their parents.

Likewise, marital relationships tend to grow stronger when partners afford each other more latitude to judge when they should disclose something, how much to tell or keep private, and when to be open about issues. Although deciding under what circumstances to reveal and conceal private information can be challenging for couples, privacy regulation grants partners opportunities to consider which issues they want to disclose, how much, when, and how to do so. For children and couples, balancing personal needs for privacy with the need to share information and thereby foster a sense of connectedness is likely to make a difference in the state of a relationship.

When families successfully strike a balance between connectedness and autonomy, they develop positive ways of managing privacy. However, there are also examples of unsuccessful privacy management in which the balance of connectedness and autonomy goes awry. For instance, privacy management may be problematic when a wife going through a divorce intentionally discloses detrimental information about her ex-spouse to his boss. In this case, the ex-wife intentionally violates a privacy rule the couple used during their marriage. This kind of imbalance further complicates family life if children are involved. For instance, divorcing parents may tell children negative information about the other parent that can damage that parent-child relationship.

In a more egregious case, there are times when family members act as if they have the right to operate in complete autonomy. They devise privacy rules without the consent of other family members, although their actions implicate those family members. The web of silence that surrounds child sexual abuse, in which children may be told not to reveal abuse because of problems that might be created, illustrates this condition of dysfunctional privacy management. This darker side of privacy management shows that privacy regulation has both positive and negative aspects for relationships. Privacy management has positive outcomes when people are able to negotiate a mutually agreeable set of

privacy rules for defining access to information that accounts for their needs, needs of others with whom they have relationships, and the desired level of autonomy and connectedness. Neglecting negotiation of privacy rules and leaving coordination about privacy issues to chance may result in mistakes, inappropriate judgments about privacy boundaries, or dysfunctional outcomes.

Thus, a main key to better understanding privacy in a social world is recognizing the necessity of communicating about privacy needs, considering those needs in relation to desired connections with others, determining the expectations that individuals have for their privacy, and accounting for the fact that people define private information as belonging to them and as a matter of personal control.

PROCESSES OF ADAPTATION IN INTIMATE RELATIONSHIPS (PAIR) PROJECT

People who watch a man and a woman courting or learn about their marriage almost invariably

wonder about the fate that awaits them as a couple. The PAIR Project, a longitudinal study of couples that began when they were newlyweds, sought to provide a sophisticated analysis of the circumstances that influence how marriages work themselves out. The Project was initiated in 1981 by Ted Huston with data gathered from 336 newlyweds (168 couples) identified through marriage license records maintained in four county court-houses in central Pennsylvania. The initial premise of the study was that the psychological and social qualities that partners bring to their relationship shape their experiences together, both during courtship and in marriage. The Project also sought to delineate key features of couples' courtships and to link these features to how well the spouses got along and how they felt about each other as newlyweds and then at yearly intervals over the ensuing 2 years. This tidy short-term longitudinal study became embedded in a long-term longitudinal study when the PAIR Project team returned nearly 14 years after couples were wed to see how the marriages had fared.

The PAIR Project used social-psychological theory and developmental methods to track how couples progress through relationship stages and how what happens in one "stage" of a relationship foreshadows what happens later. The Project ultimately traced couples' relationships from courtship, to the early years of marriage, to parenthood (for most), and to divorce (for some).

The Project had several notable design features that in combination set it apart from other research seeking to understand the etiology of marital success and failure, including (a) the large and economically diverse makeup of the sample; (b) the success the research team had in gaining the cooperation of both spouses, affording the opportunity to examine compatibility, gender issues, and cross-partner effects; (c) the in-depth information gathered concerning both partners' social background and psychological makeup; (d) the extensive data obtained about the couples' courtships, gathered independently from the husbands and wives when they were newlyweds; (e) the fact that the initial data were gathered from the couples shortly after they were wed, prior to when marital disenchantment would have had a chance to develop; (f) the diary-based information gathered each year from both spouses about their day-to-day activities, making it possible

to portray the division of labor, marital companionship, social contact with kin and friends, and the interpersonal climate of each marriage; (g) the longitudinal nature of the original study, which allowed the team to study changes in couples' married life over time; (h) regular assessments of husbands' and wives' views of each other's qualities, their love, and satisfaction; and (i) the Project's success in tracking down the original sample, making it possible to identify the fate of 97 percent of the marriages at the long-term follow-up.

The PAIR Project has produced more than 40 book chapters and publications in scientific journals. Some of the more notable findings were:

- Men's investment in the relationship during courtship plays a stronger role than women's in accounting for how quickly and smoothly courtships progress toward marriage.
- Partners' personality qualities reveal themselves before marriage, creating courtships that differ in the mix of sweet and sour elements.
- Women who sense future problems while courting generally find out after they marry that their concerns were well founded.
- Newlyweds are not blissful lovers, on the whole. Some spouses enter marriage after a rocky, arduous courtship; others take a smooth, even pathway; and still others marry after a short, intense romance. These differences in courtship experiences carry over into marriage and are reflected in the intensity of spouses' feelings toward each other as newlyweds.
- Having a baby transforms couples' lifestyles, but it does not change the interpersonal climate of their marriages or undermine spouses' feelings of love or satisfaction.
- Whether a marriage will be happy or whether it is headed for divorce can be foretold by how it evolves during the first 2 years.
- Couples that stay married and are happy nearly 14 years after their wedding day are more affectionate and less antagonistic toward each other as newlyweds than couples that stay together in unhappy unions. Both groups evince modest declines in affection early in marriage, but antagonism does not increase for either group as the honeymoon period recedes into the past.
- Two personality qualities shape the emotional climate of marriages. Men and women who possess stereotypical feminine traits—warmth, concern for others, kindness—make better spouses, whereas spouses whose nature is to be moody and emotionally up and down make worse spouses.
- Whether a marriage is fated for divorce cannot be foretold from how spouses function together shortly after they marry. The newlywed marriages of to-be-divorced couples are a particularly diverse lot: Some are intensely in love and affectionate, whereas others appear to marry despite having lukewarm feelings for each other. The long-term fate of a marriage is predictable instead from how much the spouses' romance, whatever it was at the beginning, dissipates over the first 2 years of marriage. The timing of divorce, however, depends on the intensity of the couples' newlywed romance: Initially lovey-dovey couples whose marital bliss quickly goes amiss take longer to divorce than those less enamored with each other to begin with.
- Antagonism does not develop early in marriage among the couples that divorce. Further, divorcing couples are not less compatible than couples that stay married, but their feelings toward each other early in marriage are more strongly tied to their level of compatibility, suggesting that couples that divorce are more attuned to issues of compatibility.

PAIR Project papers also have examined such matters as the carryover of work-related stress into marriage, the division of household labor, role balance, marital companionship, types of marriage, sex in marriage, and the role friends and kin play in courtship and marriage.

PROXIMITY AND ATTRACTION

Many traits or factors can lead to liking, lust, or love between two people; these factors include physical attraction, similarity, and familiarity, among others. Another construct that can lead two people to become friends or lovers is *proximity*, which is typically defined as the physical space or distance between two people. Proximity can refer to the actual individuals or their homes, workspaces, seats in a classroom, and so on. Two people who both live in a small town will, for example, have a closer proximity than if one person lives in Los Angeles and the other lives in New York City. Decades of studies that have investigated causes of attraction have found that there is a positive correlation between physical proximity and attraction—in other words, the literally closer you are to someone, the more you will like him or her. Classic research has been completed on the association between proximity and interpersonal attraction and why this link exists. With modern technological advances, the future of this topic seems open to new discoveries.

Classic Research

The most classic (and now famous) study that first made the proximity effect well known was completed by Leon Festinger and two of his colleagues, Stanley Schachter and Kurt Back. These three

researchers investigated a small community named the Westgate Housing Project, which was part of the campus at the Massachusetts Institute of Technology (MIT). They wanted to know what would happen when strangers (in this case, MIT students) were randomly thrown together in apartment buildings—in other words, the students would have a close proximity to each other. Each apartment housed a married couple, one of whom was a veteran. Each apartment building included 10 single-family units, with five apartments on each of two floors. The researchers pointed out that the residents of Westgate were similar to each other in terms of background, interests, and life goals. The real relevance of this study for proximity is that the researchers wanted to know how physical closeness would influence each resident's liking or attraction to the other residents in the complex.

Festinger pointed out that there were two kinds of proximity in this study: (1) *physical distance* from one apartment to another, and (2) *functional distance*. Functional distance refers to the idea that the buildings were constructed such that some apartments were more likely to be passed by. For example, if an apartment was at the bottom of a staircase leading to the second floor, all of the residents who lived on the second floor would have to pass that door. Thus, both physical and functional proximity were factors in this study and affected how often any given resident would be seen by the others. If two people see each other often, they are more likely to get to know each other and become friends. For example, consider neighborhoods. Individuals are more likely to know and like the residents living directly to each side of themselves, compared with residents who live three blocks away. Festinger found this pattern as well. When he asked people in Westgate to choose the three people in the entire complex whom they were most likely to see socially (in other words, their friends), they listed residents with closer physical and functional proximity to themselves. This general idea—that the physically closer we are to someone, the more likely we are to be attracted to him or her—is sometimes referred to as the *propinquity effect*. The propinquity effect was supported by Festinger's research, as well as several additional studies (some of which are described next).

Why Does Proximity Lead to Attraction?

Why does either proximity (physical or functional) lead to attraction? In some ways, this may seem obvious—if you have more chances to talk with someone because you see him or her more often, it is more likely that you will get to know each other, discover similarities, and become friends or start dating. A second explanation comes from a reward-cost perspective. Consider a couple that is involved in a long-distance relationship. The costs of that relationship are both tangible (e.g., the financial burden of driving or flying to see each other) and intangible (e.g., the extra time and sacrifices needed to maintain the relationship). The costs of dating someone with a close physical proximity are much less. Thus, when considering potential romantic partners, individuals with a closer proximity may have an advantage simply because they are close by.

In addition to these two explanations, a third perspective has been popular in research studying the proximity effect of attraction. It may be that simply being around something or someone more often leads to liking because we are comfortable with that object or person—we know what to expect. This would not require any communication or conversation with the other people—just looking at their pictures should make us more attracted to them. This phenomenon is called the *mere exposure effect* and is defined as the tendency to grow to like things over time merely because of repeated exposure.

The mere exposure effect has been shown to predict attraction. Infants are more likely to smile when they see photographs of people they have seen before, compared with strangers. Student liking of other people in a classroom goes up the more often those other people attend class over a given semester and how close their seats are to each other (even in a small room). The mere exposure effect can even work subliminally. People who view Chinese characters and geometrical shapes subliminally (too quickly to recognize) are more likely to report liking those same characters later, and the liking is stronger than their feelings toward never-viewed characters. The idea for proximity is that if one person has a close physical or functional distance to someone else, they'll be exposed to each other more and more, and over

time they will grow to like each other due to this exposure. Of course, if the person is unpleasant or rude, repeated exposure can lead to the opposite: growing dislike. One study showed that, although it is true that our friends are more likely to live close by, so too are enemies. At the least, overexposure can lead to boredom and the desire for something new.

Although these exceptions to the rule certainly exist, the heart of the matter is that, all else being equal, physical proximity can lead two people to become friends and eventually even fall in love. Proximity can thus help with initial attraction, and it can also maintain attraction. For example, findings show that long-distance partners are less satisfied with their relationships.

However, with advances in modern technology, people are meeting potential partners in different ways. Specifically, computer-based communication networks such as e-mail, Facebook, and MySpace are extremely popular for keeping in touch with people who are far away. Today, perhaps physical proximity is not as necessary because computers allow for a close functional proximity—a lover is only a double click away. Indeed, people are now able to have live video chats with each other from the other side of the world. Researchers are just beginning to explore how long-distance relationships may be helped by this form of functional proximity (sometimes called *communication proximity*). One finding is that people seem to feel high emotional intimacy with people they meet online relatively quickly. However, if people don't meet face to face, it may lead to problems ranging from inability to see nonverbal cues all the way to dishonesty about one's age or gender, as well as cyberstalking. Although technological proximity may help already formed relationships stay "close," some signs are pointing to possible dangers of attempting to form new relationships using only these methods.

In addition to the physical, functional, and communication forms of proximity, a fourth type has been suggested by Malcolm Parks. Parks adds that social proximity may also affect individuals; *social proximity* can be defined as the extent to which two individuals' social networks overlap. In other words, how many friends do they have in common? Social proximity can also lead to attraction. In one study done in The Netherlands,

for example, two thirds of individuals reported that, before they started dating their current partner, they knew at least one (if not more) of that person's friends or family members. Social proximity leading to attraction makes sense because the more social ties two people have in common, the more likely they are to meet and become acquainted.

Applications and Future Trends

Finally, proximity has applicability in almost any natural setting. For example, because of the findings on proximity and attraction, some architects are designing housing complexes and workplaces in patterns that will increase proximity. For example, cubicle walls in an office can be short enough that people can see over them to talk to each other. A water cooler can be placed in a central location to encourage social gatherings. The link between proximity and attraction is robust and can be applied to many different kinds of settings. It even seems likely that this phenomenon explains why young boys are so likely to have a crush on the girl next door.

PSYCHODYNAMIC THEORIES OF RELATIONSHIPS

In many ways, contemporary psychodynamic theories can be thought of as theories of relationships. Although Sigmund Freud's original theory was primarily concerned with the "internal world" of the mind, psychodynamic theories have evolved to encompass a more complex understanding of the interplay between interpersonal and intrapsychic experiences. Psychodynamic theories ask how relationships shape people's internal world, specifically how interpersonal experiences come to be internalized as aspects of personality. Conversely, psychodynamic theories also ask how the internal world affects relationships—specifically, how these internalized relationships color people's understanding of their interpersonal experiences.

Although there is broad agreement about the centrality of these questions, there is enormous diversity regarding the answers to these questions among the many schools of psychodynamic thought. This entry does not attempt to represent the breadth of these ideas, but rather describes three central principles about which most psychodynamic theorists could agree. First, psychodynamic theorists understand the formation of personality as beginning in the context of the earliest relationships (i.e., between caregiver and child). Second, these early relationships are thought to become internalized as representations of "the self in relationship to others," which guide subsequent interpersonal experiences, and these representations are continually elaborated by subsequent interpersonal interactions. Third, changes in thoughts and feelings are often achieved in the context of relationships. Each of these central principles is elaborated in this entry.

Understanding Relationships in a Developmental Context

Psychodynamic theories are based on a developmental perspective; childhood relationships with caregivers are thought to play a central role in shaping later relationships. Although Freud originally understood the child's relational needs to be secondary to the mother's capacity to gratify drives, subsequent theorists have elaborated the role of attachment needs as an equally significant force in development. One of the most prominent psychoanalysts to contribute to this understanding of early relationships was John Bowlby, who described babies as innately predisposed to become attached to their caregivers. The child's motivation toward establishing an attachment bond with the caregiver is an evolutionarily advanced system of survival; attachment behavior functions to maintain proximity to the caregiver to ensure protection and to have his or her needs met. If the caregiver is able to provide protection and reliable care for the child, then that child will internalize a sense of felt security. Through repeated interactions with caregivers, the child develops what Bowlby called *internal working models*, also commonly referred to as *object representations*, which are mental representations of oneself in emotional relationships with important others.

However, not all children are able to internalize representations of secure relationships, which results from an interaction among many factors, including the child's temperament, early experiences that disrupt a feeling of safety for the child, and the stage of development in which the disruption occurs. Sidney Blatt, for example, has articulated the relationship between the internalization of early experiences and the point in development at which the experience was internalized. If a child is neglected prior to internalizing a representation of the parent as separate from him or herself, the child may develop a representation of self characterized by a need to be merged with another person in order to combat intolerable feelings of separation and satisfy a need to be cared for, loved, and protected. If, at a later stage in development, the child has internalized a representation of the parent, he or she will be able to experience separateness from the parent without feeling empty. However, if the child experiences the parent as having a hostile

disappointment in the child's actions, the child may internalize a representation of self characterized by feelings of guilt, worthlessness, and exceedingly high expectations that leave the child filled with self-hatred for failing to do better.

It is important to note that the child's internalized experience of early caregivers is not thought to be equivalent to actual caregiver behavior, but rather that a caregiver's actions are one of several significant contributors to the trajectory of psychological development. A common misperception of psychodynamic theories is that they fail to recognize the importance of biological contributions to development—although the development of self-regulation is understood to be mediated through the relationship with the caregiver, it is certainly recognized that there are biological and temperamental underpinnings that either facilitate or complicate the caregiver's ability to create a feeling of security for the child.

Implications of Object Representations for Relationships

Many aspects of one's sense of self, such as thoughts and feelings, can be understood in a relational context (i.e., the feeling of guilt implies the presence of another person who has been failed), although this operates largely outside of awareness. As a result of developmental experiences, internalized object representations become dynamic templates for understanding the self in relation to others. In interpersonal exchanges, these object representations are evoked, often outside of conscious awareness, and they color one's perception of the exchange. For example, a person often belittled by a parent might perceive others as belittling even when that was not the other person's intention. It is important to note that the influence of internalized representations is thought to be tied to actual data from interactions with others, as opposed to a purely internally generated phenomenon (in the example, others may have displayed some characteristics similar to the parents, although not the belittling behavior). However, these attributions may or may not be supported by the actual interaction and are better understood as originating in internalized object representations. There is a growing body of empirical evidence in clinical,

social, and personality psychology, such as research on transference by Susan Andersen, that support these assumptions.

In psychodynamic terms, attributions about others' behaviors that are derived primarily from internal representations are referred to as *transference*. Although transference is often thought to be a linear "transfer" of feelings about one person (i.e., an early parental figure) to another (i.e., a current relationship, especially the therapist), psychodynamic theorists describe a more complex process. Transference arises when some aspect of the interpersonal exchange unconsciously evokes representations of prior relationship experiences, leading the individual's perception of the current interaction to be influenced by the prior relationship. For example, when a man with a history of abandonment by caregivers is told by his girlfriend that she will be out of town for 2 days, the external reality of a brief loss of contact with her may unconsciously elicit an internal representation of a lonely, abandoned self who was hurt by a cruel, abandoning other. In this context, the man's subsequent thoughts and feelings of upset and loss can be best understood as an interaction between his internal processes related to abandonment and the external reality of her actual leaving.

One question often raised has to do with the similarities between a psychodynamic understanding of object representations and a cognitive understanding of schemas. To be sure, there are a number of parallels between these two concepts. The difference, however, is that in psychodynamic models there is greater attention to the emotional aspects of these representations. Further, object representations are seen as having implicit or unconscious as well as explicit or conscious aspects. The implicit parts can be either simply outside of awareness or kept out of awareness for defensive purposes. For example, someone who has internalized an experience of him or herself as "cruel" may defensively keep this representation out of awareness by overcompensating, such as by acting overly nice and accommodating to others (which in psychodynamic terms would be called a *reaction formation*). This is not to say that the cruel representation is the "real" internal self-state and the nice representation is a façade; each would be regarded as an aspect of the individual's multifaceted

object representations. Rather, psychodynamic models posit that individuals may use one set of object representations to defend against other intolerable representations.

Although these object representations are thought to endure over time, this by no means implies that they are static and unchanging. In fact, representations are continually elaborated by subsequent interpersonal interactions. New experiences lead the individual to develop more differentiated representations that must be integrated into one's internal model of relationships. Thus, the interaction between internal processes and external reality not only influences understanding of current relationships, but also leads to more elaborated and differentiated internal representations that may modify the experience of subsequent relationships.

Change in the Context of Relationships

Psychodynamic theorists have placed particular emphasis on growth that occurs in relationships, noting that changes in thoughts and feelings are often achieved in the context of interactions with others. Although change in how one thinks and feels can occur through a number of processes, such as internal reflection, behavioral change, and individual life experiences, many types of relationship experiences may alter representations. Representations may adapt to the changing nature of relationships across time. For example, redefining relationships with parents as one develops into adulthood may correspond with change in representations of those relationships.

Change in representations may also occur through an especially strong emotional experience that disconfirms earlier implicit models. For example, significant interpersonal relationships with a spouse or child may lead to reconsideration of strongly held patterns of thoughts and feelings. Further, change may occur through repeated experience in other important relationships (i.e., respected peers, secure romantic partners, or a long-term therapeutic relationship) that disconfirm earlier acquired models. In other words, powerful change often occurs when one expects others to behave in particular ways but they don't.

Psychodynamic theorists place significant emphasis on the relationship with a therapist as facilitating change in representations. With a therapist, the patient can develop, resolve, and make efforts to redefine relationships with others and have powerful emotional reactions that disconfirm implicit representations. Two aspects of the therapeutic relationship are often stressed: (1) the importance of the emergence of transference, and (2) the mutative aspects of being in a real relationship with a caring and empathic other. The psychodynamic therapist facilitates emergence of transference by generally maintaining what is called *technical neutrality*, which entails remaining equidistant from all sides of a patient's conflict. To take the earlier example of an individual who is invested in a representation of self that is "nice" and unconsciously keeps a representation of self as "cruel" outside of awareness, the therapist would take a stance of technical neutrality by not judging either the nice or cruel aspects of the patient as good or bad. If the therapist were to reinforce the patient's "niceness," it would signal to the patient that "cruelness" is as dangerous and undesirable as unconsciously feared, and therefore would encourage the patient to keep that part hidden.

In fact, the goal of psychodynamic therapy is to help people bring all aspects of their internal representations into the relationship with the therapist so they can be integrated (rather than defensively split off) and the patient can experience him or herself in relationships with others as a coherent whole. The therapist helps the patient to integrate these disparate representations by using the emergent transference as a vehicle for helping the patient to understand relational patterns outside of awareness. For example, the therapist may note subtle ways in which the patient is acting cruel under the guise of being nice. Further, the therapist provides an experience for the patient that disconfirms earlier acquired models of relationships, such as the experience that his or her cruelty was not as toxic to relationships as had been feared and therefore need not be hidden. Last, by taking a nonjudgmental stance toward all aspects of the patient's internal experience, regardless of how bad or undesirable the patient may feel parts of it to be, the patient experiences the therapist as a secure base from which to explore his or her mind.

Conclusion

Although psychodynamic theories have much to offer in understanding the relationship between interpersonal and intrapsychic functioning, sadly the prominence of psychodynamic thought has been in decline; a recent *New York Times* article noted that the teaching of psychoanalysis is waning in psychology departments. Although there are several reasons for this, one reason is that many of the golden nuggets of psychodynamic thinking have become integrated into mainstream psychology—such as the importance of early childhood relationships, implicit processes, defensive functioning, and underlying dynamics—and are therefore no longer recognized as psychodynamic concepts. However, these concepts are central to the psychodynamic conceptualization of relationships, and to the extent that other theories of relationships integrate these concepts, they can be thought of as having psychodynamic roots.

PSYCHOPATHOLOGY, GENETIC TRANSMISSION OF

One of the strongest predictors of psychological problems in children and adolescents is the presence of psychological problems in one or both parents. Across the full range of diagnoses, parental psychopathology has been consistently associated with psychopathology in their offspring. For example, it has been widely documented that parental depression is associated not only with depression in their offspring, but also with behavioral problems and a variety of social, emotional, and cognitive deficits. Similarly, family studies have documented elevated rates of psychopathology in the children of parents with diagnoses of anxiety disorders, schizophrenia, antisocial behavior/conduct disorder, and alcohol/substance use disorders. Risk for psychopathology in offspring of parents with a psychological disorder is significant. Offspring of parents with schizophrenia are roughly 13 times more likely to have the disorder, compared with offspring of parents without the disorder, and offspring of depressed parents are two to three times more likely to suffer from major depressive disorder.

Given the risk for psychopathology in the offspring of parents with a psychological disorder, it has often been assumed that there is a direct environmental effect—the stress and environmental exposure to parents with psychological problems *causes* offspring to have more difficulties. Researchers cannot assume, however, that one phenomenon causes another simply because they are correlated, inasmuch correlation does not prove causation. This entry describes alternative hypotheses regarding the causes of intergenerational transmission of psychopathology, highlights relevant methods for teasing apart the causal processes underlying the intergenerational transmission, and briefly summarizes the current state of the empirical literature.

Complexity of Studying the Intergenerational Transmission of Psychopathology

Although it appears intuitive that parental depression may be associated with offspring psychopathology due to the environmental context, there

are other equally plausible alternative explanations for the association. One such explanation is selection factors, or third (confounding) variables, that influence both the parent and offspring generations *and* account for the association between the two. Historically, two main approaches have been used to investigate selection factors. First, studies have “matched” cases (samples of parents with and without psychological problems) on a number of variables thought to be possible selection factors, such as socioeconomic status, race, age, and other measured variables. Second, researchers have included as many measured selection factors as possible in their analyses of the effects of parental psychopathology to statistically “control for” selection factors. Regardless of the approach, it is difficult to know whether a study has included every salient selection factor.

Additionally, it is crucial to account for genetic factors in studies of intergenerational associations because biological parents provide the environmental context *and* transmit their genes to their offspring. Thus, parent–offspring associations may be due to environmental factors associated with parental psychopathology *and/or* genetic factors that contribute to the disorder in both generations. Thus, it is difficult to tease apart environmental factors from genetic factors that contribute to intergenerational associations. This is supported by many genetically informed studies that have documented that environmental and genetic factors are correlated. One type of genetic confound that can be problematic when studying the intergenerational transmission of psychopathology is passive gene–environmental correlation (rGE), which occurs when the same genetic factors underlying parental traits or behaviors (e.g., environmental risk factors) also influence child outcomes (e.g., depression). Although the presence of rGE renders most traditional family research uninterpretable, researchers have historically ignored the possible role of genetic factors when studying the effects of parental psychopathology.

Methods of Exploring the Processes Underlying the Intergenerational Associations

The classic twin study design has been used to understand the extent to which risk for psychological

problems are due to genetic and environmental factors. Twin studies provide a natural experiment, in that they allow researchers to compare children who share the same family environment but vary in their genetic relatedness. Identical twins share 100 percent of their genetic makeup, whereas fraternal twins share, on average, only 50 percent of their genetic makeup. Thus, if identical twins are more similar than fraternal twins on a given trait of interest, at least some genetic influence can be inferred given certain assumptions. Twin studies can provide broad estimates of genetic and environmental influences on a given trait; however, they cannot provide information about specific mechanisms contributing to the intergenerational transmission of that trait.

Other genetically informed approaches can provide insight into the underlying processes responsible for the intergenerational transmission of psychopathology. Adoption studies are useful in that they clearly separate the genetic risk that offspring receive (transmitted by the biological parents) from the environmental context (provided by the adoptive family). In adoption studies, several different comparisons highlight the importance of genetic and/or environmental factors. For example, the rate of disorder in adoptees can be compared to their biological and adoptive parents. If the adopted child is similar to his or her biological parent(s), genetic factors are implicated, whereas similarity to the adoptive parent(s) implicates the environmental context. Adoption studies are increasingly difficult to conduct, require that a number of methodological assumptions are met, and have several limitations, however.

An alternative genetically informative approach, the Children of Twins (CoT) design, circumvents some of the limitations of other research designs mentioned earlier. The CoT design is a quasi-experimental approach that affords the ability to examine the genetic and environmental processes responsible for the intergenerational transmission of psychopathology. The design is an extension of the classic twin approach, in which the genetic risk for psychopathology is essentially held constant while varying the environmental risk of being raised by a parent with a psychiatric diagnosis. This is accomplished by comparing the offspring of twin pairs who are discordant for the disorder—pairs in which one twin is affected (has the disorder) and the other is unaffected (does not have the

disorder). In the case of identical twins, offspring are genetically related to both twins (e.g., their mother and their aunt) to the same degree, but only the twin parent provides the environmental context. In other words, offspring of identical twins are genetically related as half-siblings (share 25 percent of their genes), but are raised in different households. Thus, researchers can determine whether the intergenerational association is explained by environmental processes related to exposure to a parent with a psychological problem and/or are the result of selection factors by comparing the offspring of discordant identical twins. Including the offspring of fraternal twins further allows for separation of selection factors into genetic and environmental confounds.

The CoT design also controls for unmeasured environmental factors that twins have in common (e.g., ethnicity, socioeconomic status, religious affiliation, educational attainment, shared child-rearing practices), which may be correlated with parental psychopathology. It is important to note that the CoT design does not provide complete control of genetic and environmental factors because it cannot control for environmental factors that are unique to each cotwin (e.g., characteristics of spouses). Some of these factors, however, can be identified, measured, and thus controlled statistically.

Empirical Evidence of the Processes Underlying Intergenerational Transmission

The following section reviews studies investigating whether intergenerational transmission of several common psychopathologies is accounted for by the environmental context of having a parent with psychopathology and/or genetic factors passed down from parent to offspring.

Schizophrenia

Several adoption studies have indicated that adopted children whose biological parent had schizophrenia are at substantially increased risk of having the disorder, suggesting that genetic factors help account for the intergenerational transmission. One of the most well-known CoT studies compared offspring of identical and fraternal twins

discordant for schizophrenia. The offspring of unaffected identical cotwins (i.e., the offspring were not exposed to a parent with schizophrenia) had the same risk of schizophrenia as the offspring of the affected cotwins. Because exposure to a schizophrenic parent did not increase the risk for the disorder in the offspring, the study provided strong evidence against a causal environmental theory of schizophrenia risk. Offspring of fraternal twins showed a different pattern because the offspring of the affected fraternal twin had higher rates of schizophrenia than the offspring of the unaffected twin. The overall pattern of results across study designs suggests that genetic factors account for the increased risk of schizophrenia among offspring of parents with the disorder.

Major Depression

Although there are numerous family studies of the consequences of parental depression, few studies have specifically explored whether genetic factors play a role. Three adoption studies have been conducted, with mixed results. However, the largest and most rigorous adoption study strongly suggested that genetic factors, and not environmental factors, were responsible for the increased risk of depression in the offspring of depressed parents. A recent CoT study suggests that the processes underlying the intergenerational transmission of depression may depend, in part, on the severity of the depression. For severe cases of depression, genetic risk shared by both generations appears to account for the transmission, whereas in less severe cases, environmental processes specific to exposure to a parent with major depressive disorder appears to account for the increased risk of depression in the offspring.

Substance Use Disorders: Alcohol

Adoption studies have yielded somewhat mixed results with regard to genetic versus environmental mechanisms of association between parental alcohol use disorders and substance abuse problems in their offspring. Nonetheless, findings seem to suggest that the intergenerational transmission of alcohol problems is *not* due to environmental factors specifically related to exposure to an alcoholic parent. Rather, other environmental factors that increase alcohol problems in both generations

(perhaps family attitudes toward alcohol) appear to be responsible for the intergenerational transmission. A recent CoT study of alcohol abuse and dependence similarly revealed that the direct environmental impact of being exposed to an alcoholic parent is modest at best. Consistent with the adoption studies, environmental factors (confounds) that influence both generations accounted for intergenerational transmission.

Conduct Disorder/Antisocial Behavior

Adoption studies of antisocial behavior suggest that there is a genetic component to the intergenerational transmission of antisocial behavior. This is suggested by a higher rate of antisocial behavior in the adopted-away offspring of biological parents with antisocial characteristics than in offspring of biological parents without these traits. It is important to note, however, that psychiatric diagnoses and family risk factors in the adoptive parents were also predictive of adoptee antisocial behavior. Adoption studies have also highlighted how genetic risks and environmental risks interact to confer substantially more risk for offspring conduct problems than just considering the risks independently. Adoptees who have genetic risk (indexed by biological parents with a history of antisocial behavior) *and* are exposed to environmental risks (indexed by family problems in the adopted family) were at substantially greater risk for conduct problems. Studies, therefore, must not only study how environmental and genetic factors act, but future research must also study their cumulative and/or interactive effects. A recent CoT study suggests that gender of the offspring may also play an important role: For male offspring, the intergenerational transmission of conduct problems is largely due to environmental factors, whereas for females, it is largely genetic in nature. This study suggests that additional variables (e.g., offspring gender) may influence the genetic and environmental processes contributing to the intergenerational transmission of psychopathology.

Summary

A growing body of research that explicitly tests the genetic and environmental processes underlying the intergenerational transmission of psychopathology

indicates that the intergenerational transmission of schizophrenia, depression, substance use disorders, and conduct disorder are all, at least partially, due to genetic factors passed down from parents to their offspring. All family studies that explore the intergenerational transmission of psychopathology are limited in their ability to account for potential selection factors. Because children cannot be randomly assigned to parents, it is impossible to definitely determine whether differences among children with affected and unaffected parents are due to direct environmental risk, genetic factors shared between generations, or environmental differences between families. Thus, converging evidence from designs that can disentangle co-occurring genetic and environmental processes is crucial. Certainly more research is necessary to study how genetic and environmental factors act and interact to increase the risk of problems in offspring of parents with psychopathology.

PSYCHOPATHOLOGY, INFLUENCE ON FAMILY MEMBERS

Psychopathology rates in the U.S. population are high. In a given year, about 22 percent of adults have a diagnosable severe mental disorder, 37 percent have a moderately severe disorder, and 40 percent have a mild disorder. Lifetime rates are even higher, with about half of adults meeting the criteria for a diagnosable disorder at some point in their lives. Studies using worldwide sampling produce slightly lower and yet still alarming rates of between 9 and 17 percent of the population experiencing an episode or more of mental illness in a given year. Thus, families face many challenges in adapting to life with and caring for significant others experiencing mental illness.

As care has shifted from institutions to the community and family, new challenges and opportunities exist in the care of those experiencing psychopathology. Indeed, an expanding literature documents the challenges and consequences for the family system when a member is diagnosed with a mental disorder. Although the form and severity of mental illness may vary, and the ill family member may vary (e.g., it could be a child, partner, sibling, parent), having a family member with a psychiatric problem presents a challenging circumstance for families. This entry discusses the effects of mental illness on the family, the ways in which families may cope with mental illness, and the manner in which families are involved in the treatment of mentally ill family members. In doing so, the entry focuses on factors that cut across type of mental illness and who the ill family member is. The entry deals primarily with severe mental illness. The impact on the family and the family's response may vary if the symptoms of psychopathology are less severe.

Effects on the Family

Recognizing that a loved one has a mental illness and is in need of care may be the first challenge for many families. Making this and subsequent aspects of the challenge more difficult may be the social stigma many families experience when a member is diagnosed with a psychological disorder. Indeed,

mental illness of a family member is most commonly viewed as a significant stressor that has emotional, behavioral, and psychological consequences for other members of the family. Although mental illness may be severe or mild, it is often persistent and thus presents family members with a unique and far-reaching challenge. Much in the lives of relatives is affected by the presence of mental illness in the family. Although the effects may vary based on the severity of the symptoms, after learning that a member has a mental illness, families may be called on to serve multiple roles with many demands. Such demands can push families into states of chaos. Family members may be called on to house the individual, provide direct care and/or supportive care, intervene in a crisis, manage medication and illness-related information, and navigate the mental health system. In addition to tangible demands, so-called “family burden” from mental illness often includes emotional challenges such as grieving (i.e., “loss” of who the individual was prior to the illness), the symbolic loss of hopes and wishes for the individual’s future that may be compromised, emotional ups and downs, and practical problems accompanying the illness, such as symptom-driven behavior, the challenges of caregiving, difficulty connecting or receiving services, and family disruption and stress.

Although families must navigate these new roles, families often feel ill-prepared and may experience inadequate assistance from hospitals, social workers, psychologists, and psychiatrists. Perhaps in response to this array of challenges, a plentiful literature has arisen in the form of articles in the media, self-help books, informational and support forum Web sites, and advocacy groups aimed at helping families (and service providers) cope with the variety of effects that mental illness in the family presents.

Mental illness can have a range of immediate and long-term negative effects on relationships. For instance, children raised in an environment influenced by mental illness often evidence behavioral problems, less appetite, less play, poor attention at school, and sleeplessness. Children whose parent suffers from psychopathology are also at risk for a number of negative outcomes, ranging from a less available parent to parental neglect. In these circumstances, although children may not

understand the illness, they may be forced to cope in an environment that is less than ideal for their own development. As such, children of parents with psychological difficulties are at greater risk for developing a mental illness than is the general population due to both increased genetic risk and their family experiences.

As children with a mentally ill parent suffer unique challenges, so do parents of children diagnosed with a mental illness. Parents may face substantial demands in caring for a child with psychological difficulties, including a disrupted household, financial strains, employment complications, extensive demands on their time, diminished personal or social life, and disruptions to relationships with romantic partners and among other children in the home. Parents of children with a mental illness may feel guilt or shame, and they may be confronted with a new reality for their child’s future, which often accompanies feelings of loss of hope for the future. If the illness is chronic, these stresses can compound, leading to a significant burden from which caregiver burnout is not uncommon.

Another relationship affected by the presence of psychopathology is the marital relationship or romantic partnership. Research has shown that relationship functioning and adjustment are particularly harmed. For instance, marital functioning and satisfaction often deteriorate, producing changes in the partnership and responsibilities, financial alterations, and a substantial sense of loss for one or both partners. Impairments in thinking and functioning of the partner with a mental illness also have implications for a changed lifestyle, altered roles, and uncertain future plans. Furthermore, a loss of companionship and intimacy, which may have been central to the relationship, often occurs. When one member of the romantic relationship experiences mental illness, the focus may shift from “us” to “him or her” as resources are directed toward the mentally ill partner. Although most research has examined mental illness as a consequence of divorce or breakup, some has looked at the effects of psychopathology on relationship longevity. These findings point to the higher rates of relationship dissolution among those who experience the onset of a mood, anxiety, substance, or conduct disorder during marriage, compared with those without psychopathology (in one study,

48.2 vs. 35.9 percent). Furthermore, many personality disorders are associated with an increased probability of marital disruption. Although no published research exists, some researchers have speculated that borderline personality disorder may be highly related to negative relationship outcomes. Finally, a new area of interest addresses the impact on marriage (and on the family) of veterans from the wars in Iraq and Afghanistan who are returning with alarming rates of post-traumatic stress disorder and traumatic brain injury.

Families Coping With Mental Illness

Less research has explored coping in families with a mentally ill member. As discussed earlier, relatives of individuals with severe mental illness commonly experience social, economic, psychological, and even health deterioration. These individuals are often burdened with significant caregiving responsibilities that can range from tangible care of daily living, emotional care and worrying, and active participation and encouragement to participate in therapeutic behaviors (e.g., medication adherence, therapy). Furthermore, additional factors such as stress, limited financial means, and poor community resources may exacerbate the deterioration that caretaking individuals experience. Families often cope with these challenges and new roles in different ways. Some may take behavioral action, for instance, by employing problem-solving behaviors, seeking support from others, seeking spiritual or religious support, or connecting with services for the family member and for themselves. Coping may also involve more internal strategies, such as positive reassessment or efforts to accept the situation. Alternatively, some may cope by trying to ignore the problem, engaging in distractions, or not seeking support and care from others. The extent to which these different strategies are adaptive is unknown, but it is likely that avoidance may be the least so. Further understanding adaptive coping strategies is an important area for research and will enable providers to more effectively assist families as they care for themselves and for the mentally ill family member.

By and large, research has not examined family and personal variables that might mitigate the effects of mental illness on the family or that may

produce resiliency in the family. For instance, do stress management styles or communication skills among family members improve the outcomes for family members and/or the mentally ill individual? Such information would allow providers to foster resilience through cognitive and psychoeducational approaches with the family.

Research has determined that it is not uncommon for families to cite greater strength, family bonds and commitment, knowledge, and skills as a result of coping with mental illness in the family. Families often describe themselves as more resilient after having dealt with psychopathology. Thus, it is important to acknowledge that, in addition to the burden that families face, having a family member with a mental illness may also present an opportunity for constructive change and personal growth.

Families and Interventions

The presence and expansion of family support and advocacy groups, family psychoeducation, and family therapy may aid individuals managing mental illness in their homes. There are also opportunities for families to act as allies in the treatment of the mentally ill family member. Systems theory and research on expressed emotion within families, for example, has offered new opportunities for families to aid in the treatment of those diagnosed with bipolar disorder. Another example of family involvement is in approaches to substance abuse treatment that merge drug treatment with family or couples therapy. Family involvement in the treatment of eating disorders has proved effective. For instance, family sessions have been shown to benefit those recovering from bulimia possibly because such family therapy addresses underlying problems that may contribute to the illness. Similarly, treatment for adolescents diagnosed with borderline personality disorder often includes parental involvement, as does treatment for childhood mood disorders, attention deficit hyperactivity disorder, and oppositional defiant disorder.

PSYCHOTHERAPISTS, RELATIONSHIPS WITH

The strength of the client–therapist relationship, often called the *alliance*, has been the most consistent predictor of treatment outcome across diverse types of psychotherapy. If the relationship is the major active ingredient, then any treatment approach can be effective provided the relationship is right. But what *is* the client–therapist relationship? Different theories of psychotherapy describe the relationship differently. This entry summarizes three prominent conceptual approaches to the client–therapist relationship: psychodynamic, person-centered, and psychometric. It concludes with some comments about recent research on the relationship.

Psychodynamic Concepts of the Relationship

Psychoanalytic and psychodynamic theorists, from Sigmund Freud onward, have focused on a distinction between the *real relationship* and the *transference*. As described by Charles Gelso and Jean Carter, the real relationship is characterized by genuineness and realistic perceptions. Genuineness involves being honest and open with the other. Realistic perceptions are understood as seeing the other clearly, in ways not distorted by transference or other psychological defenses.

Transference involves aspects of the therapist–client relationship that are transferred from earlier significant relationships, including inaccurate perceptions and expectations about the therapist. This may involve the repetition of past conflicts with parents or other significant people. Feelings and behaviors from these other relationships may be transferred into the relationship with the therapist. For example, a client who felt deprived by her mother may begin to feel deprived by her therapist. *Countertransference* refers to the therapist's reactions to the client's behavior in therapy, which may trigger the therapist's own past conflicts.

Both the real relationship and the transference contribute to the alliance, which is the basis for the work of psychotherapy. Primarily, the alliance is understood as the realistic joining of the client's reasonable self with the therapist's professional self for the purpose of therapeutic work. However, the working alliance may also incorporate positive elements from the transference, such as idealized expectations about the therapist's ability to help—the sorts of expectations children may have about their parents' ability to solve any problem.

Although all aspects of the relationship are important, psychodynamic interest has focused on the transference. The transference concept is a way of understanding how past hurts, including early relationships that interfered with or failed to support healthy development, can be manifested as problems in the present. Theoretically, the problematic relational patterns that brought the client into treatment are likely to be reexperienced and acted out within the therapeutic relationship. By understanding and correcting distorted feelings about the therapist, a client can resolve conflicts that have interfered with daily life outside of therapy.

Manifestations of the transference in treatment can be dramatic, and observations of transference phenomena have figured centrally in the psychoanalytic literature since Sigmund Freud's famous case studies of Anna O. and Dora. Psychoanalytic theorists have elaborated the concept of transference in many ways. For example, Heinz Kohut distinguished between *mirroring transferences*, in which the therapist is experienced as an extension of the self, as a twin, or as an appendage whose function is mainly to support the client's (unrealistically) grandiose views of the self, and *idealizing transferences*, in which the client draws strength or reassurance from being associated with an idealized therapist's exaggerated virtues. In this view, progress may come when the therapist fails to fulfill these unrealistic expectations. The client's resulting frustration brings the expectations into awareness, making it possible to examine and change them within the treatment.

Person-Centered Concepts of the Relationship

Person-centered theorists, starting with Carl Rogers, have tended to take a holistic, here-and-now perspective on the relationship. From a person-centered perspective, the therapist's job is to understand and accept client experiences—even those distorted by a history of problematic primary relationships—rather than seeking to judge or interpret them. Fully feeling, acknowledging, and communicating past experiences enables them to be considered and revalued in light of current reality. The value placed on any particular experience is up to the client, not the therapist or the theory. This conceptualization directs attention not to the history of the client's problems, but to the climate or conditions that the therapist provides within the therapy.

Carl Rogers proposed a series of therapist-provided *necessary and sufficient conditions* for therapeutic personality change. The three most often cited may be succinctly summarized as: (1) *be yourself*, (2) *trust the client*, and (3) *listen*. Collectively, they prescribe a quality of openness to experience—the therapist's own experience and the client's. They demand a tentative trust that the experience will not be overwhelmingly painful, and they underline the importance of creating a trustworthy environment.

These three facilitative conditions can be endlessly unpacked. As Rogers described them, the first condition (*be yourself*) involves genuineness, realness, or congruence. The idea is that the therapist is in the relationship, not putting up a professional front or façade. What the therapist feels, what is present in the therapist's awareness, and what is expressed to the client are all congruent with each other.

The second condition (*trust the client*) involves acceptance, caring, or prizing. In person-centered jargon, it is often called *unconditional positive regard*, meaning that the trust and caring come with no strings attached. The therapist is willing for the client to have whatever immediate feeling the client actually has—fear, anger, love, confusion, jealousy, pride, or whatever. The therapist prizes the client in a total rather than a conditional way.

The third condition (*listen*) is empathic understanding. This means that the therapist perceives and understands the feelings and personal meanings that the client experiences and communicates this understanding back to the client. Ideally, the therapist can accurately reflect experiences that the client is struggling to express even when the client can't quite find the words.

From a therapist's perspective, being genuine (and distinguishing this from switching the focus from the client to the therapist), accepting the client (who may hold beliefs or engages in practices contrary to the therapist's personal principles), and understanding empathically (when the client tells endless bland stories) can be difficult and taxing. Fortunately, person-centered theory suggests that perfect adherence to the conditions is not required. Approximations can be helpful, and beneficial effects of therapy can be expected to the degree that the conditions are fulfilled.

From the perspective of a therapist, the three conditions may seem distinct and even contradictory, but reviews of the research on the conditions have suggested that the conditions tend to blur together. From an observer's perspective, it can be difficult to distinguish the three conditions from each other or to distinguish them from a global positive evaluation. Nevertheless, a 2002 report of a task force on the psychotherapy relationship sponsored by the Psychotherapy Division of the American Psychological Association, listed genuineness, positive regard, and empathy among the

“demonstrably effective elements” or “promising and probably effective elements” of psychotherapy, based on accumulated research showing their association with positive outcomes.

Psychometric Concepts of the Alliance

In a seminal conceptualization, Edward Bordin characterized the alliance as encompassing three dimensions: (1) the emotional bond between client and therapist, (2) agreement on treatment goals, and (3) agreement on treatment tasks or means of achieving the goals. Subsequent researchers constructed scales to assess these and other dimensions, for example, using ratings on items like “I feel friendly toward my therapist” to measure bond or “I am clear as to what my therapist wants me to do in these sessions” to measure agreement on tasks. Results have typically confirmed that items with similar meaning tend to be rated similarly, so they can be grouped statistically on the same *factor*. The factors tend to be intercorrelated, however, rather than fully distinct.

The alliance has interested researchers because of its association with positive psychotherapy outcome. In the 2002 task force report on the psychotherapy relationship, the alliance was given pride of place among relationship aspects as the strongest and most consistent predictor of outcome. The research has not consistently supported the differentiation of the dimensions, however, and many researchers have used total or aggregate scores meant to assess the overall strength of the alliance.

Evaluations Versus Enactments

Researchers have often had difficulty distinguishing the subtle concepts that theorists have developed to understand the client–therapist relationship. The weak differentiation of Bordin’s three dimensions or Rogers’s three facilitative conditions is the tip of an iceberg. Theorists and clinicians use a far more complex repertoire of concepts than researchers measure. A distinction between *evaluation* and *enactment* of the therapeutic relationship can aid understanding of this research–practice gap. Whereas researchers tend to use terms like *alliance* and *relationship* to refer to evaluations (ratings on a scale), clinicians consider the client’s

relationship with the therapist as involving a variety of interpersonal activities (enactments).

Enactments of problems and solutions within the therapeutic relationship are far more complex than can be represented adequately on a small number of evaluative (positive–negative) scales. Each relationship involves specific content, specific behaviors, specific people, and specific events, and understanding of the particularities requires long-term observation of particular cases. For example, distinguishing between a mirroring and an idealizing transference is crucial in Kohut’s approach, but making this distinction in practice requires detailed contextual knowledge of the case.

Of course, global evaluation—the degree of positive or negative feeling—is part of the real relationship, the transference, empathy, congruence, trust, bond, and agreement on goals and tasks. Often the first thing people notice or want to know about a relationship is how good it is. But global evaluations gloss over the specifics of what makes relationships interesting, difficult, and, more important, therapeutic. Studying relationships in their contextual complexity will probably require theoretically guided case studies so that distinctions made by clinical theories can be compared with how the relationship is enacted in individual cases.

Developmental Concepts: The Rupture–Repair Hypothesis

Recent research has considered how client–therapist relationships fluctuate and change over time. For example, the alliance may fluctuate in connection with a therapist’s failures to understand something or a client’s resistance to facing painful memories. Or the therapy may go through stages as the relationship develops. An initially strong alliance may weaken as difficulties are encountered and later rise again in a more realistic reaction to the therapist.

One promising line of research focuses on *rupture–repair sequences*. Ruptures in the alliance may occur when previously hidden negative feelings emerge or when the therapist makes a mistake or fails to act as the client expects or wishes. Clients may then challenge the relationship by confronting the therapist or by withdrawing. Such ruptures may recapitulate the client’s relationship

difficulties outside of treatment. A rupture may offer an opportunity for valuable experiential learning in the here and now of the session, providing that the therapist recognizes the challenge and both parties work to repair the rupture. Researchers are developing methods for identifying rupture events using posttreatment interviews or by examining sequences of alliance ratings and session recordings. They then seek to describe steps in the task of repairing the ruptures.

Conclusion

The observation that evaluations of the relationship predict outcomes better than, for example, the therapist's use of particular techniques justifies the widespread conviction that the relationship is central to psychotherapy. Clinical concepts of the relationship are complex, subtle, and central to therapeutic practice.

PUBLIC POLICY AND RELATIONSHIPS

This entry describes the complex and intersecting connections between public policy and interpersonal relationships. The need for public policies that foster strong relationships, coupled with better capacity building in community settings, is stressed.

When leaders of social movements assert that “the personal is political,” they intend to underscore how individuals’ experiences of oppression in the workplace, at home, and elsewhere are rarely isolated events. Seemingly disparate experiences often stem from common systemic injustices, and collective opposition to those injustices can become a challenging force against them. This is no less true today than in earlier periods, as some of the most oppressed groups, such as immigrant families, children in poverty, and survivors of wars and natural disasters, struggle to find ways to organize a unified voice.

As a corollary to this rallying cry, it is also useful to consider the ways in which the political is personal. Indeed, public policies are often most acutely experienced at the personal level through their influence on relationships. Family relationships are affected by a range of policies, including those that impact the legal rights and economic well-being of families. For example, as tax incentives and related economic policies lead jobs and factories to relocate to less developed countries, unemployment in the abandoned communities can strain workplace relationships and family harmony and can leave taxpayers struggling to sustain basic municipal services. When schools, after-school programs, and youth service agencies are forced to “tighten their belts” as a result of local or national

economic decline, they find themselves stretching their limited resources in ways that diminish the fidelity of interventions and imperil the closeness and duration relationships. At the same time, “bottom line” federal school policies that reward a narrow range of performance goals often have the unintended consequence of reducing the quality and intensity of relationships in those settings.

Just as legislators need to recognize and take into account the implications of policies on supportive relationships, there is an onus on researchers to demonstrate the value of personal relationships and the ways in which they are affected by policies. There are countless issues (e.g., domestic violence, same-sex unions, classroom practices, foster care, incarceration, women’s reproductive rights, and divorce) that exemplify this connection, three of which are discussed next.

Domestic Violence

Feminists have long noted the ways in which public policies can influence women’s decisions to remain in violent relationships. For many years, domestic violence was considered a private family matter. This resulted in an anemic public response to the coercion, threats, isolation, and ultimately victimization that women were sustaining. Beginning in the 1970s, women’s advocacy groups engaged in activism and awareness campaigns that resulted in legal and social policy initiatives across multiple agencies (i.e., law enforcement, social service, corrections) and courts. At the same time, other policies have been enacted that have presented hurdles to leaving violent relationships. For example, immigration policies can interact with domestic violence or affect the economic resources of survivors (e.g., housing, benefits, Aid to Families with Dependent Children requirements) to effectively prevent women from leaving their violent partners.

Gay and Lesbian Couples

There is perhaps no more salient example of the intersection of policy and relationships than in the realm of same-sex relationships. Historic legislation governing the legality of same-sex marriage, civil partnerships, adoption, and access to fertility treatments has been adopted over the past decade and has affected the legal protections and benefits

that are afforded same-sex couples. In addition, in certain jurisdictions, same-sex couples’ right to become foster parents has been challenged while issues of their becoming adoptive parents have also come to the fore.

Vulnerable Youth at School

Although students’ connections with their teachers can make or break their school engagement and success, close and confiding student–teacher relationships tend to be more the exception than the rule. Given the way schools are structured, this is not surprising. Teachers have been increasingly saddled with additional obligations, and a growing emphasis on high-stakes testing has given rise to dense curricular demands, which have constrained teachers. There is unequivocal evidence that lowered student–teacher ratios are associated with improved student achievement and competence, and this is a straightforward means of improving teacher–student interactions. Similarly, educational policies that ensure more contact and continuity with teachers, such as multiyear teacher assignments, can provide students with the opportunity to forge close ties.

Scholars as Advocates for Human Relationships

Scholars have a key role to play in bridging knowledge on the vital importance of relationships in shaping developing outcomes. Several journals (e.g., *Future of Children*, *Research Into Practice*) and organizations (e.g., Child Trends, Child Welfare League, Public/Private Ventures) highlight this intersection. Yet in terms of solely advancing the importance of human relationships into the policy arena, there are fewer initiatives. Scholars sometimes unveil important and policy-relevant findings regarding human relationships (e.g., protective factors, role of informal social support), yet this information is rarely presented within a policy framework. A more concerted effort is needed to demonstrate this vital link, deploy policies that are more conducive to human relationships, and present opportunities, rather than impediments, to forging meaningful connections.

QUALITATIVE METHODS IN RELATIONSHIP RESEARCH

The term *qualitative methods* refers to a variety of open-ended and unstructured ways of collecting, analyzing, and interpreting data. Qualitative methods are used in relationship research when scholars want to gain an in-depth understanding of how participants perceive, make meaning of, and reflect on their own lived experiences. Qualitative methods are flexible and emergent. The researcher enters the data-collection process with some degree of focus. However, as unanticipated ideas and events occur in the field or during an interview, the emergent process gives permission to follow a new lead or create a new research objective. Some of the most common methods used to generate rich descriptions and deep insights include in-depth interviews, participant observation, case study, ethnography, participatory action research, document analysis, narrative analysis, discourse analysis, autoethnography, grounded theory, reflexivity, and focus groups. This entry identifies some of the unique assumptions, practices, and contributions of qualitative methods for relationship research.

Assumptions and Features of Qualitative Methods

Qualitative methods share certain features in common despite the wide variety across disciplines

and traditions. Common assumptions shared by the multiple kinds of qualitative methods include (a) triangulation, where several types of qualitative methods are employed to generate a storyline with multiple points of view; (b) thick description, where the researcher pays attention to every vivid detail and delves into a particular social world to richly describe relationship processes within broader cultural contexts; and (c) emergent theorizing, where a theoretical explanation of patterns in the data emerges from the process of gathering and making sense of the data.

The researcher is the primary instrument of qualitative data collection and interpretation because the researcher, to varying degrees, actively participates in and observes individual, couple, and family experiences in natural settings. Examples of naturally occurring settings include how private behaviors occur in public spaces, such as (a) conducting a participant observation study in a shopping mall to analyze how parents respond to a crying child; and (b) videotaping family dinnertime conversation to understand how beliefs about generational and gender privilege are demonstrated in verbal and nonverbal communication. Another primary mode of qualitative inquiry involves in-depth interviewing. Qualitative researchers ask open-ended interview questions such as “Tell me about a time when—” or “In what ways do you perceive—” when they want to understand how participants make sense of their lives. An example is an interview study in which a researcher asks newly divorced men how they feel about their ex-wives when they were married and now that they

are divorced. An in-depth interview, in which the researcher and the participant experience face-to-face interaction, can reveal more insight than a closed-ended survey, in which the response choices are predetermined and the participant is not engaged with the researcher.

Variability in Qualitative Traditions

There are many opinions about what is considered the best type of qualitative research practice. A key factor that contributes to this variability is the historical tradition of qualitative practice in particular academic disciplines. Sociologists and anthropologists have a long tradition of employing ethnographic strategies in which a social group is studied within their naturalistic setting. Ethnographers join the participants' world and try to understand their perspective from the inside out. An insider perspective is grounded in symbolic interactionist theory, which posits that meaning is co-constructed and shaped through social interaction. The goal of an interactionist account is to construct a compelling storyline. Interactionism and constructionism are theoretical frameworks used to guide researchers in the search for critical insights and new explanations about what has been seen as merely common sense or as yet invisible. When constructionist paradigms are used to guide research, typically only qualitative methods are employed.

In contrast, a qualitative researcher from a psychological tradition has traditionally been rooted in quantitative science, where concerns about validity, reliability, and generalizability are paramount. Much of the close relationships literature shares this tradition as well. Rather than using an emergent research design from the beginning, the qualitative component (e.g., open-ended questions or some participation in a natural setting) is adjunct to the major portion of the study, which is a quantitative research design. The dominant form of qualitative methods used in relationships research is more aptly known as a mixed-methods approach, which begins with a deductive statement about the relationships among variables. The qualitative (written) portion is used to supplement and give greater meaning to the quantitative (numeric) portion of the study. As more of the constructionist

and critical perspectives have made inroads into the relationship literature, more authentic examples of qualitative studies can be found.

Working With Qualitative Data

There are many ways to collect and analyze qualitative data. Researchers must consider whether to collect and analyze data in a linear fashion or simultaneously. Qualitative studies that follow the linear model have more in common with quantitative studies, in that they wait until one process is finished before they begin the analytic process.

The simultaneous process, where data collection and data analysis proceed at the same time, is most associated with the qualitative paradigm. Each new case is used to inform, refute, or refine the emerging data analysis. Simultaneous data collection and analysis are associated with grounded theory, the classic form of qualitative theory construction developed by Barney Glaser and Anselm Strauss. In recent descriptions, this style of theory generation involves three related processes. First, open coding is the initial step of breaking open segments in the raw data to begin to name them. Then the researcher searches for ways in which the codes can be grouped into more abstract categories. Second, axial coding is the stage of analysis in which an explanation is proposed of how the major categories and their subcodes work together. The goal of this process is to achieve theoretical saturation of categories so that no new information emerges that can further explain the category. Third, selective coding is the process of generating a theoretical storyline that explains the interconnections among all the categories.

Data analysis is a systematic process of data reduction. From a social constructionist perspective, the result is one of several possible and thus partial representations of the meanings that the analyst generates. The way that data are described in written reports reflects the researcher's approach to and beliefs about knowledge, that is, their epistemology. Although qualitative research is almost always coming from the interpretive and critical traditions, as noted earlier, some researchers may tend more toward a more scientific description, and others may tend more toward a constructionist description.

Regardless of the sequence of data collection and analysis, qualitative researchers must bring several acknowledged intellectual resources to the data analysis process. As a researcher sits down to read interview transcripts, field notes, journal entries, historical documents, and any other item that is included as “the data,” key ideas accompany this process. As Ralph LaRossa has said, there is no “immaculate perception” in qualitative data analysis. Codes are not embedded in the data just waiting to be discovered. Data analysis is a dialectical process where both induction and deduction are intertwined. To the data, the researcher brings key concepts from the theoretical frameworks that guided the study and a critical knowledge of the existing empirical literature on the particular topic under investigation. The research questions that have been used to shape the data-collection process are also present as the researcher begins the analysis process. Key to qualitative research, reflective awareness of how the researcher’s own hunches, passions, personal experiences, and insider’s knowledge about the topic is also integrated into the mix.

Reflexive Role of the Researcher

Reflexivity is one of the unique aspects of qualitative methods. In the qualitative paradigm, the researcher is an active participant in the research process. The researcher is not a silent partner, but is explicitly engaged in the entire research endeavor. Reflexivity refers to how the researcher critically and self-consciously reflects on the ways in which he or she is shaping the research process. Rather than ignore or deny the fact that a researcher will have an impact and a presence in the research setting, qualitative researchers are expected to openly acknowledge how their motives, beliefs, values, and commitments impact their work.

Research, then, is not an objective process, but one in which value judgments are made. These judgments need to be acknowledged, managed, and put to good use. Otherwise, they will unknowingly influence the research, often in harmful ways. For example, a researcher who is studying a population to which he or she does not belong (e.g., a middle-aged married man investigating unmarried teenaged mothers) should use a reflexive process to become aware of, and sensitive to, the ways in which his biases and privileges shape his perceptions of the

people he is “investigating.” Without this critical reflection, he will not be able to disentangle his own prejudices about “unwed teenage mothers” from what the young women are telling him about themselves. He will be more likely to treat his participants as objects or units of data, not as full human beings.

Reflexivity not only calls for theoretical and emotional sensitivity so that the people who are studied are treated in respectful and positive ways; reflexivity has many other advantages as well. Using a reflexive approach, a qualitative methodologist can build rapport with participants and ask deeper questions than would be possible on a closed-ended survey in which human beings are anonymous, voiceless, and invisible. A reflexive practitioner can use insider’s knowledge to gain access to research settings that might otherwise be closed to those considered outsiders. For example, a person interested in studying lesbian couples that are having their first child, either through insemination or adoption, may have more success recruiting a sample if they have insider’s knowledge of this population as well as credibility in terms of how to approach this group. Knowing where to advertise for sample recruitment is a key first step. Also, a reflexive methodologist is likely to work *with* and *for* groups who are marginalized, instead of just gathering data *about* them. The social action component of reflexivity is that researchers are not dispassionate about their work. Often the issues qualitative researchers study requires social change. Critical reflection on how and why to get involved in the change process is essential for examining motives and responsibilities. Reflexivity is a key strategy for researchers; they must ask themselves difficult questions so that they do not exploit those whose lives are under investigation.

QUANTITATIVE METHODS IN RELATIONSHIP RESEARCH

Of the various ways that scholars study relationships, the most common involve quantitative methods. The quantitative approach uses statistical procedures to identify trends or regularities in data, which are then examined to yield insights about the subject matter under investigation. A fundamental underpinning of the quantitative approach is that systematic statistical methods, when applied according to conventional standards, provide unbiased tests of the phenomenon or hypothesis in question. Quantitative researchers believe, “When in doubt, count.” In this respect, relationship research is built on the same empirical foundation as other quantitative sciences, spanning nearly all of the biomedical, behavioral, and social sciences.

Relationship researchers use quantitative methods in two general ways. Some studies are primarily descriptive—that is, data are collected from a reasonably large and presumably representative group of individuals and then aggregated, yielding

summary statistics. For example, the statements that the divorce rate among Americans married in the 1970s was approximately 50 percent or that women tend to be more emotionally expressive than men are intended to concisely describe general trends within these groups. Other quantitative methods, called *inferential methods*, are used to test hypotheses. This means that the researchers specify in advance the predicted nature of the association between two (or more) variables and then collect and evaluate data to determine whether the predicted association is correct. Usually these hypotheses are based on theory so that these tests amount to tests of the validity and usefulness of the relevant theories. For example, sociometer theory predicts that when individuals are rejected by members of a valued social group, their self-esteem will suffer. This hypothesis might be tested by comparing the mean level of self-esteem among rejected individuals with that of individuals who had not been rejected. If this test results in a so-called *statistically significant* difference between groups, the theory is said to be supported. A non-significant result implies that the theory was not supported, at least in this particular instance.

Quantitative methods are typically used with data collected from experiments, surveys, or archives, although in principle any data that can be quantified can be analyzed with these methods. A large majority of relationship researchers favor quantitative methods over other methods, such as qualitative methods, because quantitative methods are believed to be more objective. This is because quantitative methods rely on standardized procedures that in principle prevent, or at least substantially minimize, the likelihood of the researcher biasing the findings of research. Another reason that researchers favor these methods is their precision and elegance. With the right method, massive data sets assessing many variables from thousands of research participants can be represented in a reasonably efficient, clear, and informative manner. Indeed, for many researchers, the most fulfilling moment in the entire research enterprise occurs when years of thought and effort culminate in a statistical result. The major disadvantage of quantitative methods is that they do not allow research participants to describe the phenomena in question in rich detail from their own perspective (something that qualitative methods do well).

Quantitative statistical methods began to be developed in the 1870s, with the pioneering work of Sir Francis Galton, who sought a mathematical way to represent the influence of heredity. Others who were highly influential during this early period were Galton's protégé, Karl Pearson, who introduced the correlation coefficient; W. S. Gosset (known then as "Student" to mask his job at the Guinness Brewery), who introduced the *t* test; and Ronald Fisher, who further developed analysis of variance techniques. Since then, statistical methods have become vastly more complex and sophisticated, so much so that virtually all graduate programs involve extensive training in quantitative methods. Even then, many research projects require consultation with statistical specialists. There is little doubt that the contemporary growth of statistical theory, along with advances in the computational hardware necessary to carry out these tests, will continue and likely escalate these trends.

The remainder of this entry first reviews some of the basic quantitative methods used by relationship researchers. The subsequent section describes more advanced tools specialized for studying relationships.

Basic Quantitative Methods Used by Relationship Researchers

Among the most common quantitative methods in relationship research are techniques for comparing the central tendency in groups of individuals, most commonly the mean (or arithmetic average). The analysis of variance (ANOVA), which includes the well-known *t* test, is a flexible method for conducting such analyses. Essentially, ANOVA involves determining whether the actual mean difference between two (or more) groups is greater than would be expected by chance, which is determined by calculating the expected degree of variability in a sample. ANOVA can be used to compare preexisting groups (e.g., Americans vs. Chinese) or groups to which individuals have been assigned by the researcher. When these assignments are truly random, differing only in an experimental manipulation, ANOVA can be used to make causal inferences. For example, one might compare marital interactions following the viewing of a happy film as opposed to the viewing of a

sad film. Random assignment and the ability to infer causality is a prized feature in research, although many questions do not lend themselves to random assignment (e.g., spouses cannot be randomly assigned to be distressed or joyously in love with each other). ANOVA also can be used to examine the behavior of the same individuals at different times or under different circumstances, commonly called *within-person comparisons*. For example, developmentally oriented researchers often compare the same variables, such as the nature of friendships, at different ages during the life span, to examine processes of development.

Another common set of quantitative methods is correlational. Correlation coefficients quantify the degree to which two variables covary, such that increases in one are accompanied by simultaneous increases (in the case of a positive correlation) or decreases (in the case of a negative correlation) in the other. Correlations are particularly useful because they indicate not only whether two variables are associated, but also the relative magnitude of this association. For example, most studies find a relatively strong positive correlation between the marital satisfaction of husbands and wives. A correlation coefficient of 1.00 (or -1.00) indicates perfect one-to-one correspondence, whereas a correlation of zero indicates no correspondence at all.

Typically, correlational methods involve more than two variables. *Multiple regression* uses a composite of several variables to predict another variable, the notion being that several predictors, as long as they are not redundant, are likely to convey more information than any single predictor. For example, one might predict the likelihood of a marriage ending from measures of personality, economic well-being of the family, and the nature of spouses' interactions with each other.

A somewhat different family of correlational procedures is called *factor analysis* (similar in certain respects to *principal component analysis*). In these procedures, there are no predictors or outcomes; rather, the goal is to take a set of three or more variables and determine the underlying structure that characterizes how each variable relates to all of the others. This entails identifying a smaller number of factors (or principal components), which simplifies the researcher's task in two ways: One, a smaller set of associations is invariably easier to understand; and two, fewer factors are

easier to use in subsequent analysis. One common use of factor-analytic procedures is to reduce the number of variables obtained from a questionnaire. For example, the 20-item UCLA Loneliness Scale usually yields two factors: one for Social Loneliness (lonely feelings about one's circle of friends) and one for Emotional Loneliness (lonely feelings about a primary, special, and often romantic relationship).

More Advanced Quantitative Methods Used in Relationship Research

In contemporary science, all research areas have specialized statistical techniques that address complexities inherent in their particular subject matter. For relationship research, the most fundamental of these complexities stems from the fact that partners' behaviors are not independent of each other (e.g., one sibling's family-life satisfaction is not independent of another sibling's family-life satisfaction inasmuch as each influences the other and, moreover, each one's satisfaction may be based on the same underlying causes). Traditional statistical methods commonly assume independence of individuals within a sample. As a result, for use with samples that include individuals who interact with each other, relationship researchers have adapted existing methods not only to control these dependencies, but, more informatively, to generate insights about the ways in which relationship partners influence one another. Most researchers agree that this kind of back-and-forth influence is the central substance of a relationship. Rather than merely controlling for statistically biasing effects, then, the goal is to identify and understand them.

One increasingly popular tool is called *multilevel modeling*. Multilevel models build on the nested structure of certain phenomena, which means that the behavior of so-called lower level units reflects their common membership in a larger or higher order entity. For example, the behavior of students (the lower level unit) within a classroom (the higher level entity) likely depends on the characteristics of that classroom. Similarly, each individual family member may be influenced by the family as a broader entity. Multilevel models have proved to be particularly well adapted to

studying relationship phenomena. For example, they can identify how one family member's work stress may influence the emotional well-being of others. Another popular use of multilevel models is to analyze data collected by daily diary methods. In this protocol, research participants keep detailed records of relevant thoughts, feelings, and activity repeatedly over a number of days, eventually producing a sufficiently diverse sampling of moments and experiences to permit identification of theoretically meaningful trends. Multilevel methods are critical tools for extracting the most (and most accurate) information from such records.

A related method, called *structural equation modeling*, is designed to examine patterns of covariation (a concept similar to correlation) among multiple variables in a data set, with the ultimate goal of representing all of them in a single, parsimonious model. This technique differs from more traditional correlational methods, in which associations among a series of variables are examined one pair at a time. Instead, structural equation models simultaneously examine all pairs, determining which variables go together and which do not. The result is usually depicted in a schematic diagram in which variables are grouped together into sets preferably on the basis of an a priori theory, illustrating how each set relates to each other set in the obtained results. An oft-cited but seldom-used benefit of structural equation modeling is its ability to test competing theories, which it does by comparing which of them provides a better fit to the patterns of association observed within a data set.

One final method is called the Social Relations Model (SOREMO). Developed by David Kenny, SOREMO was first created for studies of social perception, but has proved to be valuable as well for studies of social interaction. Suppose that John likes Peggy. This observation might mean that John likes everyone (called an actor effect), that Peggy is liked by everyone (called a target effect), or that John likes Peggy specially, over and above these two more general tendencies (called a relationship effect). The importance of this method lies in the fact that each of these components describes a conceptually different phenomenon. By distinguishing them statistically, relationship researchers are able to better understand how people's behavior with particular partners reflects their own general proclivities, their partner's ability to induce

certain tendencies, or ways in which their interaction with each other is unique. This last component is believed by many researchers to be the hallmark of a relationship.

Conclusion

In all sciences, researchers use quantitative methods to derive evermore accurate and insightful understandings. Inevitably, just as new quantitative methods lead to new findings and theories, so do new theoretical advances compel the development of new methods for testing them. Thus, in relationship research, theory and quantitative methods develop symbiotically.

QUESTIONNAIRES, DESIGN AND USE OF, IN RELATIONSHIP RESEARCH

Questionnaires have been developed to assess many aspects of relationships. These include (a) characteristics of the individual's social network

such as size (e.g., number of relationships), nature (e.g., types of relationships), and frequency of contact; (b) evaluation of relationships such as social support and loneliness; and (c) measures regarding a specific relationship (e.g., marital relationship, parent–child relationship). Some of these measures are quantitative (e.g., number of specific behaviors toward another person, frequency of contact), whereas other measures involve the evaluation of the relationship (e.g., marital satisfaction, feelings of trust or intimacy).

This entry describes development and use of relationship questionnaires. The first section discusses the rationale for use of relationship questionnaires, followed by a review of methods used to develop measures and evaluate reliability and validity. A third section addresses issues concerning use of questionnaires in research and clinical settings.

Why Use Relationship Questionnaires?

Relationship questionnaires involve self-reports by the person regarding connections to other people. Such measures are easy and inexpensive to administer, and they yield information concerning the person's feelings and perceptions of their relationships that cannot be obtained in other ways. One possible problem with such measures is bias in the person's responses. For example, some individuals may want to be seen positively by others (i.e., social desirability); as a result, their relationships may be rated as more numerous or of greater quality than is true. Alternatively, other individuals may be too negative in their reports of relationships due to "dispositional negativity"; such persons may indicate that their relationships are fewer and less satisfactory than is true.

Due to these problems with self-report measures, some researchers have argued against their use, advocating for behavioral measures of relationships (i.e., observational assessments of interactions between individuals) or assessments by other social network members (e.g., their spouse). The problem is that such assessments are unable to capture the perceptions of the individual. For example, measures of relationship quality or feelings of loneliness cannot be based on the behavioral observations or perceptions of others. Furthermore, how the person perceives his or her

relationships may be more valid in predicting such outcomes as physical or mental health.

Development of Relationship Questionnaires

Writing Questions

A first issue involves the source of questions. In some cases, the theoretical conceptualization of a construct may determine questionnaire content. For example, many measures of social support are designed to assess different types of support (e.g., emotional or instrumental support) based on theory. Items would be included to assess each of these hypothesized types of support. In other cases, the items are derived from discussions with individuals regarding the concept being assessed. For example, items for the original UCLA Loneliness Scale were based on how individuals described the loneliness experience.

A problem that can arise involves item wording. If all items are worded in one direction, then individuals who tend to respond the same way will receive high or low scores. For example, assume all items on a measure of marital satisfaction are worded in a positive or satisfied direction. Individuals who tend to agree with any statement will receive scores indicating they are satisfied with their marriage. As a consequence, scores will reflect both marital satisfaction and “response sets” (i.e., the tendency to agree). To address this problem, relationship questionnaires will include some items worded in the opposite direction. For example, a measure of marital satisfaction would include items reflecting being satisfied and dissatisfied with the marriage. Responses to the dissatisfaction items would be reversed prior to computing a marital satisfaction score.

Another step in developing relationship items is selecting the response format. This reflects how individuals answer questions included in the measure. For example, respondents may indicate how much they agree with statements on a 9-point Likert scale, where 1 indicates *strongly disagree*, 5 indicates *neither agree or disagree*, and 9 indicates *strongly agree*. Another possible response format involves how often the individual feels the way described, ranging from *never* (1) to *always* (4).

Reliability

Reliability reflects the consistency or replicability of scores on a measure. Psychometric theory proposes that responses to questions are a function of two components: (1) level of the characteristic being assessed, and (2) random error. For example, responses to items assessing social support would reflect the individual’s “true” level of support and random error. The smaller the error variance, the more reliable are scores in assessing the person’s level of social support.

Items are often selected for a questionnaire based on how they affect the reliability of the measure. Initially, a large pool of items is developed and administered to research participants. Reliability is greater if responses to items are more highly intercorrelated. Items are eliminated when responses to that item are not correlated with the remaining items. A final set of items is selected where responses are intercorrelated (i.e., they measure the same construct), resulting in high reliability.

Another factor that affects the reliability of the measure is the number of items. Imagine that a researcher is observing a couple to assess its warmth and hostility. Accuracy is greater if the couple’s behavior is observed in a number of situations. Similarly, a marital satisfaction measure will be more reliable if it consists of 10 questions, rather than a single question.

Reliability is computed once a final set of items is selected. Coefficient alpha (α) is the measure of reliability typically reported. Alpha reflects the proportion of the variation in total scores due to the construct being measured; $1 - \alpha$ reflects the proportion of error variance. For example, an α coefficient of .80 indicates that 80 percent of the variance in scores is reliable, and 20 percent represents random error. An adequate level of reliability is typically $\alpha > .70$. Other forms of reliability are often reported for relationship questionnaires. Test-retest reliability is the correlation between two assessments separated by time (e.g., 6 months). Assuming that there has been no change in one’s standing on the relationship variable in question, then differences from a correlation of 1.0 reflects unreliability. This form of reliability assumes the relationship variable does not change over time; this may not be true.

Validity

Validity concerns what a questionnaire assesses (i.e., does it measure the construct?). For example, a valid measure of social support assesses the assistance from members in the person's social network that is received by the individual. There are four types of validity: content, criterion, discriminant, and construct validity.

Content validity. This involves whether the measure represents different aspects of the construct. Consider a social support measure. A content-valid questionnaire would assess different facets of support. Theoretical conceptualizations of social support determine the construct definition and the questionnaire content. For example, the Social Provisions Scale was developed based on the conceptualization of social support developed by Robert Weiss. Content validity for that measure is based on whether the items adequately assess the provisions described by Weiss. Evaluations of content validity are based on expert judgment. Different conceptualizations of the construct lead to different item wording and different criteria for content validity. An important issue concerns whether scores on measures of the same construct developed based on different conceptual models are correlated, indicating that the measures are assessing the same underlying construct.

Criterion validity. Demonstrating that scores are correlated with alternative methods of assessing the construct is the basis of criterion validity. One form of criterion validity is a "known groups" analysis, where individuals who should differ on the construct are compared. For example, a study might compare the marital satisfaction scores for couples that are and are not in marital therapy; lower scores should be found for the group receiving therapy. Another method is to correlate scores on the measure with another measure of the same construct that employs a different assessment method. For example, a spouse rating partner warmth could be correlated with an observational measure of spousal warmth. Finally, measures can be used to predict important relationship outcomes, such as marital satisfaction scores predicting subsequent separation or divorce.

Discriminant validity. This involves demonstrating that a measure assesses a distinct construct. Relationship measures are affected by a number of factors, such as social desirability (a desire to appear in a positive light), dispositional negativity (a tendency to respond negatively), extraversion, and depression. Discriminant validity would be supported by analyses demonstrating that the relationship questionnaire assesses a construct that is different from these other constructs.

Construct validity. This is referred to as the ultimate form of validity, where results using a measure are consistent with theoretical models concerning the construct. For example, models of coping with stress predict that social support should "buffer" the effects of stress. Finding that high levels of social support lessen the negative effects of stress on outcomes such as physical and mental health would support the construct validity of the measure.

Use of Relationship Measures

Relationship questionnaires are primarily used in research studies. Developing measures that are reliable and valid improves the quality of research. One issue that arises involves shortening the length of questionnaires. For example, it may be impractical to employ a 20-item loneliness measure in a large survey. Information on item-total correlations (i.e., between individual items and a total loneliness score) can be employed to select a smaller number of items.

Another issue involves the type of sample. Many relationship questionnaires have been developed using college students. Using the measure with other populations (e.g., elderly, less educated) requires ensuring that questions are understood by these individuals. Simplifying item wording and testing the reliability and validity of the measures for that population may be necessary. Similarly, the measure may need to be translated into another language. It is important to back-translate the measure to ensure that item meaning has not been altered in the translation.

A final use involves interventions with individuals experiencing relationship problems. Marital satisfaction measures are often used, and criterion scores have been determined indicating

the couple is experiencing problems. Alternatively, individuals may be identified for interventions to address their relationship problems (e.g., loneliness). An issue concerns what score represents a high level of loneliness. One method for identifying such individuals is to set a criterion based on normative data. For example, individuals receiving a score of two standard deviations above the mean or higher would be in the upper 2.5 percent of individuals on loneliness and would therefore be selected for the intervention. Alternatively, a criterion might be based on the scale items and knowledge about how much loneliness is problematic.

Conclusion

Developing questionnaires that are reliable and valid can enhance research on relationship issues. This discussion of reliability and validity is based on "classic measurement theory." New methods are being used in developing relationship measures, such as Item Response Theory. These methods may serve to further enhance the quality of

relationship questionnaires and improve the use of these measures.

R

RAPE

Although the definition of *rape* varies across jurisdictions, it can generally be defined as a specific type of sexual assault that involves penetration, force or threat of force, and lack of consent. A related term is *sexual assault*, which involves unwanted sexual contact that does not necessarily involve penetration. Although sexual assault is a broader term than rape, the two terms are often used interchangeably in research. Another related term is *sexual abuse*, which is a term often used to refer to unwanted sexual contact with a minor. This entry focuses on adult rape and sexual assault. It includes information on the prevalence of rape, factors associated with increased risk of rape, the effects of rape and treatments for rape trauma, characteristics of perpetrators, and rape prevention and avoidance. The entry also includes a section on acquaintance rape because most victims are raped by someone they know, often someone with whom they have a relationship.

Rape Prevalence

It is difficult to estimate the prevalence of rape because most rapes are not reported to the police. Therefore, relying on official statistics greatly underestimates rape prevalence. Studies that ask individuals if they have been raped also underestimate rape prevalence because many people who have experienced an event that meets the legal

definition do not define the event as a rape. The best evidence regarding the prevalence of rape comes from large-scale survey studies in which participants are asked behaviorally specific questions, such as “Have you ever had intercourse when you didn’t want to because someone threatened to use physical force if you didn’t cooperate?” Studies that use behaviorally specific questions indicate that 15 to 20 percent of women and approximately 2 percent of men in the United States will be raped in their lifetime. Not surprisingly, then, women fear rape much more than men do, and this fear significantly restricts women’s activities outside of the home. Despite the prevalence of rape, women underestimate their own risk and see themselves as at much less risk than other women.

Although much research on sexual assault has been conducted in the United States, violence against women, including rape, is a global problem. However, it is difficult to get accurate rape prevalence rates across cultures due to differences in research methods, definitions of violence, sampling techniques, and cultural differences that may affect respondents’ willingness to disclose such experiences.

Rape Risk

Several demographic factors are associated with greater risk of being raped. First, as mentioned, women are much more likely to be raped than are men. Age is a second risk factor: Most rapes occur

prior to age 25. For example, in one large study, of the women who reported being raped at some time in their lives, 54 percent were 17 years old or younger when they were first raped. A third demographic factor associated with rape risk is race. In a large national study in the United States, rape was most prevalent among American Indian/Alaska Native women and was least prevalent among Asian/Pacific Islander women.

Alcohol use also is a risk factor. Most rapes on college campuses involve alcohol use by the victim, the perpetrator, or both. In one large-scale study, women at most risk were those who frequently drink to get drunk. Studies of community samples of victims, especially those who seek help at an emergency department after the assault, also indicate that alcohol use is common among victims. Several factors contribute to this finding. For example, sexually aggressive men tend to target women who are drinking or intoxicated and also intentionally use alcohol (and occasionally other drugs) to impair a woman's ability to resist. In an effort to diminish their responsibility, perpetrators may also attribute their own behavior to the fact that they were drinking. Finally, alcohol use by men may make them more likely to misinterpret a woman's behavior as indicating sexual interest. In fact, some studies show a greater role for offender than victim drinking in sexual assaults.

A final factor that increases risk for sexual assault is prior victimization. For example, women who have experienced childhood sexual abuse are 2.5 to 3 times more likely to be sexually assaulted as adults. Many factors have been proposed to explain this relationship, but there is not clear support for any of them. One potential factor concerns deficits in risk recognition. For example, laboratory research suggests that women with multiple prior victimization experiences take longer to recognize risk when listening to a taped enactment of a sexual assault than women who have not been previously victimized.

Effects of Rape

The effects of rape are often referred to as *Rape Trauma Syndrome*. This term refers to a two-stage model of reactions to rape involving an acute phase and a reorganization phase. Although this

term continues to be used, particularly in legal decisions, subsequent research has conceptualized rape trauma in terms of specific diagnoses and symptoms, rather than stages of recovery.

For example, rape is an example of a traumatic event that can lead to post-traumatic stress disorder (PTSD) as defined in the *Diagnostic and Statistical Manual* of the American Psychiatric Association. Symptoms of PTSD include intrusive thoughts about the event, avoiding places or activities that remind one of the event, and hypervigilance to danger. The vast majority of rape victims meet the diagnostic criteria for PTSD immediately post-rape, and approximately 50 percent continue to meet the criteria at 1 year post-rape. Current PTSD prevalence rates among victims raped several years previously range from about 12 to 17 percent in the best-designed studies. Studies consistently show that rape victims report more symptoms of PTSD than do victims of other kinds of traumas.

Numerous studies have examined other negative psychological consequences of rape besides PTSD primarily among female victims. For example, compared with nonvictims, women who have been raped report more symptoms of depression, fear, and anxiety and higher rates of substance abuse, eating-disordered behavior, and risky sexual behavior. Women who have been sexually assaulted also are at greater risk of poorer health, chronic pain, and more physical symptoms (especially related to sexual health), compared with women who have not been assaulted. These differences can persist for years after the rape.

Factors that are associated with greater post-rape distress include having experienced a prior trauma (e.g., previous sexual victimization), self-blame, and greater use of avoidance coping (e.g., social withdrawal). Victims who receive more negative reactions from others following the rape (e.g., being blamed by others) and who experienced "secondary victimization" by medical or legal personnel (e.g., not being believed) also report more distress. Factors associated with less distress include greater use of cognitive restructuring as a coping strategy (e.g., trying to see the situation in a different light) and greater perceived control over the recovery process. Interestingly, male rape victims tend to report more distress than do female victims.

Other studies have moved beyond a focus on the emotional consequences of rape to investigating the social costs of rape. With regard to costs to victims, women who have experienced a sexual (or physical) assault are more likely to fall into poverty, become divorced, and become unemployed than those who have not experienced interpersonal violence. With regard to costs to society, one study estimated the cost of rape based on lost productivity, medical care/ambulance costs, mental health care services, police/fire services, social/victim services, property loss/damages, and effects on quality of life as approximately \$100,000 per incident for rapes/sexual assaults. Given the number of rapes in the United States, this amounted to an almost \$700 per year “rape tax” for every taxpayer.

Although there are clearly detrimental effects of rape on victims and on society, as is true of other traumatic events, a sexual assault can lead to positive changes in victims’ lives. These can include greater life appreciation, more concern for others in similar situations, better relationships with family members, reevaluating life and goals, becoming more assertive, increased involvement in social or political action, and increased spirituality. Factors associated with reporting growth post-rape include greater use of cognitive restructuring and less use of avoidant coping strategies, less self-blame, and more perceived control over the recovery process. Factors uniquely associated with growth (that are not also associated with less distress) include having more supportive friends and family and greater use of religious coping.

There are several effective treatments for PTSD. These include exposure therapy, cognitive behavior therapy, exposure plus cognitive therapy, and Eye Movement Desensitization and Reprocessing (EMDR) therapy. Medications can also be effective, with the selective serotonin reuptake inhibitors showing the best results. Exposure therapy and cognitive behavior therapy have the most support in studies of rape victims. In exposure therapy, the victim repeatedly confronts traumatic memories or feared situations that have become associated with the trauma. Cognitive behavioral therapy focuses more on identifying dysfunctional thoughts (e.g., self-blame) and replacing them with new, more adaptive thoughts.

Characteristics of Perpetrators

A large body of research has identified characteristics of men who are more likely than others to commit rape. These characteristics include greater hostility toward women, greater acceptance of rape myths, growing up in a violent home or experiencing abuse as a child, having friends who are sexually aggressive and who tolerate or encourage sexual aggression, believing that men should be dominant, and engaging in more impersonal sex.

Rape Prevention and Avoidance

Because of the prevalence of rape, particularly on college campuses, numerous rape prevention programs have been developed. Most of these programs focus on reducing rape myths, identifying risky dating behaviors, and increasing empathy for rape survivors. Although these programs typically result in short-term changes in attitudes, they have not been shown to be effective in reducing the actual prevalence of rape.

Although victims are not responsible for rape because women (as the primary victims of rape) still are at risk, it is important for them to be knowledgeable about effective resistance strategies. Research suggests that several active resistance strategies are effective for avoiding rape without increasing risk of physical injury, including forceful (e.g., biting, hitting, using a weapon) and nonforceful (e.g., fleeing, struggling) physical resistance. Forceful verbal resistance (e.g., screaming, yelling) also can be effective. Although more research is needed, it appears that resistance should match the strategy used by the perpetrator. In other words, if the perpetrator uses verbal threats, screaming may be enough to avoid rape, whereas if the perpetrator is physically attacking the victim, she or he may need to fight back to avoid being raped. However, even if resistance can be effective, this does not mean that it is the victim’s fault if she or he was unable to stop the rape.

Acquaintance Rape

As stated previously, most victims are raped by someone they know, including family members, acquaintances, and dates. However, men are more

likely to be raped by strangers than by someone they know. Thus, acquaintance rape is more common than stranger rape overall because women are more likely to be raped and are more likely to be raped by someone they know than by a stranger. One reason that acquaintance rape is so common is that women tend to resist much less when attacked by acquaintances, and they are thus less likely to avoid being raped. However, college women were more likely to respond assertively to sexual aggression by acquaintances if they were not concerned about preserving the relationship, if they felt angry and confident, if they engaged in less self-blame, and if they had greater resentment. These findings need to be incorporated into rape prevention programs. Finally, although some critics argue that acquaintance rape is not a serious crime, acquaintance rape is no less traumatic to victims than is stranger rape.

RAPPORT

Rapport is a fundamental characteristic of well-functioning human relationships. Relationships in

which individuals experience rapport are characterized by mutual liking, trust, empathy, comfort, responsiveness to the other's needs, and self-reported feelings of closeness and harmony. An individual experiencing rapport with another might also report that he or she feels "in sync" with that person or that the two have connected or "clicked."

Rapport can be experienced in any type of relationship. Long-term relationships, such as familial relationships or the relationship between an individual and his or her partner, are almost certainly characterized by some degree of rapport. However, rapport is not unique to relationships where there is a high degree of codependence over extended time periods; friends, acquaintances, colleagues, teammates, and coworkers can also experience rapport. Even strangers can develop rapport, assuming they have some time and a reason to interact (e.g., students unknown to one another who are assigned by their professor to work together for a course project).

Strategies for Developing Rapport

There are many strategies that people can use to develop rapport with others. Some of these strategies are deliberate, meaning that people use them intentionally and with awareness; for example, people could make a conscious effort to share personal information with others and invite them to do the same in an effort to find things shared in common, which would create feelings of interpersonal closeness and harmony. People might also engage in similar behaviors as a relationship partner or choose to use similar phrases or words. Nonverbal behaviors can also be used deliberately to create a feeling of intimacy with another person; individuals might intentionally smile frequently, make eye contact, or exhibit other engaging behaviors (e.g., looking attentive, leaning forward, using open body posture). All of these behaviors foster positive feelings between people, and they can be purposefully used to accomplish this objective.

More often than not, however, feelings of rapport are a result of behaviors enacted outside of awareness that create feelings of closeness with another. These unconscious behaviors are almost

always nonverbal, and they are called unconscious because they are effortless and occur without awareness, intention, or deliberate control. For example, research has indicated that when interacting with another person, people will often display similar facial expressions, emotions, intonations, and speech rates all without consciously realizing they are doing so. Another unconscious strategy for creating rapport is behavioral mimicry, which is sometimes called mirroring or the chameleon effect. Like a social chameleon, behavioral mimicry occurs when individuals “blend in” to their relationships and their surroundings by adopting the postures, gestures, and mannerisms of their interaction partners. This behavioral imitation usually happens unconsciously; in fact, most people believe (correctly) that if they are “caught” consciously imitating the behaviors of others, hostility or other negative consequences will follow. On the contrary, imitation without awareness or recognition is usually regarded as positive.

Regardless of whether strategies for developing rapport are used consciously or unconsciously, the experience of similarity that results from sharing emotions and behaviors in common with another person is a powerful contributor to feeling in sync or harmonious with that person, and therefore aids in the development of feelings of interpersonal closeness and rapport. In addition, similarity of any type is often a strong predictor of whether two people will develop a lasting relationship.

The Relationship Between Behavioral Mimicry and Rapport

There is a strong relationship between exhibiting similar behaviors as those of interaction partners and the development and maintenance of rapport. For example, parents imitate the behaviors of their children, and students tend to mimic the behaviors of their teachers. In both cases, the degree of observed behavioral mimicry is positively related to self-reported ratings of rapport and being in sync with the other person. Counselors who mimic the behaviors of their clients are also better liked than counselors who do not do so perhaps because of the empathy that is created from this shared experience.

Behavioral mimicry does not just occur in relationships that have already flourished; people also

mimic the behaviors of complete strangers. This is especially likely to occur in situations where people are trying to affiliate. Recent research has indicated that when people are pursuing affiliation goals, they mimic the behaviors of an interaction partner more than if they do not have an active affiliation goal. People also mimic the behavior of interaction partners more when they have recently been socially excluded or ostracized and are trying to recover from this negative experience.

The Importance of Rapport in Human Relationships

Rapport is not the only positive consequence of behavioral mimicry; mimicking others also leads to liking, trust, feelings of closeness, and helpfulness, all of which contribute to the experience of rapport with another person. Moreover, because mimicry is more likely to occur in situations where it is useful or beneficial to the person who engages in it (e.g., when people try to make a favorable impression on someone of higher status or when people interact with others who share group memberships), it is both functional and adaptive in a number of ways. Yet the importance of rapport in human relationships is demonstrated most by the fact that mimicking the behaviors of others often happens with intention or conscious awareness; if people had to think consciously about how to develop rapport with all the important people in their lives, they would have little time left in the day to accomplish other tasks that are crucial for survival. In other words, the fact that people have developed and engage in unconscious behaviors that help them to create rapport with others suggests that the development of rapport in human relationships is critical.

REASSURANCE SEEKING

Reassurance seeking is the act of going to others to request assurance that one is lovable, worthy, or in other ways adequate. Unlike *support seeking*, which is a normative and often formative component of interpersonal relationships, reassurance seeking is generally construed as maladaptive, especially when exercised in excess.

The majority of research on reassuring seeking has focused on the related construct of *excessive reassurance seeking* or the tendency to repeatedly seek reassurance from others despite their previous attempts to provide it. This construct is best known in the context of James Coyne's Interactional Theory of Depression. According to this model, mildly depressed individuals request reassurance from others that they are worthy and lovable. Others initially provide reassurance, but the depressed person, noting the discrepancy between the reassurance and his or her own negative self-concept, feels it is not genuine or is motivated by pity and again seeks reassurance. Eventually, the other person grows tired of repeatedly providing reassurance and begins to act rejecting. The reassurance seeker notices the rejection and becomes more depressed, and the cycle continues.

Thomas Joiner and colleagues expanded on Coyne's model, identifying excessive reassurance seeking as the active agent in this process. They proposed that people with a tendency to excessively engage in reassurance seeking set in motion a process leaving them at risk for both depression and interpersonal rejection. Research has supported these ideas. A recent meta-analysis of 38 studies found that excessive reassurance seeking was positively related, concurrently, to both depressive symptoms and interpersonal rejection. Studies also show that people who engage in excessive reassurance

seeking tend to experience increases in rejection and depression over subsequent weeks and months, providing evidence that excessive reassurance seeking is not only concurrently associated with depression and rejection, but also might lead to the development of symptoms in the future.

Since Joiner and colleagues' initial work, numerous studies have examined different aspects of excessive reassurance seeking, including its association with related interpersonal constructs, clinical implications, and neurological underpinnings. Although most research has examined excessive reassurance seeking in college-age community samples, emerging research has replicated findings in children, adolescents, and adults, as well as in clinically depressed samples. In addition, the link among excessive reassurance seeking, depression, and rejection has been tracked across different relationship types (including romantic relationships, friendships, classmates, and college roommates).

The association between excessive reassurance seeking and psychopathology is relatively specific to depression; unique associations to other symptoms (e.g., anxiety, eating disorders) have generally not been found. Excessive reassurance seeking also is implicated in *depression contagion* or the tendency of people who spend a lot of time with a depressed person to become depressed. For example, one study showed that associations between depression scores of participants and their romantic partners were most strong among participants who were high on excessive reassurance seeking. Overall, research on the role of excessive reassurance seeking in depression has demonstrated the importance of interpersonal relationships in the development, maintenance, and exacerbation of depressive disorders. Further research is needed, however, to verify the more specific tenets of Coyne's model. In addition, given its role in maintaining and worsening depression, reducing excessive reassurance seeking may be an important goal of psychotherapy; as such, interventions designed to do so should be developed.

Although the majority of research on reassurance seeking has centered on Coyne's theory, the concept of reassurance seeking is relevant to other theoretical models. For example, Attachment Theory holds that children develop internal models of self and others based on experiences with caregivers. If the caregiver is consistent in providing

support and validation in childhood, the individual eventually learns to internalize this and can usually self-reassure, rather than having to seek reassurance from others. If the caregiver is inconsistent in providing validation, however, the individual develops a negative model of the self, fails to learn to self-reassure, and thus seeks reassurance from others. This relational style is known as anxious (or preoccupied) attachment. Supporting the link between anxious attachment and reassurance seeking, one study found a positive association between excessive reassurance seeking and measures of preoccupied attachment. Another study found that excessive reassurance seeking was related to depression only because of its relationship to anxious attachment. In addition, reassurance seeking is relevant to the construct of interpersonal dependency. Because they feel unable to care for themselves, people with a dependent personality have an excessive need for reassurance and often put themselves in unpleasant situations or act overly compliant to receive approval from others. Studies have shown that dependency and excessive reassurance seeking are positively correlated. Further research has suggested that excessive reassurance seeking may explain the link between depression and sociotropy (a personality trait associated with excessive dependency and the desire to please others) because sociotropic individuals excessively seek reassurance, which in turn leads to depressive symptoms.

RECIPROCITY, NORM OF

Alvin Gouldner postulated that the *norm of reciprocity* (i.e., the implicit or explicit expectation that individuals will behave prosocially and refrain from behaving antisocially toward others who have behaved prosocially toward them) is universal across human societies. Gouldner reasoned that the norm of reciprocity is buttressed by societal moral codes and, in turn, helps buttress societal structures. This entry examines the evolutionary basis for the norm of reciprocity, as well as the norm of reciprocity across human relationships.

Evolutionary Basis for the Norm of Reciprocity

Robert Trivers ushered in a new era for evolutionary studies of cooperative partnerships with his classic paper entitled “The Evolution of Reciprocal Altruism.” Trivers put forth the simple hypothesis that altruism (helping others at a cost to oneself) evolves by means of natural selection provided that the fitness costs for behaving altruistically are returned to the altruist in the future (i.e., reciprocity). From an evolutionary point of view, if a donor’s fitness costs are low while the fitness benefits to the recipient are high, reciprocal altruism is more likely to evolve provided the low-cost favor is returned at a later date. Furthermore, specific conditions are required for reciprocity to spread throughout a population—namely, a long life span, memory of who was a reciprocator, and repeated interactions. Since Trivers’s classic paper, there have been hundreds of mathematical models and empirical studies on reciprocity from an evolutionary perspective.

The most novel and counterintuitive theoretical advancement on Trivers’s theory in recent years is David Haig’s proposal that intrapersonal reciprocity

exists between genes *within* the organism. Haig hypothesized that genes within an organism have conflicts of interest over their phenotypic expression and that such internal genetic conflicts could be resolved via reciprocal agreements between the conflicting genetic elements. Selection for reciprocal agreements between genes may have been particularly strong because such gene expression inequities within the organism can lead to major developmental disorders for the individual. According to Haig, reciprocity may evolve more easily within than between organisms.

Questions remain about whether reciprocity is common in nature, and some researchers may question whether reciprocity is a human universal (i.e., found in all cultures and social relationships). Evidence that reciprocity is not a human universal could lead one to erroneously conclude that it must not be an evolutionary adaptation. However, universality is not necessarily a hallmark of adaptation. It is also possible to have adaptive variation in a population (e.g., in some cases, not all individuals will share the same cognitive mechanisms because of differing ecological and life history contexts).

The Norm of Reciprocity Across Human Relationships

Elaine Walster, Ellen Berscheid, and G. William Walster drew on Gouldner's norm of reciprocity in formulating their version of Equity Theory. For example, Equity Theory proposes that, within every human society, it is expected that individuals will behave prosocially toward others who have behaved prosocially toward them. Within families, results of empirical studies suggest that not only do adults reciprocate emotional acceptance toward their spouses, but adults also reciprocate emotional acceptance with their offspring. Through words and deeds, adults directly and indirectly teach the norm of reciprocity to their offspring. In turn, as offspring make the transition from childhood to adulthood, offspring typically develop romantic relationships via reciprocity of self-disclosure and maintain romantic relationships via reciprocity of emotional acceptance.

By the same token, drawing on Walster, Berscheid, and Walster's Equity Theory, Margaret Clark and Judson Mills distinguished conceptually and

empirically between exchange orientations (whereby individuals are expected to give benefits in response to partners' giving of benefits) and communal orientations (whereby individuals are expected to give benefits in response to partners' need for benefits). Clark and Mills argued that nonintimate relationships tend to reflect exchange orientations, whereas intimate relationships tend to reflect communal orientations. However, Clark and Mills acknowledged that one might find exchange as well as communal orientations in intimate relationships.

The communal versus exchange orientation is not the only dimension on which intimate relationships may be distinguished from nonintimate relationships. For instance, nonintimate relationships tend to involve similar commodities or resources, whereas intimate relationships involve resources that are not necessarily similar. Moreover, nonintimate relationships frequently are limited to giving and receiving of resources over a relatively short period of time, whereas intimate relationships frequently involve giving and receiving of resources over a relatively long period of time.

At first glance, gift giving seems to violate the norm of reciprocity. After all, gift giving may occur in nonintimate as well as intimate relationships, and gift giving need not reflect a response to partners' giving of gifts or to partners' need of gifts. Nevertheless, at least in intimate relationships, gift giving may well involve reciprocity over the long-term. In fact, to the extent that gifts cannot be repaid, individuals may perceive their relationships as inequitable.

Conclusion

In the years since Gouldner published his classic paper on the norm of reciprocity, many evolutionary and social psychologists have incorporated the norm of reciprocity into their theories and research. Indeed, studies of personal relationship processes provide considerable support for the norm of reciprocity. Future researchers might find it useful to focus increasingly on the limits of the norm of reciprocity in explaining the dynamics of particular types of intimate relationships (e.g., platonic vs. romantic relationships, same-sex vs. opposite-sex relationships).

RECIPROCITY OF LIKING

Reciprocity is a central feature of human relationships. The ethic of reciprocity is espoused by nearly every major religion, and human culture would grind to a halt if people did not routinely exchange goods, services, and other benefits with one another. *Reciprocity of liking* (also called *reciprocity of attraction* or *reciprocal liking*) is a particular type of reciprocity that refers to the tendency for people to like others who express liking for them. Reciprocity of liking is a key principle of attraction; at times, it has even been called a cultural truism. This entry reviews research and theory about reciprocity of liking.

Theoretical Explanations

Many major social-psychological theories predict the emergence of reciprocity of liking. When our interaction partners like us, they treat us in ways that maximize our rewards and minimize our costs. Interdependence Theory predicts that we will like people with whom we have such gratifying interactions. Indeed, the simple fact that another person likes the self is rewarding because it validates that the self has likable qualities. In

addition, people who like us often want to continue interacting with us in the future. Therefore, they may reward us by providing costly support in times of need, assuming that we ourselves might later reciprocate the support. In this sense, liking and helping are linked, and social exchange theorists suggest that, because individuals tend to reciprocate helping behaviors, this tendency should extend to the reciprocation of other benefits such as liking.

Balance theory, which emphasizes people's desire to maintain a cognitively consistent state, also predicts the emergence of reciprocity, at least for people who like themselves. That is, cognitive consistency is achieved when self-likers like those who like them. Intriguingly, cognitive consistency is also achieved when self-dislikers like people who *dislike* them. Reciprocal liking should therefore be less pronounced for individuals with low self-esteem, and, in fact, some evidence for this prediction has been found among married couples.

Finally, when someone likes us, it signals his or her willingness to provide care and support; Attachment Theory predicts that we will like such supportive individuals and provide care and support for them in turn. There is no shortage of theoretical explanations for the existence of reciprocity of liking.

Experimental Evidence

Researchers have tackled two central empirical questions regarding reciprocity of liking. The first question is causal: If A expresses liking for B, does this cause B's liking for A to increase? Psychologists first derived support for this prediction almost half a century ago. In an initial study, participants were led to believe in advance of a group discussion that certain members of the group (chosen at random by the experimenter) would probably like them. After the discussion, participants expressed more liking for the group members who they believed liked them. Other research found evidence for this causal pathway using the *bogus stranger* paradigm, in which participants did not meet face to face, but instead viewed questionnaire responses from another "participant." Participants' liking for such an unknown stranger correlates positively with the amount of liking the

stranger expresses for the participant on the questionnaire. In addition, the more attractive the stranger is, the greater the impact that stranger's liking has on participants' reciprocated desire. That is, when we find out that an attractive person likes us, we are especially likely to reciprocate that liking. Finally, there is also evidence that likers (i.e., people who like others, in general) are themselves well liked by participants. In studies in which targets express liking for many other individuals (e.g., politicians, cafeteria workers), participants tend to like those targets more than targets who express liking for few other individuals. In general, the experimental data support the prediction that liking causes liking: We do indeed like people more when we learn or infer that they might like us.

In romantic contexts, the possibility of not being liked is often especially salient. People are loath to risk romantic rejection, and experimental research has found that people are reluctant to initiate romantic overtures without some indication that the desired other might like them in return. For example, some evidence suggests that a small proportion of men (3 percent) would be willing to ask a woman who they desired out on a date if she had not indicated any interest in him. In a classic study conducted by Ted Huston, men who did not know for sure that an attractive woman would say "yes" to a date with him were less willing to risk asking her out (compared with men who were assured acceptance). For many people, some evidence of reciprocal liking is a critical precursor to initiating any overt romantic gesture.

Reciprocal Liking in Natural Social Contexts

There is a second empirical question regarding reciprocity of liking: Do the people we like in the course of our everyday lives tend to like us as well? As it happens, many early studies found that such reciprocity correlations (A's liking for B correlated with B's liking for A) were surprisingly low, often near zero. Reciprocity correlations did appear to be larger for participants who had known each another for a longer (compared with a shorter) period of time, but even in these cases, the correlations were small to moderate in magnitude. Adding to the confusion was the abundant

evidence that participants overwhelmingly *assume* reciprocity. That is, people tend to believe on average that their liking for someone is reciprocated, and many studies that professed to offer evidence for reciprocal liking used designs that offered strong evidence for assumed reciprocity, but little evidence for actual reciprocity of liking.

David Kenny, in developing the social relations model in the early 1980s, offered an explanation for the low naturally occurring reciprocity correlations. He noted that a simple correlation between A's liking for B and B's liking for A actually confounds two different kinds of reciprocity. The first is called *generalized* reciprocity: If A tends to like everyone on average, is A well-liked in return? In other words, there are individual differences in the tendency to like and to be liked, and these individual differences could be correlated and would therefore influence a simple reciprocity correlation. The second is called *dyadic* reciprocity: If A uniquely likes B (above and beyond A's tendency to like everyone and B's tendency to be liked by everyone), does B uniquely like A? When these two types of reciprocity are examined separately, the data typically reveal rather weak generalized reciprocity correlations, but strong dyadic reciprocity correlations. That is, there is only a weak tendency for likers to be well-liked (which contrasts somewhat with the experimental evidence described earlier), but people's unique liking for each other is likely to be reciprocated. Furthermore, it is the dyadic reciprocity correlation in particular that increases with the length of the relationship. When researchers calculated the simple correlation between participants' liking for each other, this procedure inadvertently combined a strong dyadic correlation with a weak generalized correlation. Once individual differences in people's tendency to like and be liked are separated from the unique liking that people experience for one another, we do find evidence for a healthy amount of (dyadic) reciprocity in people's naturally occurring relationships.

To separate generalized from dyadic reciprocity using the Social Relations Model, researchers must employ an intensive design in which participants report their liking for many other participants and are reported on many times. Until recently, all such studies had examined platonic liking; there were no data on naturally occurring reciprocity of *romantic* liking. However, with the advent of

speed dating and its emergence as a research method, scholars could now use the Social Relations Model to examine romantic reciprocity. Speed dating employs a design in which romantically available individuals meet one another on brief dates and decide whom they would or would not be interested in meeting again. One recent speed-dating study found evidence for dyadic reciprocity: Even after a brief 4-minute date, speed daters' unique romantic liking for one another tended to be reciprocated. Curiously, generalized reciprocity in this study turned out to be negative, indicating that participants who experienced strong romantic liking for the other speed daters on average were not well-liked. These data suggest that, within the romantic domain, only selective liking is reciprocated, whereas unselective liking is actually not reciprocated.

Finally, there is also evidence that reciprocal liking stands out for participants in their memories of falling-in-love experiences. People often report that they learned that another person romantically desired them shortly before developing affectionate feelings in return. In fact, reciprocal liking plays a more prominent role in people's falling-in-love memories than any single other variable, including similarity and the presence of desired characteristics (e.g., good looks, appealing personality) in the partner. Reciprocal liking also plays a prominent role in participants' memories of falling in friendship, although it is typically more pronounced in falling-in-love experiences. Although romantic liking may only be reciprocated when it is selective, as discussed earlier, it still seems to be a critical ingredient in sparking many, if not most, romances.

Desire for Reciprocal Liking

Reciprocal liking is one of the central principles of attraction, along with similarity, familiarity, proximity, and physical attractiveness. (Of course, this is not to say that reciprocity is unimportant as relationships mature. As mentioned earlier, dyadic reciprocal liking becomes stronger as relationship length increases, and couples that reciprocate negative affect are more likely to experience relationship dissatisfaction and dissolution.) But in the domain of initial romantic attraction, reciprocal liking exhibits a curious feature: People's perceptions of

reciprocal liking can fluctuate dramatically, even from one moment to the next, especially during the early stages of a potential romantic relationship. In other words, just minutes after a desired romantic partner signals that he or she might like us (e.g., by returning a phone call), the same desired partner could then signal that he or she might not like us after all (e.g., by ending the conversation abruptly). The other principles of attraction, such as physical attractiveness or proximity, probably only rarely fluctuate to such a degree.

Perhaps for this reason, people often exhibit an intense desire for reciprocal liking in developing romances. In her research on *limerence* (a term roughly synonymous with high levels of passionate love or infatuation), Dorothy Tennov determined that a central part of the falling-in-love experience is the yearning for one's affections to be reciprocated. People who are infatuated with a desired partner frequently engage in fantasies where the partner professes his or her love in return. In fact, in many cases, sexual contact is not the ultimate object of infatuated individuals' desires; instead, they fantasize about the reciprocation of affection that will alleviate any concerns that their love is unrequited and lead to an emotional union with the love object. The desire for reciprocity can be a consuming experience for infatuated individuals because they may frequently spend time replaying interactions with the desired partner in their minds, sifting for evidence of reciprocation. After all, reciprocal liking brings great rewards in this context, but because it can also prove ephemeral, it is frequently a source of considerable rumination for infatuated individuals. For infatuated individuals' emotional euphoria to be achieved, the reciprocity needs to be exclusive; that is, the infatuated individual also must find evidence that he or she is *selectively* desired by the love object. As reviewed previously, selectivity is a central component of reciprocal liking within the first few minutes of romantic encounters; its role may well intensify as an initial encounter grows into a full-blown infatuation.

REJECTION

Rejection refers to being dumped, left out, snubbed, or otherwise made to feel excluded. People feel rejected when they are made to feel that they do not belong in a relationship or to a group. Rejection tends to have negative effects on behaviors, thoughts, and emotions. When people who are rejected feel that they are able to connect with others, the negative effects of rejection usually are eliminated. This entry discusses how rejection thwarts a fundamental need for relationships, summarizes different types of rejection people experience inside and outside of the laboratory, and examines the effects of rejection—both positive and negative—on behavior, thoughts, and emotions.

Rejection Thwarts a Fundamental Need

Most psychologists agree that people are motivated to have positive and durable relationships with other people. Roy Baumeister and Mark Leary refer to this motivation as a “need to belong” and suggest that it is among the strongest and most basic of all human needs. From this perspective, people naturally try to think, feel, and

act in ways that will earn them social acceptance and avoid rejection. Rejection thwarts the need to belong. As such, the consequences of rejection are consistent, strong, and mostly negative.

Rejection Inside and Outside of the Laboratory

Rejection is a common experience. People experience divorce, romantic breakups, or show romantic interest in another person only to have their romantic advances rebuffed. Some people seek membership in college fraternities and sororities, only to be told that they are not wanted. Children are left out of games on the playground, or they are told that they cannot sit by a person on the school bus. Rejection is a common theme in television and movies. Most reality television shows involve some sort of rejection. Some reality television shows involve contestants being voted off an island, whereas others involve contestants experiencing eviction from an apartment or house for various reasons. These examples provide at least some suggestion that rejection is a familiar experience for most people.

Psychologists use a variety of methods to study the effects of rejection. The methods psychologists use to understand rejection involve exposing people to situations that are considerably milder than the types of rejection people experience outside the laboratory (e.g., divorce, breakups), mostly because it would be unethical to expose people to those types of events for the purpose of research. Although laboratory manipulations often involve vague or impersonal experiences of rejection, the effects of these manipulations are quite strong. Listed next are the five most common methods psychologists use to study rejection. In each method, some people experience a type of rejection, and their responses are compared with those of people who do not experience rejection.

The first method (“group rejection”) involves some participants being told that no one in a group wanted to work with them, whereas others are told everyone wanted to work with them. In a second method (“lonely future”), some participants receive false feedback that they have a personality type in which they can expect to end up alone later in life, whereas others are told they can expect a future filled with social acceptance or negative events unrelated to their social relationships. A third

method (“personal vs. impersonal rejection”) involves participants expecting to meet with a partner. Some participants are told that their partner refused to work with them, whereas other participants are told that they will not be able to meet their partner because the partner had to leave for a forgotten appointment. The fourth method (“rejection in a virtual environment”) involves participants completing an online ball-tossing game with two or three other players (whose actions are actually programmed by the researcher) and having some participants receive almost no tosses from the other players, whereas other participants receive a high number of tosses from the other players. In the fifth method (“think of a time when you were rejected”), some participants write an essay about a time in their life when they felt rejected, whereas other participants write about a time they experienced social acceptance.

What Are the Negative Effects of Rejection?

As noted earlier, the effects of rejection are usually negative. This section discusses the negative effects of rejection on behaviors, thoughts, and emotions.

Behavior

One of the most common—and potentially disastrous—consequences of rejection is that it can cause aggression. Case studies suggest that the majority of school shooters have experienced chronic rejection. In the laboratory, manipulations of social rejection cause people to behave aggressively. Rejection increases aggression not only toward the people who rejected the person, but also toward people who were not involved in the rejection experience.

Another negative behavioral result of rejection is that it makes people less helpful. Compared with people who have not been rejected, rejected people tend to behave in less helpful ways when the recipient of help does not represent a potential source of social connection. This includes donating less money to charities, cooperating less on activities with others, and volunteering less. Even when helping will allow them to earn money, rejected people help others who do not represent a source of reconnection less than do people who have not experienced rejection.

Rejected people are also less willing than non-rejected people to control their impulses. People usually control their impulses because doing so increases their chances of being accepted by another person or a group. When people are rejected, they are unwilling to exercise impulse control because they do not believe that controlling their impulses will earn them acceptance. Compared with nonrejected people, rejected people eat larger amounts of fatty and smaller amounts of healthful foods, quit working sooner on frustrating activities, and refuse to control their attention. The relationship between rejection and impaired impulse control tends to wear off quickly (less than 45 minutes) among most people. Among people with high levels of social anxiety (i.e., people who are constantly concerned about being rejected), rejection impairs impulse control up to an hour after the rejection experience.

Following rejection, people also tend to behave in ways that allow them to avoid thinking about themselves. In one study, rejected people sat in a chair that was not facing a mirror (thus avoiding their own reflection) more so than did nonrejected people. Apparently rejected people are motivated to behave in ways that do not remind them of the flaws and other defects that caused them to be rejected.

Thoughts

One of the ways that rejection affects the thoughts people have is by reducing their intelligence. Rejected people perform worse on intelligence tests than do people who have not experienced rejection. This includes lower scores on IQ tests, lower levels of reading comprehension, and impaired logical reasoning performance. Rejected people do quite well on activities that do not require much effort (i.e., easy memorization), but they perform poorly on tasks that require them to use a lot of mental energy.

Rejection also causes people to perceive the actions of others as aggressive. When given vague information about a person, rejected people are more likely than nonrejected people to think that the information is aggressive in nature. In one study, rejected people, compared with those who had not been rejected, were more likely to rate the actions of another person as aggressive. This tendency to

perceive vague information as aggressive helps to explain why rejected people behave aggressively.

Rejection impairs people's ability to use their thoughts to make good decisions. Compared with people who have not been rejected, rejected people are more likely to take risks that result in them losing money. When given time to study for an upcoming math test, rejected people are more likely than nonrejected people to choose pleasurable activities not related to the math test (playing games and reading magazines). These findings suggest that rejection interferes with the ability to make wise decisions.

Emotion

Most people believe that rejection causes high levels of emotional distress. Some studies have shown that rejection causes people to feel negative emotions like sadness, anger, and anxiety. When describing rejection experiences, people frequently use words that are used to describe physical injury. For example, people who have been rejected might say that their heart was "broken," that they were in serious "pain," or that they felt "crushed." Describing rejection as painful is not merely a metaphor. In one study using brain-imaging technology, Naomi Eisenberger, Matthew Lieberman, and Kipling Williams showed that the brain responded to rejection in the same way that it does to physical injury.

Other work has shown that rejection causes temporary physical and emotional numbness. Just as the body goes numb after a serious physical injury, people become numb to physical pain after they have been rejected. Rejected people also show signs of emotional numbness, such as expressing low levels of empathy toward another person in distress and predicting an unemotional response to their favorite football team winning or losing to a rival opponent. The physical numbing response to rejection is strongly related to the emotional numbing response, suggesting that there is overlap in how the brain responds to physical pain and socially painful events like rejection.

Are There Positive Effects of Rejection?

Up to this point, this entry has focused mainly on how rejection negatively influences behaviors,

thoughts, and feelings. There is some evidence, however, that rejection can increase some positive responses. Most of the positive effects of rejection are due to rejected people wanting to connect with possible sources of social acceptance. Just as people seek food when they are hungry, people seek out potential friends when they have experienced rejection. This section discusses how rejection can have a positive effect on behaviors, thoughts, and emotions.

Behavior

There is some evidence that rejected people are helpful to others who seem like they could be potential friends. For example, rejected people are more likely than others to give money to a stranger when they expect to meet the stranger. When no interaction is anticipated, however, rejected people give less money to the stranger.

Rejected people tend to behave in ways that will impress others, possibly as a way of showing others that they are worthy of social acceptance. Women who feel rejected, for example, are more likely than nonrejected women to work hard on behalf of their group. Rejection also increases the tendency for people to behave in agreement with others, which could be interpreted as an effort to impress the group by behaving similarly to others.

Thoughts

Although rejection can cause people to think that vague information is aggressive, there is also evidence that rejection influences thoughts in ways that make rejected people feel accepted. People who are rejected perceive neutral facial expressions as friendly more so than do people who have not experienced rejection. Experiencing rejection also increases memory for events related to acceptance and rejection. People who are chronically lonely (i.e., feeling rejected most of the time) are better than nonlonely people at accurately identifying facial expressions and vocal tones.

The desire to connect with new friends following rejection influences thoughts at the level of responses that require only a few milliseconds. For example, rejected people are faster than nonrejected people at identifying a smiling face (a sign of social acceptance) in the middle of many other nonsmiling faces. When presented with a picture

of many faces displaying various facial expressions (sadness, anger, disgust, smiling), rejected people have their attention captured by smiling faces more than people who have not experienced rejection. The implication is that rejection motivates people to connect with possible new friends, causing their attention to be captured by signs of social acceptance.

Emotion

Rejection thwarts a basic and fundamental human need, making it likely that there would be a deeply ingrained emotional coping response to rejection. Consistent with this idea, there is some evidence that rejection sets in motion a coping response in which people seek out positive emotional information in others and their environment. For example, rejected people are more likely than nonrejected people to complete word fragments (“J O _”) with positive emotion words (“JOY”) as opposed to neutral words (“JOT”). Rejected people are unaware of this coping response, suggesting that this way of managing one’s emotions in response to rejection operates at the level of the unconscious (i.e., outside of people’s awareness).

REJECTION SENSITIVITY

Because rejection is painful, it can sensitize people to expect and be concerned about its recurrence. Geraldine Downey and colleagues have studied how people become sensitized to expect and fear rejection and how this sensitization shapes their relationships and well-being. *Rejection sensitivity* is defined as the disposition to anxiously expect, readily perceive, and intensely react to rejection. People who are high in rejection sensitivity (RS) are motivated to avoid rejection and make considerable efforts to prevent it when they perceive its prevention to be possible. When people perceive rejection to have occurred, they often react in hostile ways that elicit the rejection they fear. This entry traces the development and operation of the RS system and its personal and interpersonal implications.

The RS Measure

RS has a long history in psychodynamic psychiatry. Downey and colleagues describe rejection sensitivity in social-cognitive terms (i.e., in terms of the thoughts and emotions experienced in situations whether acceptance or rejection from someone important is possible). The Rejection Sensitivity Questionnaire (RSQ) measures individual differences in the level of threat that people experience in such situations. The RSQ presents a series of hypothetical situations in which people make a request of someone important to them (e.g., “You ask a friend to do a big favor”). Respondents then indicate their level of both (a) expectations of rejection (e.g., “I would [not] expect that he/she would want to do the favor”), and (b) concern or anxiety about the outcome (e.g., “How concerned or anxious would you be over whether or not your friend would want to do the favor?”). RS scores are calculated by multiplying the level of expectation of rejection by the level of anxiety/concern about it and then averaging those multiplied values across

the situations. Someone deemed high in RS consistently expects rejection and feels anxious about the possibility of its occurrence. In contrast, someone deemed low in RS calmly expects acceptance. Because the particular situations that elicit rejection concerns vary by developmental stage, appropriate RSQs have been developed and validated for children, college-age students, and adults.

A Defensive Motivational System

There is considerable evidence that RS is a defensively motivated system that prepares the individual to respond rapidly and intensely to learned cues of social danger. High- and low-RS individuals react differentially to rejection cues (i.e., angry faces, not being chosen for the team, or even rejection words) and acceptance cues (i.e., a smile, flattery, or even pictures of a positive social interaction). First, the attention of people high in RS is disrupted by rejection cues but not acceptance cues. Second, people high in RS show a lower threshold for detecting anger in static faces and for detecting rejection in video clips of individuals who are supposedly evaluating them. Third, people high in RS interpret negative or ambiguous social cues, such as cool and distant behavior, as intentionally and personally threatening. Fourth, RS is associated with extreme behavioral reactions to perceived rejection, such as hostile behavior, depression, and social withdrawal. When these take the form of hostility, they create the potential for a self-fulfilling prophecy.

At the physiological level, people high in RS react with a heightened startle response when viewing images conveying rejection, indicating the activation of defensive systems that detect and defend against threat. A functional Magnetic Resonance Imaging (fMRI) study (which assesses intensity and location of brain activation) found that, when viewing rejection images, individuals high in RS show reduced activation, relative to those low in RS, in prefrontal brain areas implicated in effective threat regulation.

Negative Consequences of RS

Accommodating Social Behavior

During interactions where acceptance is possible, people high in RS both subtly and overtly

accommodate their behavior and self-presentation toward that of the potential rejecter. For example, women high in RS subtly mimic the speech of conversation partners. When in danger of rejection, men high in RS change their self-presentation to seem more like their potential rejecter and are willing to ingratiate with money or favors. Although accommodation can be benign and even effective in eliciting acceptance, it can also be harmful. To preserve relationships, high-RS people tend to self-silence their opinions and values in ways that may compromise their safety. For example, high-RS women at risk for HIV reported acceding to their partner's decisions about both sexual behavior and inconsistent use of contraception.

Hostile Reactions

High-RS individuals show intense hostility following rejection. A study of dating couples found that women high in RS were more likely to get into hostile conflicts with their partners when they felt rejected. Also, high-RS men who are invested in romantic relationships behave more violently toward their romantic partners, whereas high-RS women are vulnerable to involvement in violent relationships.

Social Anxiety

RS is linked to social anxiety and social avoidance. For example, students who entered college high in RS took longer to enter romantic relationships, had fewer of them over the college years, and felt socially anxious.

Psychopathology

RS is a core symptom in two chronic, debilitating psychiatric disorders: borderline personality disorder (BPD) and avoidant personality disorder (APD). BPD is characterized by volatile relationships involving both desperate efforts to connect to others and intense reactions to the threat of rejection, including inappropriate anger, impulsive and self-injurious behavior, and extreme fluctuations in mood and sense of self. APD is characterized by pervasive social inhibition and reluctance to assume roles that entail risk of exposure to rejection or criticism. Individuals with either disorder typically show RS levels above the 95th percentile of the normal range.

Protective Factors

Self-regulatory competency, including the ability to delay gratification and to regulate one's attentional focus, protects high-RS individuals from negative outcomes. For example, RS predicted drug use, educational underachievement, and borderline symptoms in adulthood, but only among people with difficulty delaying gratification at age 4. Supportive relationships are also protective. Acceptance by peers reduces RS in middle-school children, and supportive romantic relationships reduce RS in college students.

RELATIONAL AGGRESSION

Relational aggression involves behaviors intended to hurt or harm others through damage to interpersonal relationships and includes gossip, social exclusion, or threatening to end a friendship. This entry defines *relational aggression* and discusses sex differences in relational aggression, developmental changes in relational aggression, correlates and contributors to relational aggression, and the implications of relational aggression for functioning within relationships.

Defining Relational Aggression

Although all forms of aggression include intentionally harmful behaviors, relational aggression is unique in its focus on interpersonal manipulation and harm. Many studies of relational aggression contrast it with commonly studied forms of aggression, such as *physical aggression*. Physical aggression includes behaviors where damage to one's physical well-being serves as the vehicle of harm (e.g., hitting, kicking, or punching); in contrast, relational aggression involves behaviors where damage to relationships serves as the vehicle of harm. Threatening to end a friendship ("I won't be your friend any more unless you give me a bite of your ice cream cone"), giving someone the "silent treatment," intentionally excluding someone ("I am inviting the whole class to my birthday party, and you can't come!"), and spreading nasty rumors about a peer are all examples of relational aggression.

Conceptually similar forms of aggression, such as *indirect aggression* (i.e., covert behaviors in which the perpetrator does not confront the target) and *social aggression* (i.e., behaviors that damage self-esteem or social status), do include some behaviors that overlap with relational aggression. For example, covertly starting a malicious rumor about a peer is an example of both indirect and relational aggression. However, many examples of indirect and social aggression do not specifically involve damage to relationships (e.g., indirect aggressive behaviors such as sending a nasty, anonymous e-mail) and thus are not relationally aggressive. Despite the conceptual distinctions among relational, indirect, and social aggression, some researchers have argued that these terms are interchangeable, and many studies adopt measures that do not correspond to the terminology employed. These differences in definitions and measurement across studies have created confusion in the literature, and there have been recent calls for more precision in terminology in studies of relational aggression.

Sex Differences

A number of researchers have proposed that females are at greater risk for involvement in relational

aggression. This proposal is based on two related arguments. First, gender socialization research suggests that females are more likely than males to focus on and invest in interpersonal relationships. Given the high value placed on relationships, females may be especially likely to target relationships when attempting to harm others. In addition, because relational aggression is more consistent with the female gender role than other forms of aggression (e.g., physically aggressive behaviors such as hitting), females may not receive as many sanctions against engaging in these behaviors. As a result, relational aggression may provide females with a relatively effective and socially acceptable means of aggression. In contrast, males may engage in physical forms of aggression because they are consistent with the male gender role of instrumentality, physical dominance, and competition.

Studies examining sex differences in relational aggression have been mixed. A number of studies have reported that females are more relationally aggressive than males. However, other studies have found no sex differences or have reported that males are more relationally aggressive than females. These findings may reflect the widely different measures used to assess relational aggression. For example, compared with research employing peer, teacher, or self-reports, studies using observational methods to measure relational aggression are more likely to find that females are more relationally aggressive than males. In addition, gender differences in relational aggression may differ depending on the age group examined. For example, some evidence suggests that gender differences in relational aggression increase over the elementary school years. In contrast, sex differences in relational aggression are less frequently reported in studies of adolescents and adults. However, age is also associated with measurement of relational aggression (e.g., self-reports are more common in adolescence and adulthood); thus, these age differences might reflect different measurement techniques.

A recent meta-analysis reported that females were significantly more relationally aggressive than males; however, the effect size was trivial in magnitude. These findings suggest that both males and females employ relationally aggressive behaviors. However, when girls are aggressive, they are more likely to use relational rather than physical forms of aggression. As a result, the inclusion of

relational aggression is important in understanding the aggressive behavior problems in girls.

Developmental and Relational Aggression

Relational aggression emerges quite early and has been documented in children as young as 2½ years of age. Children of this age have been observed to ignore peers by covering their ears, to tell other children that they can't play with their group of friends, and to threaten to terminate a friendship ("Do what I say or I won't be your friend"). Relational aggression in early childhood tends to be direct and becomes more covert and sophisticated across early and middle childhood. For example, as children get older, they are more likely to involve third parties in their relational aggression and to aggress behind their target's back. During adolescence and young adulthood, romantic relationships serve as a salient context for relational aggression. Once romantic relationships emerge, relational aggression can be used against romantic partners (termed *romantic relational aggression*; e.g., threatening to break up with a partner) and to target others' romantic relationships (e.g., stealing a friend's boyfriend).

Relational aggression appears to become more common across early and middle childhood. As children's verbal and cognitive capacities mature, they may be better able to understand how relational aggression can be used to harm others, and they may have the skills necessary to employ these behaviors. As a result, children may increasingly engage in more subtle forms of aggressive behavior such as gossip, rather than direct or physical forms of aggression. Consistent with this hypothesis, aggressive behaviors such as gossip and exclusion become increasingly common across early and middle childhood, whereas physically aggressive behaviors decline. Preliminary evidence, however, suggests that relationally aggressive behaviors begin to decline in frequency in adolescence.

Causes and Correlates of Relational Aggression

A number of studies have identified cognitive, social, and physiological factors as potential contributors to relational aggression, although these

studies tend to be correlational in nature. First, relationally aggressive children and adults appear to attribute hostile intentions to others in situations where their motives are ambiguous. For example, not being invited to a party by a peer may reflect intentional exclusion (a hostile attribution) or an accident (a benign attribution). The tendency to assume malicious intentions in such situations is termed the *hostile attribution bias* and has been demonstrated in both physically and relationally aggressive individuals. However, relational aggression is associated with the hostile attribution bias in situations involving relational slights (e.g., being left out or excluded), whereas physical aggression is associated with the hostile attribution bias in situations involving instrumental provocation (e.g., a peer breaks a prized possession). The hostile attribution bias is thought to contribute to aggressive behavior because aggressive strategies may be used to respond to perceived threats or provocations by peers. Relational aggression is also associated with the belief that relationally aggressive conduct is acceptable and will result in positive outcomes.

A variety of environmental and social factors may also contribute to involvement in relational aggression. For example, the home environment appears to play an important role in the development of children's relationally aggressive behaviors. Parents' use of relational aggression against each other and psychological control techniques against their children (control attempts that exploit the parent-child bond; e.g., threatening love withdrawal and using guilt induction to control the child) are both associated with children's relational aggression in the peer group. Relational aggression is also common in the context of sibling relationships, and the use of relational aggression by older siblings predicts the younger sibling's relational aggression against peers. This suggests that children may learn to aggress based on modeling by parents and siblings. In addition, child maltreatment, particularly sexual abuse, is associated with relational aggression among girls. Social experiences in the peer group may also increase children's risk for relationally aggressive conduct. For instance, children who are frequently picked on by other children and who have a number of relationships characterized by mutual dislike in the classroom appear to be at heightened risk for involvement

in relational aggression. These children may use relational aggression to aggress against or retaliate against their disliked peers.

Relationally aggressive individuals also appear to have unique physiological responses to stress. Recent research suggests that relationally aggressive girls exhibit greater physiological reactivity (e.g., increases in systolic blood pressure) to relational stressors than their nonaggressive peers. Girls who experience especially high levels of reactivity to relational stressors (e.g., being excluded) may retaliate against peers with relationally aggressive behaviors. Other studies have documented associations between relational aggression and levels of the stress hormone cortisol.

A number of studies have demonstrated the damaging nature of relationally aggressive behaviors. Perpetrators of relational aggression are at increased risk for a variety of concurrent and future adjustment problems, including depression, borderline personality symptoms, disordered eating, poor school engagement and achievement, drug and alcohol use, and aggressive behavior problems. Moreover, many of these risks remain even when controlling for co-occurring physical aggression. Children who are the frequent targets of relational aggression are also at risk for a variety of adjustment problems, including depression, anxiety, loneliness, and impulsivity. Although few in number, emerging longitudinal studies suggest that relational aggression leads to increases in adjustment problems over time, suggesting that involvement in these behaviors contributes to adjustment problems. Despite the risk associated with involvement in relational aggression, school professionals report that relational aggression is less serious and less often warrants intervention than physical aggression.

Implications for Relationships

Relational aggression has several consequences for interpersonal relationships. Relational aggression appears to be related to social status in groups; for example, relationally aggressive individuals tend to be disliked by many peers (i.e., *rejected* by peers) and liked by few peers (i.e., low on measures of *peer acceptance*). Interestingly, relational aggression is also associated with heightened levels

of popularity, particularly in adolescence. These findings suggest that popular individuals may use relationally aggressive behaviors to maintain their status and power. Alternatively, popularity may have a “corrosive” influence, leading individuals to engage in harmful behaviors.

Relationally aggressive children are also more likely than their peers to be central members of prominent *cliques* (i.e., friendship-based peer networks) in their classroom. Children and adolescents may establish and maintain their centrality in cliques through aggressive behaviors; moreover, central clique members may be especially effective when using relational aggression given their high level of interpersonal power and control. Recently, researchers have proposed that relational aggression will be associated with positive social outcomes for individuals who also engage in prosocial behaviors. In contrast, relational aggression may be most strongly associated with negative outcomes (such as rejection and psychological maladjustment) among individuals who predominantly engage in coercive and aggressive behaviors. Overall, this pattern of findings highlights the fact that, although relational aggression may confer some social benefits for some individuals (e.g., popularity in the peer group and being prominent members of cliques), it also frequently has social costs (e.g., being disliked by peers).

Relationally aggressive children are as likely as their peers to have close friendships. However, the qualities of relationally aggressive children’s friendships differ from those of their peers, with their friendships being characterized by relatively high levels of conflict, intimacy (e.g., sharing secrets), exclusivity (e.g., feeling jealous if a friend wants close ties with another peer), and relational aggression within the friendship. These findings suggest that relationally aggressive children may frequently use aggressive tactics against their close friends. Moreover, although intimacy is generally conceptualized as a positive quality in close relationships, it can also confer risk in certain contexts. For example, secrets provided through intimate exchange in the friendship context may serve as ammunition for relationally aggressive children’s manipulative behaviors (e.g., threatening to share a close friend’s secret unless the friend complies with a request).

Finally, relational aggression has implications for functioning in romantic relationships. Studies

with college students and adult samples suggest that the use of relational aggression against romantic partners (i.e., *romantic relational aggression*) is fairly common in both males and females. In one study, college students frequently identified relationally aggressive behaviors when asked open-ended questions about what behaviors individuals use to hurt others. In another study, only 4 percent of young adults reported that they “never” used relational aggression against their romantic partner; however, frequent romantic relational aggression was relatively uncommon. Moreover, romantic relational aggression is associated with poor romantic relationship qualities, such as high levels of frustration and jealousy and low levels of trust.
