RELATIONAL MESSAGES

Paul Watzlawick, Janet Beavin Bavelas, and Don Jackson, prominent researchers of the Mental Research Institute in Palo Alto, CA (the Palo Alto Group), were among the first researchers to formulate two fundamental dimensions of all communication: Apart from their *content* or *report* level (what is said), all messages also carry a *relational* or *command* level (how it is said). This definition makes two important points that are the focus of this entry: (1) All messages contain information about the relationship, and (2) all relationships exist through and are defined by message exchange.

Relational Messages Provide Information About the Relationship

Relational messages provide interactants with information about the nature of the relationship, the interactants' status in the relationship, and the social context within which the interaction occurs. Relational messages play a particularly important role in those interpersonal relationships that have the potential of becoming increasingly more interdependent (one partner responds to the behavior of the other partner). Because they provide information above and beyond the concrete content of a message, relational messages are considered *metacommunication* (*meta-* means "about"; thus, these messages are about messages). Consider a father asking his daughter: "Is that actually your new boyfriend?" Depending on the quality of their relationship (e.g., both father and daughter have a more or less loving relationship), as well as the relative status of each person (e.g., the father may be more or less authoritative), as well as the specific context within which the statement is made (e.g., the family may sit at the dinner table), the father may ask this question teasingly, angrily, or admiringly.

Enormous research efforts have been expended to identify the kind of information that people send and receive during social interactions. Virtually every one of these research efforts owes a conceptual debt to Gregory Bateson, an anthropologist who studied the New Guinea Latmul tribe in the 1930s and who later contributed significantly to the Palo Alto Group. He proposed that relational messages provide information about relational control: the extent to which one person possesses the power to influence the other person. An interaction can be either complementary (one person is dominant, whereas the other person is submissive; e.g., one person decides where to go for dinner, whereas the other person acquiesces) or symmetrical (both people are equally submissive or equally dominant; e.g., both partners either assert their views or submit to one another). William Schutz added two additional kinds of information that people communicate through relational messages—namely, *inclusion*, which is the need to establish and maintain satisfactory relationships, and *affection*, which involves the perception that one is liked, loved, and held in regard by another.

In an exhaustive review of the dimensions that inform relational messages, Judee Burgoon and Jerold Hale deduced seven types of information referred to as *fundamental relational themes*: (1) dominance/submission (similar to relational control), (2) level of intimacy (similar to affection or affiliation), (3) degree of similarity (the extent to which people coordinate their nonverbal and verbal behaviors), (4) task/social orientation (the extent to which people are engaged in work-related or leisurely interactions), (5) degree of formality (the extent to which communication is distanced and serious), (6) degree of social composure (the extent to which people present themselves as confident and competent in a conversation), and (7) level of emotional arousal (the extent to which an interaction is pleasant and active). Of these, relational control and the level of intimacy are the two primary dimensions that are metacommunicated in all message exchanges.

Relational Messages Define Interpersonal Relationships

Relational messages have been examined from functional-strategic and consequential-cultural perspectives. The first perspective captures all

those relational strategies and tactics people use to pursue a concrete relational goal (e.g., raising one's voice to win an argument). The second perspective is based on the idea that we tend to frequently reify our relationships (i.e., we often say that we "have a relationship," much like we have cars or clothes). Yet relationships are not tangible; rather, they are instantiated through everyday talk that is often mundane and trivial. It is this kind of day-to-day talk that often becomes patterned and idiosyncratic, particularly in long-term relationships. The consequential approach to relational messages suggests that these messages make up the lion's share of all relational communication and consequently fabricate a relational culture. Much like any other culture, relationships thus possess a unique language complete with routines and norms. Consider a couple that has been married for 40 years; it is likely that this couple has a richly developed relational culture with its own rituals and habits.

Relational Messages Are Communicated Nonverbally

Relational messages are commonly exchanged via nonverbal cues (e.g., eye gaze, vocal cues). Consequently, relational messages are richest in face-to-face interactions, where people can use a maximum of nonverbal channels, such as the voice, the face, the eyes, or the body. It is important to note that no one nonverbal cue carries the entire relational message. Rather, nonverbal cues are processed together with other nonverbal cues. However, some nonverbal cues tend to do a better job at communicating the aforementioned relational themes. These nonverbal cues are referred to as *nonverbal immediacy cues* and send relational messages of physical and psychological closeness as well as interpersonal warmth. Part of a larger construct called *nonverbal involvement*, these immediacy cues consist concretely of touch, close proxemic distancing, direct body orientation, forward lean, eye gaze, and positive affect cues (smiling, vocal warmth). Indeed, perceptions of dominance and affiliation are differentiated primarily on the basis of the presence (or absence) of positive affect cues.

RELATIONSHIP DISTRESS AND DEPRESSION

To better understand the role of interpersonal processes in depression, researchers have focused specifically on the quality of depressed individuals' romantic relationships. This focus is warranted in light of evidence suggesting that the interpersonal difficulties of depressed individuals are most likely to manifest in the context of their long-term, committed relationships, such as marriage. Furthermore, there is consistent and robust evidence to suggest that marital distress and depression tend to co-occur. This finding has been replicated using different methods of assessment and across different samples (e.g., samples recruited from the community, treatment-seeking samples). The purpose of this entry is to describe how marital distress and depression relate to each other causally and to describe some mechanisms that explain *why* these phenomena are related.

The robust cross-sectional association between depression and marital distress has prompted researchers to examine whether these variables are

causally related using longitudinal designs. Most of the early studies focused on testing two contrasting causal models: Does marital distress lead to depression or, conversely, does depression lead to marital distress? The findings from these studies were discrepant, with some evidence suggesting that initial marital distress predicts the development of depression symptoms in depressed wives, whereas initial symptoms of depression predict later marital distress in depressed husbands. More recent theoretical developments have shifted away from determining the causal primacy of either variable and have conceptualized the longitudinal association between these variables as bidirectional and reciprocal. Subsequent research has supported a dynamic and bidirectional association between these variables. However, these findings are limited by the use of samples characterized by subclinical symptoms of depression.

Research with clinical samples has tended to focus on the role of interpersonal processes in influencing the course of depressive illness. These studies suggest that marital difficulties predict a more severe and chronic form of the illness and can increase the risk of relapse for both men and women. Some researchers have noted that, in light of epidemiological data suggesting that the age of onset of depression is continuing to decrease while age of first marriage is continuing to increase, longitudinal studies that examine the link between depression and marital dysfunction are most likely investigating cases of recurrent or chronic depression, rather than cases of first onset. However, depression is a recurrent and progressive condition: Most individuals diagnosed with major depressive disorder will experience multiple episodes, and the risk of recurrence increases with each successive episode. Thus, examining the factors that influence the course of recurrent/chronic depression is an important public health priority.

To understand *how* interpersonal factors affect the course of depressive illness, researchers have focused on the mechanisms of this prospective association. According to Steven Beach and his colleagues, marital distress may decrease available social support, thus increasing an individual's vulnerability to external stressors and increasing his or her risk for developing depression. Consistent with this, researchers have found that a perceived lack of spousal support is a prospective predictor of

depressive symptomatology. However, it has yet to be established whether the prospective association between marital dysfunction and depression operates, in part, through perceptions of diminished spousal support. It is important to note here that the evidence suggests that *perceived* rather than *observed* social support is more strongly related to depression, and it may be particularly fruitful to examine perceptions of spousal support in models of depression and relationship dysfunction.

The mechanisms that underlie the causal link from initial depressive symptoms to later marital dysfunction have also received theoretical and empirical attention. Relevant theories were developed as broader interpersonal models of depression, but they inform the field's understanding of how depressive symptoms can lead to marital dysfunction. Constance Hammen's stress-generation model of depression posits that depressed individuals may inadvertently create interpersonal stress in their lives, and the increased interpersonal stress may, in turn, lead to the maintenance or exacerbation of their symptoms. In a similar vein, James Coyne has argued that depressed individuals seek repeated reassurance and support from others in their interpersonal environment, but when the reassurance is provided, they doubt its veracity and continue to seek feedback, leading others to become frustrated and ultimately to reject them. Support for these theoretical models comes from several lines of research. Investigations of the quality of marital interactions of depressed individuals have found that relationships with a depressed partner are characterized by higher levels of negativity and lower levels of positivity than are relationships of couples where neither partner is depressed. However, given the high comorbidity of depression and marital distress, it remains unclear whether the observed patterns of communication are due to a distressed marital relationship, depression, or both. More direct support for the theoretical perspectives outlined earlier has come from studies investigating theoretically derived, depression-related interpersonal behaviors. For example, consistent with Coyne's model, evidence suggests that excessive reassurance seeking is a specific vulnerability factor for depression. Evidence also suggests that depressed individuals selectively attend to, process, and retain negative information about themselves. Research by Constance Hammen and

colleagues demonstrates that, compared with non-depressed women, depressed women are much more likely to engage in interpersonal conflict.

Depression is a complex, heterogeneous disorder with multiple causal factors at different levels of analysis (intrapersonal, interpersonal, and cultural) that affect its onset and course. No single theoretical perspective or level of analysis can fully explain the variance in depressive phenomena. Increasingly, researchers are developing and testing integrative models that combine interpersonal and intrapersonal perspectives and have greater explanatory power than when either perspective is considered alone. In particular, models that integrate key elements of the cognitive perspective on depression, which emphasizes the role of negative thinking patterns in causing and maintaining depression, with interpersonal processes are promising avenues for future research.

RELATIONSHIP SCIENCE, DISCIPLINES CONTRIBUTING TO

A simple way of thinking about a scientific discipline is as a field of study. A key component of a discipline is a corpus of knowledge including the

body of concepts, methods, and findings of the field. Disciplines, however, include more than just a body of knowledge. They rest on a communal approach that entails norms and a perspective on the phenomena being studied. Disciplines set boundaries on what scholars do and don't study, and they typically involve organizational structures. This entry asks: Is the study of personal relationships a disciplinary, multidisciplinary, or interdisciplinary endeavor? What are the pros and cons of multidisciplinary and interdisciplinary approaches? Which disciplines have historically contributed to the study of personal relationships? Which disciplines are the major contributors today, and how, briefly, can they be characterized? This entry does not cover depictions and insights about relationships that can be gleaned from the arts (e.g., drama, art, music, literature), although they can be powerful and vivid.

The Study of Relationships: Disciplinary, Multidisciplinary, or Interdisciplinary Endeavor?

In the late 1970s and the early 1980s, eminent relationship scholars including Robert Hinde, Ellen Berscheid, and L. Anne Peplau called for a science of relationships. They envisioned a science of relationships that would be descriptive in the sense of identifying the various forms that relationships can take and predictive in the sense of identifying the factors that shape and are shaped by personal relationships. Although there had been work on relationships in several fields, their calls were aspirational, implying that they wanted a relationship science that was something more than what Philip Blumstein depicted as “the neglected stepchild of the social sciences.” Almost 30 years later, is there now a separate discipline uniquely and cohesively devoted to the study of relationships?

To determine whether a discipline exists, one can look for institutional markers and the communal aspects of scientific endeavors. The institutional markers include such things as professional societies, journals, university departments, students obtaining their degrees in the field, being labeled as a discipline, and the like. The study of relationships has some of these

markers, including a professional association, the International Association for Relationship Research, and journals (e.g., *Personal Relationships* and the *Journal of Social and Personal Relationships*). Some individuals call themselves relationship scholars, but relationship science is not a commonly used department name in universities. There are degrees from family studies departments, the University of Minnesota has a doctoral minor in Interpersonal Relationships Research, UCLA has an Interdisciplinary Relationship Science Program, and students in some more traditional social science departments can concentrate within their discipline on the study of relationships. Relationship science doctoral degrees per se, however, are rare, if they exist at all. Thus, the study of relationships lacks some of the organizational properties of more senior, larger academic disciplines. Equally important, relationship researchers lack the communal component that classically marks a discipline: They do not all share the same intellectual heritage and tradition.

At present, scholars from several disciplines—sometimes each largely in their own solos, sometimes together—engage in the study of personal relationships. Some (e.g., Harry Reis, the coeditor of this encyclopedia) have labeled the field *multidisciplinary*, whereas others (e.g., textbook author Dale Wright) have treated it as *interdisciplinary*. At issue here is the degree of integration. Multidisciplinary research is additive and complementary, but less integrative. The multidisciplinary type of science exists if scholars in different disciplines are each working on relationship issues from their own perspectives, but have some awareness of one another, perhaps making some comparisons between approaches. Interdisciplinary research requires more integration: It is characterized by such attributes as significant citation of work from other fields, coinvestigators from different disciplines formulating problems and working together, having variables associated with different disciplines together in the same study, blending conceptual frameworks from different disciplines in the interpretative framework for discussing the results, and the like. Much of the work published in personal relationship journals at this time qualifies as multidisciplinary; a smaller—but hopefully growing—proportion of it is interdisciplinary.

Pros and Cons of Interdisciplinary Research

There are various challenges to interdisciplinary work. For example, interdisciplinary work may be judged stringently by disciplinary-oriented reviewers, presenting barriers to getting interdisciplinary work funded or published. Departmental administrators may dislike interdisciplinary projects if the money that departments often receive from hosting grants is split with or siphoned off to other units. In promotion and tenure decisions, committee members may not fully appreciate signs and symbols of excellence outside their own domain. Thus, junior researchers may worry that being substantially engaged in interdisciplinary research will decrease their chances of gaining tenure. The challenges of interdisciplinary research can be synthesized by saying they exist along two interrelated lines: the discipline-based structure of universities and the difficulties researchers face when working together across disciplines.

Nonetheless, interdisciplinary research is flourishing. Agencies such as the National Institutes of Health (<http://nihroadmap.nih.gov/interdisciplinary>) are promoting it. Clearly, the case for its benefits can be made. For example:

- In everyday life, many factors typically operate simultaneously—any given variable likely accounts for only a modest proportion of the variability in what happens. Having different levels of variables helps more fully predict outcomes and may illuminate moderating factors limiting the conditions under which scientific principles operate that would go undetected in purely discipline-based studies.
- By providing a more rounded understanding of phenomena, multidisciplinary and interdisciplinary research can enhance scientists' capacity to contribute to the solution of social and technological problems.
- In bringing together scholars with different perspectives, interdisciplinary projects can lead to spotting previously unrecognized issues worthy of investigation, the spreading of useful techniques, fresh and unexpected insights, and so on.
- There can be personal benefits for scholars to engage in interdisciplinary work. Moti Nissani cheers that interdisciplinarians “are forever treating themselves to the intellectual equivalent

of exploring exotic foreign lands.” For some, crossing disciplinary boundaries can lead to career flexibility and opportunities.

- Although not necessarily interdisciplinary in nature, Stefan Wuchty, Benjamin Jones, and Brian Uzzi document the recent raise and scientific benefits of teams, as opposed to individual investigator projects. In the social sciences (circa 2000), articles by two, four, and six or more authors had 2.50, 5.04, and 13.01 times more citations than the average sole-authored article. Interdisciplinary projects encourage a team approach.

Disciplines That Historically Contributed to the Development of Relationship Science

Given that the study of relationships is a multi- or interdisciplinary endeavor, which disciplines are involved? Historically, interest in relationships can be traced back at least as far as the writing of several Greek philosophers. Aristotle’s analysis of friendship in his *Nicomachean Ethics* and his treatise on *Rhetoric* are especially noteworthy, but several other Greeks—as well as later philosophers, theologians, and essayists—addressed various aspects of relationships. Their analysis of relationships was based on informal observation and reasoning. In the second half of the 1800s and early 1900s, major intellectual contributors of the day laid the foundation for modern scientific disciplines, including biology, psychology, and sociology. Their ideas had implications for the field’s understanding of relationships. For example, in 1859, naturalist Charles Darwin published his *On the Origin of Species*, which would come to be a key underpinning for contemporary evolutionary views of close relationships. Psychoanalyst Sigmund Freud wrote on the role of parent–child relationships in personality development, giving rise to the idea that people may seek marital partners similar to their opposite-sex parent. Sociologist Émile Durkheim, who was concerned about social organization, saw social relations as a key force in holding societies together. Another sociologist, Georg Simmel, examined the unique properties of dyads as opposed to individuals by themselves or larger groups.

As industrialized nations entered the 20th century, a major revolution occurred in social analysis: The use of empirical investigations began gaining importance. By the mid-1920s, there was a sufficient body of

research for Ernest Burgess to publish a survey of the literature on the family. In addition to the disciplines already mentioned, he noted the contributions of anthropologists studying family life in preliterate societies, social workers in analyzing family disorganization, and home economists in illuminating family economics. After surveying the literature at that time, Burgess was dissatisfied with the ways others were investigating the family. He went on to outline the conceptual elements he considered essential to analyzing the family as a behavioral and social phenomenon. He has been credited with inaugurating the modern field of family studies.

Moving toward the mid-20th century, subareas within psychology began emerging in significance (e.g., developmental and personality psychology). In the third quarter of the century, social psychologists did especially noteworthy research on interpersonal attraction (i.e., the question of why people like some individuals more than others). By the early 1960s, gerontologists were reporting that seniors’ social activities declined as they aged and were debating reasons for this. From the mid-1970s to the mid-1980s, communications scholars published both theoretical pieces and analyses critical of the attraction work that had demonstrated that similarity fosters liking. The classic epidemiological study by Lisa Berkman and S. Leonard Syme showing the key role that social networks play in people’s living longer was published in 1979. As the century progressed though its last two decades, research on health and relationships continued to accumulate and gain in importance.

Disciplines Contributing to Relationship Science in the 21st Century

Analysis of membership data provides a vantage point for viewing the current mix of scholars engaged in relationship science. The International Association for Relationship Research (IARR) is the organization most closely aligned with relationship science. Its membership directory asks with which discipline members are associated. As of July 2008, one member listed “close relationships.” The main disciplinary identities of IARR members were as follows: psychology 55 percent, communication studies 23 percent, family studies

12 percent, sociology 4 percent, and developmental science (child development, gerontology, and life-span development) 3 percent. Another 3 percent was from a potpourri of other disciplines (e.g., anthropology, computer science, counseling, ethology, management, marriage and family therapy, psychiatry, and, last, social work). Thus, psychologists are the numerically dominant group, and one analysis of citations done by Linda Acitelli suggests influence patterns are intransitive with psychologists being dominant: References to the work of psychologists were more likely to be cited by communication scholars than vice versa.

Given the largely multidisciplinary nature of relationship research, the issue of how to characterize various disciplinary lines of research becomes crucial. This is a challenge because disciplines change over time and, even at any given time, encompass considerable within-discipline heterogeneity and may have similarities to other disciplines. Nonetheless, at least some loose generalizations can be made about disciplinary characteristics along such dimensions as the prototypical factors investigated, units of analysis, dominant theories, methods used, approaches to fostering change (if any), and the like.

Psychology

Psychology is often described as the study of the human mind and behavior. There is an emphasis on individuals. Consistent with these attributes, psychologists have been leaders in studying the individual difference, cognitive, and emotional aspects of relationships. They use both experimental and correlational methods, but many psychologists especially value experimentation and often do extensive psychometric work in developing their scales. Psychological studies frequently rely on college students as participants. During the past 25 or so years, psychologists have advanced three major theoretical approaches to understanding relationships: interdependence (or social exchange) views, the evolutionary perspective, and Attachment Theory. In simple terms, these theories suggest, respectively, that humans form and continue relationships on the basis of the outcomes they receive (rewards minus costs); that they are driven by a genetic imperative to perpetuate their genes; or

that they seek the security of being attached to a responsive, caring parental or romantic figure. Clinical and counseling psychologists, like marriage and family therapists, have an interest in repairing relationships.

Communication

Communication scholars focus on verbal and nonverbal interactions between partners. Such interactions are the units of analysis. For communication scholars, both the content and structure of communication are important. Communication is seen as defining the type of relationship that partners have, affecting the course of relationships (development, maintenance, and dissolution), and contributing to the success—in terms of partner satisfaction—of relationships. Communication scholars contend that it is through communication that partners establish family roles, maintain rules, socialize children, perform functions such as providing emotional support, and sustain behavioral pattern. Changes in relationships are seen as associated with changes in communication. Communications scholars frequently use questionnaires or observational methodologies and university students as participants. The dialectical and uncertainty reduction theoretical traditions stem largely from the communications tradition. The central notion of dialectical theory is that of contradiction, which is an interplay between opposing forces in relationships (e.g., a need for interdependence vs. a need for independence). Uncertainty theorists postulate that a desire to reduce uncertainty is a driving force behind people's communication behavior that assists individuals in their effort to establish relationships and maximize the rewards of social interaction.

Family Studies

Family scientists have traditionally been concerned with marriage and the family, including courtship, the dynamics of members' relations within the family, and the family's interactions with broader social institutions. Parent-child relations as well as postmarital relationships are of concern. Thus, dyads and larger family constellations are the optimal unit of analysis. The focal interests of family scientists foster research with

broader populations than college students. Family scholars draw on several theoretical perspectives used in other disciplines; perspectives such as Family Developmental Theory and Family Stress Theory are relatively unique to family studies. Classically, Family Developmental Theory postulated that families go through a series of normative stages (the honeymoon, childbearing, etc.). Today there is more concern with how the timing of various marital and other life events influences individual and marital outcomes. Family Stress Theory is concerned with the stressors that families face and how they cope with them. Many human development and family studies programs espouse a desire to foster the well-being of individuals and families in their everyday lives. Family life educators do this via psychoeducational methods. For example, there are marital preparation and marital enrichment programs that share information with participants, get them to engage in activities on their own, and so on. Family life education typically involves neither professional diagnosis of problems nor feedback on performance.

Sociology

Sociologists see relationships as part of larger social systems. For them, positions in the social system, norms (i.e., social expectations), and roles (i.e., the norms associated with a position) are important. For example, in considering family roles, sociologists have been concerned with the relations among various family roles, how personal qualities fit with roles, and how family roles go together with nonfamily roles. Sociologists also examine networks of relationships, as well as how macroforces such as race, socioeconomic status, urbanization, religion, and so on, influence relationships. Sociologists are concerned about the representativeness of the samples so they often prefer large-scale surveys even if it means using brief measures of variables. Symbolic interactionism and network theory are two theoretical perspectives that sociologists have contributed. Symbolic interactionists are concerned with how people construct and present the self (or “identity”). They believe that human actions are based on the meaning assigned to things and that this meaning arises out of interactions with others and society. Network theorists are concerned with the

properties of personal networks and how networks play a role in information flow, decision making, social contacts and activities, and social support.

Developmental Science

Developmental scientists, be they considered their own discipline or included with psychology or family studies, focus on how relationships change over the life course, as well as how life events, relational histories, and the like influence relationships. Thus, longitudinal research is key for them. Of necessity, they study individuals at all stages in the life cycle. There are theories of how children’s understanding of relationships changes as they mature, as well as how the needs that relationships serve shift. Attachment Theory has relevance in both childhood and adulthood. In research on relationships in mid- and later life, Robert Kahn and Toni Antonucci’s Social Convoy Theory and Laura Carstensen’s Socioemotional Selectivity Theories have been influential. Kahn and Antonucci see social convoys as a set of three concentric circles of relationships that vary in their closeness. Their theory addresses not only the structure and function of our networks at a given point in time, but also how networks change over time (e.g., inner circle relationships are more likely to persist). Carstensen’s Socioemotional Selectivity Model is concerned with how time influences people’s goals, suggesting that with a shortened time frame people concentrate on those partners who will best satisfy their emotional needs (e.g., friends and family members).

Conclusion

In summary, the science of relationships at the present time can best be described as a multidisciplinary area of research. Although there are challenges to multidisciplinary and interdisciplinary work, they are exciting and have substantial benefits. Several disciplines have made some contribution to understanding relationships (e.g., philosophy, anthropology, biology, epidemiology, history, home economics, medical sciences, social gerontology, and social work). Currently, the main clusters of scholars studying relationships have backgrounds in psychology, communication studies,

family studies, sociology, and developmental science. Their approaches can be distinguished, at least on a broad basis, in terms of the aspects of relationships they study, their methods, and the theories they employ.

RELATIONSHIP TYPES AND TAXONOMIES

Most scientific fields depend on classification systems. Chemistry has its periodic table of elements, biology has its classification of species, and personality psychology has a model of fundamental traits. Each of these classifications is a scientific taxonomy: a systematic way of describing a field of knowledge. Taxonomies serve several important functions. First, they enumerate the varied phenomena that exist in a particular field. By comprehensively describing these variations (e.g., stating how many types of elementary particle exist), a taxonomy provides a map of its scientific territory. Second, taxonomies enable communication, supplying people with a shared terminology for exchanging information. Third, taxonomies often go beyond simply listing and naming things, and they say something about how those things relate to one another. A classification of mental disorders, for example, tells us which psychiatric conditions are closely associated with which other conditions, and how different conditions can be distinguished. This entry describes taxonomies that have been developed to describe, name, and organize the diversity of human relationships.

Taxonomies serve these descriptive, communicative, and organizing functions in varying ways. For instance, some propose a set of categories, whereas others propose a set of dimensions. A categorical taxonomy, such as the classification of chemical elements or biological species, includes a number of discrete types. Anything it classifies either falls into a particular type or it does not: An organism either is a dog or it is not, and a molecule

either does or does not contain hydrogen. A dimensional taxonomy, in contrast, does not sort things into types, but provides a set of continuous dimensions on which they can be located, just as we can find a location on a map using its coordinates. The most widely accepted personality taxonomy, for example, proposes that there are five factors along which people differ by degree.

Another important difference between taxonomies relates to categorical classifications. Some of these, like the taxonomy of biological species, classify each entity into a single type. A particular bird may be either a spotted owl or a barn owl, but cannot be both at the same time. Other taxonomies allow entities to be classified into multiple types. The periodic table, for example, allows us to determine the different elements that constitute a particular molecule (e.g., hydrogen, oxygen, and carbon). Categorical taxonomies can therefore either tell scholars the mutually exclusive types that things belong to or the building blocks that compose those things. We can refer to these types of taxonomy as “exclusive” and “elementary.” All of these distinctions between taxonomies may seem rather abstract at this point, but this entry shows how they help researchers understand attempts to classify relationships.

Relationship Taxonomies

Taxonomies are needed in the study of human relationships as much as in any other scientific domain. Relationships take a bewildering variety of forms, and the field needs a principled way to classify them. At first blush, this might seem to be a simple matter because everyday language offers many ways to describe relationships. There are nouns like *acquaintance*, *spouse*, *lover*, *boss*, and *parent*, as well as adjectives like *warm*, *romantic*, *casual*, *close*, and *long-term*. Unfortunately, everyday language will not take one far. First, there are far too many terms to give us a usable classification. For example, an enormous number of adjectives can be used to describe relationships, and there is no obvious way to decide which ones are especially important or how they should be organized. Second, many of the nouns refer not to particular kinds of relationships between people, but to particular social roles that one person in a

relationship may occupy. Indeed, language provides us with few terms to describe relationship types (e.g., *friendship*). Because it is difficult to develop taxonomies of relationships out of everyday terminology and intuition, relationship scholars have tried to develop scientific taxonomies that rely on empirical research and theoretical insight.

One of the basic problems in developing a relationship taxonomy is that it is not obvious what type of taxonomy it should be. Should relationships be classified into a set of discrete types or should they be described along a set of continuous dimensions? Do they differ in kind (qualitatively) or only by degree (quantitatively)? If a categorical taxonomy is preferred, should it be one that classifies each relationship into a single, mutually exclusive type, or should it propose relational building blocks out of which that relationship is composed? Many laypeople seem to subscribe to an exclusive categorical approach, believing that romantic and work relationships, for example, are quite distinct. Different theorists have taken different approaches to these basic questions, and we review some of their taxonomies here.

Dimensional Taxonomies

One way to classify relationships is in terms of a few basic dimensions. This has often been done by empirically determining the dimensions that underlie people's perceptions of relationships. Although the actual or objective dimensions along which relationships vary may not be identical to those that people perceive, this way of developing a relationship taxonomy has the benefit of being psychologically real. It starts with people's judgments of similarities and differences between particular relationships. These perceived similarities and differences are then analyzed using complex statistical procedures such as multidimensional scaling, which extract the smallest number of dimensions that underlie them. When this is done, two or three relationship dimensions usually emerge.

The first dimension is usually labeled *intimacy*, *solidarity*, or *affiliation*. Relationships that are high on this dimension are warm and friendly, whereas those that are low on it are cold, competitive, and hostile. In short, this is a highly evaluative

dimension that corresponds roughly to pleasant versus unpleasant relating. The second dimension is often labeled *power, inequality, control*, or something similar. Relationships that are high on this dimension are marked by dominance and submission, inequality, and asymmetrical control over resources, whereas those that are low on it are egalitarian, with the relational partners having relative autonomy. Occasionally, a third dimension emerges, contrasting formal, task-oriented relationships with those that are more informal and expressive or emotional.

Several points are worth noting about the two-dimensional structure that usually emerges from this sort of work. First, it implies that the great diversity of relationships can be distilled in a simple and economical way. Second, the two relational dimensions are independent of each other, indicating that the degree to which relationships are warm and friendly is unrelated to their degree of equality or asymmetrical power. This may seem contradictory, but parent-child relationships, for example, are generally warm, but contain a difference in status or power. Third, similar dimensions emerge from taxonomies of other social phenomena, such as social roles and linguistic forms of address (i.e., ways of addressing to people of different closeness and status). It would seem that there is something about the dimensions that is quite fundamental to social life.

A related dimensional taxonomy of relationships links the structure of dyadic relationships to the structure of the interpersonal behavior of individuals in those relationships. There is considerable evidence that interpersonal behavior can be described by two dimensions that are closely related to the two main relationship dimensions. Interpersonal behaviors vary on independent dimensions of warm versus cold and dominant versus submissive, with every blend of these dimensions being possible (e.g., warm dominance and cold submissiveness). This two-dimensional model, first proposed by Timothy Leary, is called the *interpersonal circle* (or *circumplex*) because these blends can be represented as falling in a continuous ring around the two dimensions.

In principle, a dyadic relationship can be described in terms of the typical kinds of interpersonal behavior that each individual enacts, and thus by two circles. Some interpersonal researchers

have argued that relationships vary in how the two partners' behavior is linked. A relationship is symmetrical to the extent that the two individuals' behaviors occupy the same position on the interpersonal circle (e.g., the extent to which both are warm, both dominant, both cold, etc.). Alternatively, a relationship is complementary to the extent that the two individuals are the same on the warm versus cold dimension and different on the dominant versus submission dimension. For example, a complementary relationship would be one in which person A's level of dominance is matched by person B's level of submissiveness regardless of whether their relationship tends to be warm, cold, or neutral. Symmetry and complementarity are therefore ways of describing relationships that are based on a dimensional taxonomy of interpersonal behavior. Interestingly they are not identical to the dimensions (e.g., warmth and inequality) that emerge from studies of perceived similarities and differences among relationships. For example, neither complementarity nor symmetry is the same as warmth, and both kinds of relationships may be friendly or hostile.

Categorical Taxonomies: Exclusive

Categorical taxonomies propose that relationships take a few discrete forms or types, and the difference between them is qualitative rather than quantitative. Several theorists have proposed taxonomies of relationship types. Some of these taxonomies are exclusive in the sense described earlier, so that any particular relationship belongs to only one type. Others are elementary in the sense that a particular relationship may represent a combination of several relational building blocks or elements.

Perhaps the best-known relationship taxonomy, developed by Margaret Clark and Judson Mills, proposes that there are two distinct relationship types: communal and exchange. Communal relationships are those in which people feel a mutual responsibility and obligation to one another. These relationships tend to be relatively long lasting and involve feelings of warmth and caring. More important, people in communal relationships do things for one another without expecting anything in return, and they do not keep track of who has done what for the other person (e.g., who owes

whom). People in communal relationships help out because they are able to, and they receive help because they need it. Typical examples might be relationships between close friends, family members, or romantic partners.

Exchange relationships are quite different. People in these relationships do not feel a lasting bond to one another and do not feel strong responsibilities or obligations. Instead, they engage in the relationship in order to get something out of it. The relationship is more of a transaction, where each person aims to get something in return for what they put in, so they keep track of what each has given and received. Rather than giving and receiving out of ability and need, as in communal relationships, people in exchange relationships expect their contributions to be reciprocated, and they expect that the other person's contributions will be equitable, matching their own in value. Typical examples are relationships between acquaintances or coworkers and between clients and service providers.

Although simple, the communal versus exchange distinction has been fruitful in relationship research. The two relationship types appear to operate according to different dynamics and norms. When people violate these rules and expectations—keeping track of obligations in a communal relationship or expecting uncompensated help from the other person in an exchange relationship—people become upset.

Other binary distinctions of this nature are also common in relationship research, although they are rarely presented as exhaustive taxonomies. For example, research on social networks often classifies “ties” (i.e., dyadic relations between network members) as positive or negative, strong or weak, or expressive or instrumental. One question that arises here and with other categorical taxonomies is whether these sorts of distinctions reflect true relationship types or merely shorthand ways of describing what are, in fact, continuous dimensions. We may call some people “tall” or “short” without meaning that there are distinct tall and short types of person and while recognizing that height falls on a continuum. At present, there is little evidence that the relationship types proposed in most categorical taxonomies really represent distinct categories. However, even if they are not true types in that sense, they may still be useful ways to describe the diversity of relationships.

Categorical Taxonomies: Elementary

A final way to develop relationship taxonomies is to propose elementary building blocks from which relationships are composed or constructed. Theorists who take this approach generally do not claim that their categories represent relationship types because they are attempting to classify aspects or components of relationships, rather than whole relationships. In addition, these theorists tend to focus on people's cognitions about relationships, rather than on how relationships are actually conducted. In short, these theories refer to the mental models that people use when they think about relationships.

One early and prominent theory of this sort is Resource-Exchange Theory, proposed by Uriel and Edna Foa. The idea that some relationships are based on exchange is familiar from the communal versus exchange distinction, but proponents of Resource-Exchange Theory argue instead that *all* relationships have an exchange basis. Where relationships differ is in the particular resources that the participants are exchanging. The resource-exchange framework proposes six distinct resources to which people attend: Love, Status, Information, Money, Goods, and Services. The first two of these resources are more abstract and social, whereas the last four are more concrete and economic. These resource types are mental categories that people employ in making sense of their interpersonal relations, and people tend to exchange resources of the same kind. For example, when someone seeks information, people have a tendency to seek information from them in return and may be uncomfortable trading that information for the other person's respect (status), payment (money), or undying gratitude (love). This is an elementary rather than an exclusive taxonomy because relationships need not be based on a single resource. In a marriage, for instance, although particular interactions may tend to focus on a single resource, many different resources may be exchanged at different times. Partners may give and receive love, status, information, and services, for example.

Another taxonomy that refers to cognitive structures as relational building blocks is Relational Models Theory, developed by Alan Fiske. This theory, based on anthropological fieldwork and an integration of other theories of social relations,

proposes that there are four fundamental and cross-culturally universal ways to think about, evaluate, and conduct relationships. In the Communal Sharing (CS) model, relational partners see themselves as fundamentally equivalent to one another, nurture one another, contribute what they can and take what they need, and seek consensus. Relationships based on the Authority Ranking (AR) model are hierarchical: People differ in rank or status, and one person takes precedence and dominates while the other follows and obeys. The Equality Matching (EM) model is based on strict egalitarianism: Everyone contributes the same amount, receives equal resources, takes turns, reciprocates favors, and keeps track of the balance or imbalance in the relationship. According to the Relational Models Theory, equality (EM) is not simply the absence of inequality (AR), but is a distinct form of relationship in its own right. In the Market Pricing (MP) model, finally, people base their relationship on the principle of equity, striving to receive benefits from the relationship that are proportional to the time, money, or effort that they have invested in it.

In theory, the four relational models are qualitatively different from one another, so they can be combined in particular relationships, but not blended. That is, research has shown that people commonly employ more than one model in any particular relationship, but typically do so in different relationship domains. For example, a couple might employ strict equality (EM) when doing a domestic chore, expect one partner to make all decisions regarding child care (AR), share a common bank account (CS), and pay for home renovations in proportion to their salaries (MP).

General Comments

We have briefly reviewed several of the better known relationship taxonomies, but many others have been proposed. One thing that is clear is that many of the existing taxonomies cover similar ground in different ways. Even if the entities that they propose have different names and represent different structures (dimensions and exclusive or elementary categories), they can often be mapped onto one another. For example, the intimacy, affiliation, or solidarity dimension obtained in multidimensional scaling analyses has close links

to the communal relationship type, expressive ties in the Social Network Theory, love in the Resource-Exchange Theory, and CS in the Relational Models Theory. The power and control dimension is linked to status in the Resource-Exchange Theory, AR in the Relation Models Theory, and in some respects to the complementarity principle. The other end of that dimension, often labeled *equality*, is related to the EM model and the symmetry principle. The formal/task-oriented dimension appears to overlap with the exchange relationship type, instrumental ties in network theory, the more economic resource-exchange categories (e.g., money, goods, services), and the MP model.

Existing taxonomies may diverge conceptually from one another, but they plainly converge on a few basic ways of characterizing the diversity of relationships. Each taxonomy has its own strengths and limitations, and there are few grounds for claiming that any one has general superiority. There has been remarkably little research that directly examines associations among the different taxonomies or that compares their capacity to illuminate relationship processes, the ultimate goal of any taxonomy. Similarly, there is almost no research examining whether relationships are best described using dimensions or categories, a basic taxonomic question. Nevertheless, these and other relationship taxonomies provide a solid foundation for the empirical study of human relationships.

RELIGION, SPIRITUALITY, AND RELATIONSHIPS

Social scientists have conducted many studies on the individual's perceived relationship with the sacred (i.e., God, the divine or transcendent reality), especially during times of stress. Findings indicate that positive perceptions of the sacred promote physical and psychological well-being, whereas spiritual struggles carry potentially high psychic and health costs if left unresolved. However, much less research has been conducted on the roles that religion and spirituality play within human relationships. This entry describes this growing body of research, which suggests that religion and spirituality hold important implications for family relationships.

Abstract Definitions Versus Concrete Data

There is controversy among social scientists about the best ways to define *religion* and *spirituality*. Increasingly, these broad, abstract concepts have become polarized. For example, *being religious* tends to be portrayed as involving membership in a given religious community; adherence to institutional dogma, worship, or rituals; and external pressure. In contrast, *being spiritual* tends to be defined as a personal connection to the sacred; a private search for enlightenment, purpose, meaning, or virtues; and internal motivation. Kenneth Pargament's popular definition of *religion* as a "search for significance in ways related to the sacred" reconciles these divergent views. This definition recognizes that religion serves a variety of significant psychological and social purposes, but first and foremost, religion is designed to facilitate the individual's spirituality; that is, the search for the sacred. Ironically, when it comes to family relationships, debates over abstract definitions of religion or spirituality are largely irrelevant because researchers have overwhelmingly relied on simple,

concrete items to assess this realm. Most indicators focus on whether individuals from the United States endorse a religious affiliation (e.g., 70–75 percent say Catholic or Protestant/Christian, 10–15 percent say none), attend religious services or pray, and the degree of similarity between two family members on these factors. Few studies have delved deeper into the interface of faith and family relationships.

Religion/Spirituality and Marriage

General Religiousness

Based on general indicators, like religious affiliation or frequency of prayer or worship attendance, religion continues to shape Americans' decisions about who to date and marry and whether to have premarital sex, cohabit outside of marriage, or get married if pregnant. Among the married, religious involvement by, and similarity between, spouses is tied to better marital functioning. For example, those who are more religiously engaged report being somewhat more satisfied and committed to their marriages. Such people also seem to enjoy better marital communication patterns and are less likely to experience affairs or divorce. Likewise, similarity in spouses' religious affiliation correlates slightly with greater marital satisfaction while similarity in church attendance is tied to greater marital commitment and happiness. In contrast, those rare U.S. couples that have major disagreements about the Bible also have more conflict about housework and money. But, contrary to fears that religion fuels domestic violence, frequent churchgoers are less likely to engage in physical violence than those who rarely attend services. Taken together, the evidence suggests that higher general religiousness may play a protective factor in sustaining marriage.

Religiously Based Beliefs and Practices About Marriage

The previous findings raise intriguing questions as to what exactly it is about religion that matters for marriage. One empirical approach to these questions has focused on what happens when couples perceive marriage as a spiritual experience. For instance, one study found that most husbands

and wives view their marriage as being infused with sacred qualities (e.g., holy, blessed) and connected to God. Such religiously based perceptions about marriage were tied much more strongly to better marital functioning than general religiousness perhaps because viewing marriage as a sacred union may heighten both cognitive expectations and behavioral efforts to protect the bond. Other evidence suggests that couples that engage in religious activities together (e.g., praying together) may possess unique resources to build intimacy and resolve conflicts (e.g., perceived support from God). Further, religious communities may offer couples valuable social support in forming and sustaining marriages (e.g., provide adaptive guidelines for marital conduct). However, religion also seems to raise the stakes for marriage. Both divorced and young adults whose parents divorced report feeling more traumatized when a marriage that was once viewed as sacred is lost or violated, and they often experience painful spiritual struggles about the divorce (e.g., doubts and anger toward God).

Religion/Spirituality and Parenting

Parenting With Children

More frequent church attendance is associated with having more children, but little is known about specific religious beliefs or practices that facilitate the transition into parenthood. Most research on religion and parenting deals with spanking and Christian conservatism. Greater endorsement of fundamentalist views of the Bible has been repeatedly correlated with a stronger belief in and greater use of spanking young children. However, conservative Christian membership or beliefs have not been linked to child physical abuse. In fact, in one rigorous study that tracked parents over 17 years, those who regularly attended church were half as likely to be physically abusive than parents who rarely attended church. Other desirable parenting outcomes repeatedly tied to general religiousness and Christian conservatism include greater involvement, affection, and warmth, especially by fathers. Interviews of parents of young children with developmental disabilities or serious medical illness also suggest that religion often offers parents unique resources to

cope with these circumstances, although it can also trigger spiritual struggles. Finally, one large-scale, longitudinal study indicates that greater parental religiousness translates into better adjustment for children, although questions remain as to why this is the case.

Parenting With Adolescents

Intentionally or unintentionally, parents shape the kind of religious affiliation and religious beliefs their adolescents adopt, as well as their involvement in religious social networks. In turn, greater general religiousness of adolescents has been consistently tied to less delinquency, substance use, and premarital sexuality, as well as to higher volunteer work and civic engagement. Surprisingly little is known about whether and how parental or adolescent religiousness influences the quality of their relationships. However, available studies imply that more religiously engaged parents and adolescents are closer and have better lines of communication.

REMARRIAGE

Remarriage is a common occurrence in modern society due to high divorce rates. Many adults and children experience multiple divorces and remarriages during their lifetimes because the divorce rate for subsequent remarriages increases with each succeeding divorce. Prior to the divorce revolution

of the 1960s, most remarriages were formed after the death of the spouse. This is no longer the case.

From a demographic perspective, remarriage refers to couples in which one or both members have been previously married. The causes for the remarriage may be due to a divorce or death of one or both spouses. Remarried couples may or may not have children from previous relationships or marriages. If the remarried couple has one or more children, then they are referred to as a remarried or stepfamily. Marriages in stepfamilies are strongly influenced by the presence of children. This entry describes common issues and relationship patterns in remarried families.

Stepfamilies

Where did the term *stepfamily* begin? It originated in England, and its history is informative about the current meaning. The prefix *step* is from the Anglo-Saxon word *steop*, meaning *to bereave or to make orphan*. This name was applied to children whose parents had died. Prior to the divorce revolution, steprelations were primarily established because of loss through death. Today, a stepfamily is usually created after divorce.

The most common type of stepfamily is the divorce-engendered stepfather family. The man, who may or may not have been previously married, marries a woman who has children from a previous marriage or relationship. Other types of stepfamilies include stepmother and blended families. Blended families have both parents who have custody of children from a previous marriage. Most stepfamilies are created after a remarriage, but with the increase in cohabitation, many *repartnered* families are formed without the legal sanction of matrimony. This entry uses the term *remarried family*, which encompasses families that have custody of the children and those that do not, married and unmarried couples, opposite-gender and same-gender couples, families with one or two biological parents, and divorced, widowed, and previously unmarried families.

Remarriages

Although the divorce rate is high, it appears that Americans are in love with the institution of

marriage, but with a series of partners. The divorce rate for second and subsequent marriages is higher than for first marriages. Remarried people are also likely to divorce and remarry for a third time; thus, a common pattern for many adults is *serial monogamy*. It is estimated that between 70 and 75 percent of women and 80 and 85 percent of men previously married will eventually remarry. The percentages vary because younger adults are more likely to remarry, whereas older adults are less likely to remarry. Most adults remarry quickly, within 5 years of their divorce. White and Hispanic adults are more likely to remarry than Black adults.

Most research and clinical writings are based on remarried couples involving White, middle-class individuals. Further research is needed to examine ethnic and economic diversity in response to marital and nonmarital transitions because of the different patterns of marriage, divorce, and remarriage rates among ethnic groups. For example, for many low-income African-American families, children are more likely to come from nonmarital unions, and the role of the nonresidential parent and his family may vary in relationship quality and access. In these families, grandparents and nonbiological kin (often called *Aunties*) play an important role in childrearing. It is unclear how these multigenerational and nonkin relationships affect remarried couples and what role they play in successful couple relationships. Given the increasing diversity of the population, these potential differences warrant further exploration as well as the development of cultural specific marital interventions.

There is some evidence that remarried partners "select downward" for their new mate. This means that they look for a younger partner (both males and females) or someone with less education than their first mate. In addition, people frequently look for a partner different from their first partner. However, this selection process often results in selecting someone who appears different than the previous spouse, but has similar traits, but at the other end of the same dimension. For example, control may have been an issue in the first marriage; that is, the divorced person had a spouse who was perceived to be overly controlling. In the second marriage, he or she might look for someone different (i.e., not controlling), ending up with a spouse who is neglectful or controlling through less obvious, passive-aggressive means.

Marital relationships in stepfamilies differ from those in first-marriage families. Spouses in the former see their relationship in more pragmatic and less romantic terms. Remarried partners tend to share both household and childrearing responsibilities more than in first-marriage families. The quality of a marital relationship between remarried adults is often negatively affected by the presence of stepchildren, although the influence is not always large. After the marriage, newlywed couples normally spend time alone and create a marital bond. In remarried families, this is compromised by the demands of caring for children from the beginning of the relationship. The quality of the marital relationship tends to be poorer when both parents have children from previous relationships than when only one adult is a stepparent probably because of increased complexity and more opportunities for conflict. This is more difficult when people remarry and have young adolescent children. In general, it is easier to form a remarried family with young children than with older adolescents.

In addition to forming a new marriage, remarriages have the added stress of bringing unresolved and old patterns from previous marriages into the current one. These are referred to as the “ghosts at the table” because they often operate in unseen ways and pop up to create problems in the relationship. For example, in the previous marriage, a husband may have overspent their money and run up large debts that a wife was saddled with after the divorce. Early in her remarriage, she had conflict with her spouse about his spending, although he remained within their budget, because of her fear that this pattern would repeat in this marriage. Helping couples identify these old ghosts and how they operate in the current relationship is an important step in ridding themselves of ghosts or at least changing them to friendly ghosts.

Forming Relationships in Remarriages

In the first few years of remarriage, couples need to form a strong marital bond. This is particularly challenging for stepfamily couples with residential stepchildren. The couple with children faces challenges in time and energy to nurture and attend to their marital and adult needs. However, it is critical that couples form a well-functioning marriage because it is difficult to handle other family issues,

especially parenting, if the marriage is rocky. Helping couples develop a common ground and understanding in their marriage, taking time to meet their adult needs, and having fun and enjoyment in the marriage is essential. Household chores and responsibilities need to be more equally shared in order for the woman to feel that she has the time and energy to attend to the marriage. It is often important that couples actually schedule their time together because other issues and demands often get in the way.

Family relationships in remarried families, and particularly the stepparent–child relationship, tend to be more distant and have more conflict than those in first-marriage families. In addition, these relationships have more coalitions and triangles than do first-marriage families. Thus, there is higher risk for step– and parent–child relationship problems in remarried families, especially with adolescents.

However, it is important to note that, although these relationships are more negative in remarriages than in first-marriage families, they are not necessarily pathological or problematic. There are differences between family structure groups on various measures and ratings of family relations, but they generally are relatively small and represent differences within a “normal range.” Although there are often more negative and conflictual relationships in remarriages, compared with first marriages, the mean ratings for *both* groups are in the positive range. Thus, it is not accurate to characterize remarriages as “negative, conflictual, and distant.” This can lead both scholars and social policy analysts to misinterpret the data.

The marital subsystem appears to affect other family subsystems differently in remarriages than in first-marriage families. Sources of conflict experienced by remarried couples include boundary ambiguity, conflicting loyalties, stepparent–stepchild relationships, and stepparents’ disciplinary role. There seems to be more disruption and conflict in parent–child relationships during the early stages of remarriage than in first-marriage families. Disagreements between couples usually focus on stepchildren issues, such as discipline, rules for children, and the distribution of resources to children.

During early remarriage, marital adjustment and satisfaction are not related to children’s behavior problems. This contrasts with first-marriage

families, in which marital problems are usually predictive of adjustment difficulties for children. After several years in a stepfamily, marital relationships have more impact on children's adjustment and marriage, and parent-child interactions are similar to those in first-marriage families.

Conflict

First-marriage family conflict includes marital conflict, interparental conflict, parent-child conflict, sibling conflict, parent-grandparent conflict, and other general forms of family disharmony. Remarried families can also experience conflict like first-marriage families, and there is also the possibility for stepparent-parent conflict, stepparent-child conflict, and conflict between former spouses. Family and interparental conflict involving the children are key predictors of children's adjustment, especially in divorced or remarried families. Overall, conflict within the family is more predictive of children's adjustment in remarried families than in first-marriage families.

Nonresidential Parents in Remarriages

Unlike first marriages, adults in remarriages usually have an ex-spouse who may have an ongoing influence on their marriage. This is especially the case when there are children from the prior relationship or marriage. With remarried families, the ex-spouse/nonresidential parent may continue to influence the marriage through ongoing contact with the children. This comes in two forms: direct contact because of visitation/childrearing issues with the children and the children's influence because of the ongoing contact with their nonresidential parent. Old patterns of conflict can continue after the remarriage, and these issues can reverberate in the new marriage with destructive force. In addition, children may react differently to a parent or stepparent after visiting their nonresidential parent. The stepparent may react negatively to this change, and this reaction may negatively affect the couple's marriage.

Conclusions

Remarriages and remarried families are an established feature of contemporary culture in the

United States. Remarriage entails a number of risk factors for family members, such as increased stress, disrupted family roles, and increased conflict. Warm, supportive relationships between children and adult parents and cooperative, understanding relationships between residential and nonresidential parents are all important factors that contribute to better relationships after remarriage. Overall, research has found similar family processes among remarriages and first-marriage families, and a large proportion of stable, long-term remarriages seem to function in similar ways to first-marriage families. Over time, remarriages tend to function similarly to first-marriage families. The field needs a closer examination of the factors that contribute to the success of remarriages and how they can contribute to the development of healthy and happy family members.

REPAIRING RELATIONSHIPS

Sooner or later, all relationships have problems. Some problems are minor irritations, whereas others are major threats to the future of the relationship. Some problems develop slowly, whereas others occur instantaneously. Some erode relationships over relatively long durations, whereas others are short-lived. Regardless of the nature of the problem, unless partners elect to ignore it or to end their relationship, some sort of repair strategy will be needed. This entry describes four general approaches to relationship repair, what is known about the operation of each, and their consequences. Although this entry emphasizes romantic relationships because repair strategies have been studied most often in these relationships, most researchers believe that these processes also apply to other types of close relationships, such as between siblings, family members, and close friends.

Naturally Occurring and Informal Approaches to Relationship Repair

Most of the time, partners attempt to resolve their problems by themselves. Resolving differences is a normal part of interdependent relationships. Problems arise and, to restore harmony, partners must put the problem behind them in some way. Among the most influential of the various models for describing these maintenance strategies is Caryl Rusbult's model of accommodation. Rusbult proposes four behavioral strategies: voice (active, constructive attempts to discuss and improve the situation), loyalty (optimistically but passively waiting for the situation to improve), neglect (avoiding the partner and the problem), and exit (behaving in an actively destructive manner, such as threatening to end the relationship). Much research has shown that relationships benefit from the use of voice, whereas they are harmed by neglect and exit. Evidence about the impact of loyalty is more equivocal, sometimes showing

relationship benefits, whereas other times showing little or no effect.

When a relationship problem is ongoing—for example, a habitual pattern of damaging conflict, substantial disagreements about core issues (e.g., money, parenting practices), or an extramarital affair—a more focused attempt to resolve the problem and repair damage to the relationship is needed. Although outside professional help is sometimes sought for such problems, it seems probable that all couples first try to resolve their issues on their own, and many do so repeatedly and successfully. One study showed that about two thirds of couples whose difficulties were sufficient to warrant professional intervention did not seek such help, and another study showed that couples may delay seeking outside help for as long as 5 years after a problem surfaces. Some, of course, end their relationships without trying professional help.

Unfortunately, there is little systematic, methodologically solid evidence as to whether couples' efforts at self-repair are likely to be successful, particularly once problems are entrenched. Marital researchers commonly assume that spontaneous remission of serious marital problems is rare, but this assumption has not been adequately tested nor does it take into account the nature of the coping strategies that couples use to attempt to solve their problems. One of the more optimistic accounts comes from the multiwave longitudinal National Survey of Families and Households, which showed that 62 percent of unhappily married couples who stayed together reported being happily married 5 years later. This figure implies that 38 percent remained unhappily married, and it remains to be discovered what processes can distinguish these two groups. As for spontaneous remission in nonmarital couples (e.g., cohabitators), little is known. Presumably because the institutional and psychological barriers to separation and divorce tend to be weaker in nonmarital couples, enduring problems would be more likely to result in termination.

The fact that unhappiness is frequently not a permanent state in relationships indicates that couples can find within themselves (and perhaps their social network) strategies and resources for repairing relationship problems. Indeed, the ability to engage in repair strategies in the face of disagreements, hurt feelings, and relational transgressions may be the

hallmark of a healthy relationship. Existing research points to many potentially effective strategies, whose benefits will depend on the partners' motivation and ability to put them into action (e.g., forgiveness, apologies, sacrifice, accommodation, accepting influence, commitment, shared play, humor, affection, sexual pleasure, and finding higher meaning or a sense of purpose in a relationship). Relationship repair may also be facilitated by the alleviation of external factors that create stress in relationships (e.g., lessening of job-related or parenting stress or successful treatment for substance abuse).

Popular Media and "Self-Help" Approaches

Relationship repair is an enormously popular topic for self-help books, advice columns, the Internet, and television talk shows. Bookstores typically have multiple shelves of books dedicated to helping readers find solutions to relationship problems, and, increasingly, the Internet provides not only information and advice, but interactive quizzes and courses designed to improve relationship functioning. Unfortunately, a large proportion of widely disseminated relationship-relevant messages are written or produced by individuals with little training in relationship science or couples therapy, who are not conversant with existing literature or empirically validated interventions, and whose work is not bound by the professional ethics of researchers and clinicians. Not surprisingly, then, there is no existing evidence that the advice offered in these media is effective in helping partners repair problematic relationships. In fact, there are numerous examples in which self-help books offer advice that has already been documented to be ineffective (e.g., simplistic exhortations to "think positive thoughts about a partner," which fail to consider the reasons that such thoughts are not happening) or worse.

Of course, sometimes popular media deliver reasonable suggestions that a couple may find helpful. Moreover, self-help and popular media approaches are increasingly becoming a conduit for dissemination of empirically informed advice by scholars and practitioners with legitimate credentials in the field. Popular media provide an important channel for bringing insights from relationship science to the public. However, navigating the

dizzying array of often contradictory suggestions for relationship repair and distinguishing expert advice from personal anecdote is a formidable challenge for the potential consumer.

Relationship Education Programs

Relationship education programs are formal, often highly structured interventions designed to strengthen and improve relationship functioning. Couple or marital relationships have been the primary target, with programs originally embracing one of two goals: problem prevention, on the assumption that "an ounce of prevention is worth a pound of cure," and enrichment, on the assumption that even a good relationship could be better. In modern programs, whatever distinctions may have existed have largely disappeared. Furthermore, although these programs are predicated on the idea of preventing as opposed to redressing problems, couples often decide to try them when problems, perhaps of a minor or ambiguous sort, have already appeared. Regardless of whether the goal is prevention, enrichment, or problem resolution, relationship education programs are intended not only to teach partners ways of avoiding problems, but also ways of minimizing their impact when they do inevitably occur.

Although in principle, relationship education is designed to forestall, as opposed to fix, problems, some amount of repair focus is central to all such programs. Avoidance of problems is discouraged; these programs teach partners ways of addressing disagreements and conflicts, small and large, when they do occur so that "molehills do not become mountains." Furthermore, these programs also aim to provide partners with strategies for restoring harmony and enjoyment of each other's company when relationship problems or external stress (e.g., jobs, children) have engendered tension or distance. Research increasingly suggests that these positive processes, in sufficient dosage, may neutralize the erosion caused by negative interactional processes. Enhancing the positive aspects of a relationship provides fertile ground and the goodwill needed to engage in regular repair strategies when disagreements or misunderstandings occur.

Many relationship education programs exist, although few are based directly on empirically

supported principles, and fewer still have been shown by evaluation research to have demonstrable short- or long-term benefits. Two of the better-grounded programs are Howard Markman's Prevention and Relationship Enhancement Program (PREP) and Bernard Guerney's Relationship Enhancement (RE) program. Both are based at least in significant part on principles that have received consistent support in the relationship science literature. Also important is the fact that both have been shown in evaluation studies to benefit participants, compared with control groups, in areas such as communication, problem resolution, and relationship satisfaction. Just how long such benefits endure is largely unknown at this point. One study showed that PREP had benefits lasting as long as 4 years after participation. Some programs now offer "booster sessions" and other resources (e.g., Internet-based activities) in an attempt to reinforce program-based gains over time, although the incremental value of such additions has not been established.

Relationship education programs vary widely in their features. Some are brief (e.g., a single day), whereas others are more like a college course, with weekly sessions over a number of weeks (e.g., 5–12 weeks). Some are formal and highly organized, whereas others are informal and mostly unstructured. Some are delivered to individuals, whereas some require participation of both partners. Some, particularly those that are evidence-based, tend to follow a prespecified format (thus achieving fidelity with the program features that have been empirically demonstrated to be beneficial), whereas others play out in more idiosyncratic fashion, often based on the participants' goals and predilections. Program activities typically involve varying amounts of didactic instruction, experiential exercises, and discussion, along with supporting material such as movie clips, videotaped examples of desirable and undesirable interactions, and homework assignments.

Although programs differ in their specific goals, most programs share certain elements: to teach effective communication skills; to develop partners' capacities for resolving problems and managing conflicts in constructive ways; to foster openness, empathy, support, and responsive caregiving; to encourage partners to make the relationship a continuing priority in their lives; to enhance fun,

affection, and a sense of togetherness in everyday life; and to motivate partners to take responsibility for their own actions and feelings. Most programs also try to raise awareness about the sorts of issues and problems likely to arise in the relationship's future, thus priming partners for the need to engage in relationship repair processes.

Relationship and Couple Therapy

Relationship issues are one of the most common reasons for seeking help from a professional therapist or counselor. Although one partner may seek help alone, it is difficult to effectively address dyadic or relationship issues without involvement by both members of the dyad. When married or romantic partners are unable to resolve problems by themselves, they may seek assistance from a couple therapist who typically will meet with both partners simultaneously in conjoint sessions. In general, various approaches to couple therapy share the following common goals: (a) providing a safe environment in which relationship difficulties can be communicated and negotiated, (b) increasing mutual acceptance, (c) ameliorating individual and relationship crises, (d) improving communication—including decision-making skills as well as emotional expressiveness and responsiveness, (e) building partners' friendship and emotional bonds, and (f) improving sexual and other physical intimacy.

Although the literature describes numerous approaches to couple therapy, only six have been demonstrated to be effective in clinical trials that compare couple therapy to an appropriate control group. Traditional Behavioral Couple Therapy (TBCT) has been studied far more extensively than any other single approach to couple therapy, with the average individual receiving TBCT is better off at the end of treatment than 72 percent of individuals not receiving treatment. TBCT teaches partners to communicate more effectively around hurt feelings and resolving disagreements, as well as to negotiate more positive ways of interacting. Cognitive-Behavioral Couple Therapy (CBCT) builds on TBCT by targeting partners' relationship assumptions and standards, expectancies, and attributions that contribute to distorted emotions or maladaptive behaviors underlying couple

distress. Various adaptations of CBCT have been shown to be effective for treating couple distress related to a variety of physical health and emotional or behavioral disorders. Integrative Behavioral Couple Therapy (IBCT) goes beyond CBCT in promoting tolerance and encouraging partners to appreciate differences and to use these to enhance their relationship. A large randomized clinical trial comparing IBCT with TBCT showed that both treatments produced clinically significant improvement by the end of treatment and comparable separation/divorce rates (about 25 percent) at 5-year follow-up.

Three approaches to couple therapy from non-behavioral perspectives have also been shown to be effective. Emotionally Focused Couple Therapy (EFCT) combines an experiential, intrapsychic focus on inner emotional experience with an emphasis on cyclical, self-reinforcing interactions. In four randomized trials, EFCT was superior to a control condition (remaining on a waiting list for couple therapy) in reducing relationship distress, yielding recovery rates of 70 to 73 percent. Another approach, Integrated Systemic Couple Therapy (ISCT), seeks to disrupt repetitive, self-perpetuating negative interactional cycles by changing the meaning attributed to these cycles. In a clinical trial comparing ISCT with EFCT, both were found to be superior to a control condition and to be equally effective in alleviating couple distress. Finally, Insight-Oriented Couple Therapy (IOCT) emphasizes the interpretation and resolution of long-standing maladaptive relationship patterns (e.g., recurring struggles around issues of intimacy, control, or fears of abandonment) that were acquired in previous problematic or traumatic relationships (e.g., in the family of origin). In a clinical trial comparing IOCT with TBCT, couples in both treatment conditions showed significant gains in relationship satisfaction compared with a wait-list control group. However, at a 4-year follow-up, 38 percent of the behavioral couples had experienced divorce, in contrast to only 3 percent of couples in the insight-oriented condition.

Despite the overall effectiveness of couple therapy, a substantial percentage of individuals fail to show improvement from these treatments; moreover, among those individuals who initially respond favorably, approximately 30 to 60 percent deteriorate significantly over time. Such findings have led

to the development of integrative models of couple therapy incorporating the most effective elements of diverse treatment approaches. A “depth-behavioral” approach to integrative couple therapy incorporates both behavioral therapy and object relations therapy (an approach based on object relations theory, a psychodynamic theory that views relationships as a fundamental motivating factor in life). An alternative pluralistic, hierarchical approach to couple therapy incorporates behavioral and cognitive techniques earlier in therapy and insight-oriented techniques later in treatment if the couple distress is resistant to change earlier in therapy. The insight-oriented component of this pluralistic approach, labeled *affective reconstruction*, examines each partner’s previous relationships to identify maladaptive patterns and ways in which coping styles established in earlier relationships may obstruct emotional intimacy in the current relationship.

Although couple therapy is most commonly used for reducing relationship distress and promoting couple well-being, the co-occurrence between couple distress and specific individual or relationship problems has led to couple-based interventions for addressing these comorbid difficulties. For example, couple-based treatment for sexual difficulties helps partners to discuss and resolve specific challenges in their sexual interactions. Couple-based interventions have improved sexual functioning for women with orgasmic disorders at rates ranging from 65 to 90 percent. Couple-based interventions emphasizing anger management and communication skills have been effective in treating mild to moderate levels of physical aggression; however, most clinicians agree that couple therapy is inappropriate for severe physical aggression.

A recent integrative approach for treating couples in which one or both partners has had an affair emphasizes three phases that target: (1) coping with initial emotional and behavioral disruption of individual and relationship functioning following discovery or disclosure of the affair; (2) exploring individual, relationship, and outside contextual factors contributing to the initial onset or maintenance of the affair; and (3) reaching an informed decision about how to move on, either individually or as a couple. A preliminary investigation of this treatment indicated that, at termination, the

majority of participants reported less emotional and relationship distress, and individuals whose partner had participated in the affair reported greater forgiveness toward their partners.

Couple-based treatment for both alcoholism and drug abuse produces more abstinence and fewer substance-related problems, happier relationships, fewer couple separations, and lower risk for divorce than does individual-based treatment. Behavioral Couple Therapy has also been shown to be effective in relieving depression when provided to distressed couples with a depressed partner. Finally, recent findings have supported the effectiveness of couple therapy in treating patients suffering from anxiety disorders, chronic pain, cancer, terminal illnesses in general, obesity, coronary artery disease, and post-traumatic stress disorder. Although research shows that paraprofessionals (e.g., clergy) can effectively implement structured relationship education programs (e.g., PREP), there has been little empirical study of this issue as applied to couple therapy for serious relationship problems.

Conclusion

One of the more idealistic (and unhelpful) beliefs that people sometimes voice about long-term committed relationships is that conflict should occur rarely or not at all, problems should be inconsequential, and that the trajectory over time should proceed more or less smoothly and effortlessly. The need for repair, under this belief, is seen as a sign of fundamental flaws in the relationship, in the individuals involved, or in both, rather than as part of the natural life cycle of relationships. Such stigmatizing beliefs, aside from the fact that they are not grounded in reality, may contribute to the worsening of problems by postponing the engagement of potentially helpful repair processes until problems have progressed too far. Repair behaviors and processes, both formal and informal, are a normal and critically important part of the evolution of relationships. When properly engaged, they contribute in a significant way to making relationships fulfilling and enjoyable for all concerned.

RESILIENCE

Intimacy, betrayal, trust, jealousy, attachment, love, and loneliness are terms that point to the salience of relational processes in both human suffering and striving. In cases of pronounced adversity, the primary developmental threat may be a distorted or

malevolent relationship, as in child abuse and neglect. Yet interpersonal relationships, such as those with supportive, caring adults, are similarly powerful conduits of positive developmental pathways in the wake of adversity. Early relationships with caregivers are especially salient contexts within which core relational experiences occur (e.g., trust, love, connection), primary relational abilities develop (e.g., perspective-taking, regulation, empathy), and influential expectations of self and others are internalized. This entry focuses on relational processes in resilient adaptation and *why* relational processes are central to understanding *how* individuals achieve positive developmental outcomes, especially in adverse contexts.

Resilience Defined

Resilience is a dynamic developmental process wherein the individual is able to utilize resources in and outside of the self to negotiate current challenges adaptively and, by extension, to develop a foundation on which to rely when future challenges occur. In contexts of prior or current adversity, resilience reflects *both* the absence of psychopathology and the presence of competence wherein the individual is able to negotiate age-salient issues effectively. In infancy, these issues center on the challenge of negotiating a consistent pattern of relating to caregivers, whereas the emphasis shifts toward the negotiation of peer relationships and the challenge of self-regulation in the toddler and preschool periods. Thus, resilience is a multidimensional, culturally embedded, and developmentally anchored process.

Resilience is a feature of development, not of individuals. Resilience follows from the operation of normal developmental processes despite extraordinary circumstances, rather than from exceptional individual capacities. To the extent that typical developmental processes are protected or enabled despite adverse experience, resilience is fostered. Relational processes are central among these developmental capacities: relationships between different developmental systems such as biology and psychology; relationships among different levels of the environment such as families, schools, and communities; and, as discussed here, relationships between people.

Resilience-Fostering Relationships

Interpersonal relationships have been a key focus of resilience research since its inception. Pioneers of this field, such as Norman Garmezy, Lois Murphy, Sir Michael Rutter, and Emmy Werner, were the first to document the powerful and positive impact of a supportive, caring, and connected relationship with an adult on developmental trajectories of high-risk youth. In childhood, caregiving relationships are of primary significance, but relationships in other arenas increase in salience over time. Relationships with teachers, coaches, spiritual leaders, mental health providers, and peers take on increasing importance across childhood, whereas adolescence and adulthood bring romantic relationships, employee–employer, and collegial connections to the fore. Yet the nature and quality of these later relationships are uniquely influenced by early patterns of sensitivity and reciprocity in the caregiving milieu. Evidence clearly points to the unique importance of the early caregiving environment for the development of basic capacities, such as self-regulation, perspective taking, and self-esteem, which shape individuals' responses to current and future developmental challenges.

From the earliest days of life, interpersonal relationships influence developmental trajectories, for better or worse. Associations with deviant peers, for example, may engender disruptive, antisocial behaviors among high-risk youth. Yet prosocial peer connections may provide opportunities for high-risk youth to apprehend and practice positive, rule-abiding behaviors. Having documented the importance of relationships for both typical and atypical developmental trajectories, contemporary resilience research has shifted toward delineating processes by which such relationships, particularly early relationships, engender positive adaptation despite exposure to significant developmental threat. Although initially conceptualized at the level of dyads and later families, these relational processes have since been examined at group and cultural levels, as well as at biological, social, and cognitive levels.

Relational Processes in Resilience

Across populations and developmental periods, relational processes take on disproportionate salience in adverse or traumatic contexts. In the

framework of resilience, positive interpersonal relationships operate as protective factors because they decrease the strength of the association between adverse experience and negative outcomes. Across settings and levels of risk and adversity, assets operate as resources that increase the probability of positive outcomes for all individuals, whereas risks undermine adaptive functioning. As complements to assets and risks, respectively, protective and vulnerability factors are disproportionately influential in conditions of adversity moderating the relation between adverse experience and negative developmental outcomes.

Of the myriad factors associated with positive development in adverse contexts, relationships take on unique significance. Trusting, consistent, and supportive interpersonal relationships foster positive development for all people, yet their protective and restorative capacity is magnified in conditions of adversity. Thus, positive human relationships are a protective factor engendering better-than-expected outcomes in the context of adverse life experience. The presence of a supportive mentor may help all youth, but it takes on a unique importance when provided to a youth whose life is otherwise devoid of positive influences, role models, and nurturance.

How, why, and for whom such relationships exert their developmental impact is of great interest to researchers. Relational processes underlying resilient adaptation span cognitive, emotional, and biological systems. Positive relationships with others provide social, moral, instrumental, and emotional support, as well as opportunities for learning and practicing new skills. Further, growth-fostering relationships engender positive self-regard and heighten individuals' regard for others, thereby increasing self-efficacy and the motivation to pursue additional interpersonal connections. At other levels, positive relational processes may activate protective or restorative biological systems and engender adaptive socio-emotional regulation. Yet the impact of relationships on human development is not uniform. As the mechanisms by which relationships exert their protective influence in risk contexts come into focus, efforts to understand individual differences in responsiveness to these processes grow stronger.

Implications

The study of resilience holds important implications for understanding and fostering human development. Resilience follows from a coherent and cumulative developmental pattern wherein key relational capacities are supported, protected, or restored. These capacities operate at biological, psychological, and social levels to enable individuals to develop and sustain growth-fostering connections with other people. Individuals who are able to achieve the developmental expectations of their culture despite adverse experience (i.e., whose development typifies resilience) have been able to develop or sustain necessary capacities to build positive, reciprocal connections with others. Research is needed to identify factors that enable individuals to develop or sustain these abilities despite adversity.

Interventions that aim to promote resilience must introduce the potential for new relationships (e.g., mentors) while supporting core cognitive, biological, and regulatory systems that enable such connections in the first place (e.g., stress reactivity, emotion regulation, relational expectancies, and beliefs). As discussed previously, early childhood is an especially important context for the development of these systems. Thus, applied efforts to support resilient adaptation must identify and protect key processes that enable sensitive and responsive caregiving to infants and young children. In turn, these interventions foster relational processes that are critically important for resilient adaptation.

RESOURCE THEORY

Resources are the objects, activities, processes, concepts, and emotions that have value to relationship partners. A resource can be valued, in and of itself, or only serve as a tool to acquire something of value (a means to an end). The value of any resource is defined by the meaning assigned to it, rather than by the resource. Similar meanings can be frequently assigned by individuals, such that some resources (e.g., money, attractiveness, loyalty) can take on a common or normative value. Resource exchanges occur across many types of human relationships (e.g., parent–child, romantic, friend, work, peer). Indeed, the nature of these exchanges can contribute to the development, maintenance, and/or decline of relationships. Resource theories focus on the identification, valuation, and exchange of resources.

Uriel Foa and his colleagues identified six categories of resources. *Love* represents care, kindness, emotional support, and intimacy. Thus, it reflects a myriad of positively based emotions toward others. *Status* represents the degree of respect, achievement, rank, or admiration. Status can be socially defined at a community level (e.g., national fame, social class, awards), small-group level (e.g., leader among friends), or relationship level (more-powerful/less-powerful partner). *Service* represents the activities performed by individuals to benefit relationship partners. Service often requires people to engage in some effort or work for their partners. Service, however, does not automatically imply subservience (power imbalance/exploitation). For example, parents provide many services for their children, but the parents might not feel exploited. Rather, parents might be quite happy to provide such services.

Goods represent objects, substances, manufactured products, or raw materials. Some goods,

such as meals, are essential to daily existence, but many nonessential goods or luxuries are common to relationship exchanges—for example, gifts. *Information* represents facts, knowledge, insights, guidance, or feedback. Informational resources (e.g., advice) are not limited to formal education, but can be garnered from life experience as well. *Money* represents currency as well as other forms of wealth accumulation, such as investments. Although money might be considered a primary resource in some relationships—for example, employer–employee—it also plays a role in other relationship types (e.g., couples negotiate spending/saving priorities).

Comparatively, love, status, and information are more abstract resources, whereas services, goods, and money are more pragmatic resources. For example, giving feedback (information resource) would require thought, but would not require the use of objects or materials. In contrast, cleaning house (service resource) would require the use of physical objects to achieve resource provision. A single act can be perceived as more than one resource. Thus, cooking can be perceived as a service, a status symbol (for highly skilled cooks), or an expression of love (cooking as a sign of affection). In addition, relationship partners can differ in the meanings that they assign to the same behavior. Thus, individuals can engage in cooking as a gesture of love, but it can be perceived by partners (the recipients) as a service.

Resources can also be contrasted on the degree of specificity. Specificity refers to the extent to which a resource is particular or unique to relationships. Love, status, and information are more specific resources, whereas goods, services, and money are less specific resources. Love and money are considered polar opposites in the specificity dimension. Thus, individuals might expect that the love offered by their romantic partners is particular (and exclusive). If individuals learned that their partners expressed the same love to others, this might be reason to end the romances. Indeed, the individuals might doubt whether the love was ever “real.” However, the same dynamics don’t seem to apply to money. Cash is not exclusively limited to one type of relationship and it is treated as equally real across interactions.

Research has shown that individuals typically prefer to exchange resources that are within the

same category (e.g., exchange love for love) or across similar categories (e.g., exchange goods for services). Thus, individuals might not need to make identical exchanges within categories for their relationship to be stable. Rather, it might be the cumulative exchange across categories that serves as the basis for evaluating relationship quality. If the overall exchange is unsatisfactory, then individuals might alter their exchanges or dissolve their relationships.

There has been some consideration that not all resources might fit easily into the six classifications. So broader conceptualizations of resource categories (e.g., demographics, personal attributes, relationship characteristics, and community) have been offered. These broader categories have been helpful to understanding normative resources, in which members of a community/culture share meanings that guide their exchanges. For example, males and females who hold traditional gender roles expect differences between partners. Traditional men would have more decision-making power than women because men are considered the “heads of the households.” Traditional women would have more closeness to children than men because women are considered the “emotional centers of the families.” For such couples, the resource differences can enhance relationship satisfaction as they fulfill expected norms. In addition, such couples can make complementary exchanges across resource categories. Thus, they might perceive that the rate of resource exchange is equitable even if the resource categories differ.

Relationship partners will not always agree on the value of the resources that they exchange. That is, partners can assign different values to resources. Individuals might offer resources that they value highly, but the partners might see little value in the resources. For example, individuals might perceive that their advice (information resource) is insightful, but their friends might perceive the advice as useless. The different values that they place on the resource could impact their interactions. For example, friends might avoid discussion of problems (where advice might be offered), but enjoy leisure activities. It is important to note that others outside relationships (e.g., family, coworkers, research observers) might also place different values on the resource exchanges. This difference might explain why it is sometimes difficult for outsiders to understand how relationships work for the partners (e.g., spouses, friends).

Norms exist for many relationship types (e.g., parent–child, marriage, friendship) and can affect the nature of resource exchanges. For example, one norm for parent–child relationships is that parents will provide guidance—praise, criticism/punishment—and children will comply with the guidance by continuing good behavior or eliminating bad behavior. It is important to note that awareness of norms does not inherently reflect compliance. Individuals can enact relationships in ways that defy normative guidelines. Defiance can occur from one member of a relationship. For example, as children grow and become adolescents, they may refuse to abide by their parents’ guidelines. For others, both members of a relationship might engage in defiance. So, couples might reject traditional weddings, but utilize goods/services resources to enhance their sense of uniqueness (e.g., “We’ll exchange vows while skydiving because our relationship is too special for a conventional ceremony”). Thus, resources can be utilized to actually defy norms and personalize relationship experiences.

In summary, resource theories provide valuable conceptual models for understanding a wide range of relationship processes. The theories can help us understand the exchanges that occur in casual and close relationships. In addition, the theories provide an explanation for why relationship partners (as well as outsiders) can view the same events/exchanges in different ways.

RESPECT

Respect is a concept referred to in many situations and viewed as important in various kinds of relationships. This entry defines respect and discusses the ways in which it is displayed in human relationships, particularly romantic ones.

The word *respect* can convey admiration, approval, and high valuing of a person or even a thing or an idea (such as respect for religious faith). The focus of this entry is person-to-person respect. Respect has both a cognitive component (such as thinking well of another) and an emotional component (such as feeling admiration toward another). Some writers have emphasized respect as something given to another simply because that other is a part of our human community. Ideally, respect in this sense crosses racial, ethnic, and religious lines and even national boundaries, granting respect (or a sense of worth) to everyone.

If one listens and watches, the word *respect* is heard through the media, is seen on signs in public schools and university hallways, and may even be heard in musical lyrics on occasion. In daily life, however, respect seems sometimes to be less visible than *disrespect*, which is defined as rudeness and disregard. Disrespect is relevant to injustices, status and power differences, social inequities, and the like. For example, persons in authority may have power over others simply because they have an authoritative role, and the role has been given power. Yet the way such persons enact their role and exercise their authority will impact whether they are respected in that role. For example, an authority figure may be feared, yet not respected.

Respect in educational settings, work settings, and the public arena is essential for maintaining social order. Disrespecting others can lead to major breaches of the social order such as crime or even war. Yet minor breaches—being rude to a salesperson or cutting off another car/person on the freeway—may impact social life more negatively than the larger breaches simply because they weaken respect slowly but surely over time.

Respect in the workplace is related not only to effective interpersonal relationships and resulting productivity, but more fundamentally to hiring practices and how people are treated after they are

hired. For example, men have often been viewed as more competent in many work settings, aside from child care, elementary school teaching, and other vocations seen as “women’s work.” Deborah Tannen has said that women in the workplace want to be liked, whereas men want to be respected. If this is so, it may have implications for who is likely to be promoted, given larger raises, and so on. Respect is relevant in all cultures and countries, although criteria for and ways of displaying respect may differ.

Respect has been identified as an important component of friend and family relationships, although it may be shown in different ways in different cultures. For example, in some cultures, it is respectful to make eye contact with another person, whereas in other cultures, a lack of eye contact indicates proper respect. Many cultures pay particular attention to respecting one’s elders.

Respect plays a central role in marital/romantic relationships. No matter what the task division may be in a relationship, mutual honoring and respect are important for satisfaction with and success in a relationship. In fact, respect has been identified as a component of love and as an important factor in marital quality. In some relationships, respect given may depend to an extent on the respect-worthiness of the partner, but in other relationships, respect is a freely given gift, a bestowal of respect.

Sara Lawrence-Lightfoot positioned respect as multifaceted, and she proposed six themes that in her view constitute respect, including attention, curiosity, dialogue, empowerment, healing, and self-respect. What does each of these six themes really mean in a romantic relationship? *Attention* means just that—focusing on the partner and ignoring, at least temporarily, media, children, chores, jobs, and all the things that draw our attention away from the key person to whom we should be attending. It means giving this attention ungrudgingly. We have *curiosity* about our partner—what they are feeling, thinking, and doing. An intimate partner is someone who we know well, yet who can sometimes surprise us and who simply interests us. *Dialogue* implies a mutual and reciprocal conversation; it is a dance in which no one leads and no one follows. It requires clear and frequent communication. *Empowerment* involves supporting and strengthening our partner in whatever

ways we are able. It does not mean that we always agree, but our disagreement needs to be constructive and aimed toward helping our partner. *Healing* is intertwined with empowerment, but is not the same thing. Healing is caring for, supporting, and providing a place of refuge for our loved one. If our relationship is a healing one, surely it is also an empowering one. Finally, *self-respect* places us front and center in the respecting process. It has often been said that we must love ourselves in order to love others, and the same is true of respect. Self-respect and other respect go hand in hand.

It is important to remember that respect can be a part of virtually all of our relationships, including our most intimate ones. It is an act of valuing that we should give others and one that we should also expect from others.

RESPONSIVENESS

Responsiveness lies at the heart of many important relationship processes and plays a vital role in any human relationships involving effective communication, caregiving, social support, mentoring, and leadership. Definition and measurement of *responsiveness* vary depending on the relationship context; however, most definitions encompass interaction partners behaving in a warm, sensitive manner that is contingent on and supportive of the other person's needs, emotional

states, and circumstances. Although much of the research has focused on the role of responsiveness in the provision of caregiving and social support within the context of parent-child relationships, adult close relationships, and therapeutic relationships, responsiveness also has been shown to play a central role in many processes in educational, organizational, and health care settings. This entry discusses conceptualization and measurement of responsiveness, reviews relational consequences, and examines other determinants of responsiveness.

Conceptualization and Measurement

Similarities and differences exist in conceptualization and measurement of responsiveness for child-parent relationships and adult relationships. The nature of caregiving in child-parent relationships tends to be one sided, whereas caregiving in adult relationships tends to be mutual and reciprocal with more complex sets of needs and circumstances. Nevertheless, both types of relationships share similarities, in that responsiveness entails reacting in a positive, sensitive, and appropriate manner to the other person's needs and emotional states.

Child-Parent Relationships

Much of the research on child-parent relationships examines how responsive or unresponsive parenting behavior influences the formation of attachment security and affects social and academic development. Typically, the mother is the focus of the investigation. Responsive parents provide warm, sensitive, and consistent caregiving that is contingent on the infants' physiological and emotional needs, including carefully monitoring and attending to the child's distress signals. Parents who offer such security then serve as a secure base from which children can explore their environment, and responsive parents encourage and support such exploratory behaviors that are directed by the child. In contrast, unresponsive parents provide insensitive, neglectful, critical, or inconsistent caregiving that is not contingent on the infant's needs; unresponsive parents do not provide a secure base for their children and may also restrict or become overly involved with the child's exploratory behaviors.

Other research on responsive parenting examines the role of active engagement with the child, such as providing order and structure, teaching cooperativeness, and providing rich language input.

Research on parenting responsiveness usually takes the form of naturalistic observation of child–parent interaction, either in the laboratory or in the child’s natural environment. A coding system is often used to record the behaviors of both the parents and the children. For example, parents may be coded on sensitivity to the child’s needs, their accepting mannerisms, and engagement of the child in a noninterfering manner. This observation can occur once or multiple times over an extended period of time. Other research may take the form of an intervention study, where parents are experimentally assigned to receive either responsive-parenting training or no training, and the effects of the training on the children are measured.

Whether the research is observational or experimental, the outcome typically focuses on infant behaviors, such as distress and contact-seeking behavior upon separation, and on markers of development, such as cooperative behavior, exploratory behavior, and motor and language skills. For older children and adolescents, outcome measures may include social skills, parent–child relationship quality, and levels of motivation and academic achievement. In research where both parents’ report of own responsiveness and child’s perception of parental responsiveness are obtained, much of the evidence suggests that perceived responsiveness of parental responsiveness by adolescents is a better predictor of children’s achievement than parental report of their own responsiveness.

Adult Relationships

Responsiveness in adult relationships encompasses a diverse set of relationship phenomena and is thus more difficult to define and measure. Often providers, recipients, and outside observers report differences and disagreements on what constitutes responsive behavior by providers. Responses that can be considered as sensitive and appropriate to one person’s self-expression and behavior may vary considerably across different people and even within the same person depending on both parties’ needs and circumstances at the time. The complex,

dynamic, and sequential nature of responsiveness also suggests the importance of examining the needs, motives, and behaviors of both interaction partners.

Adult interactions can also be observed naturally, longitudinally, or experimentally using an experimenter-defined coding system for measuring observable responsiveness, by experimentally creating situations in which responsive behaviors can be measured, or through self-reports. For example, research on marital relationships found that, compared with happy couples that communicate warmth and validate each other’s points, unhappy couples communicate more hostility or reject each other’s thoughts and opinions. Outcomes can vary considerably, including personal well-being, relationship development and well-being, and adult exploratory behaviors, such as pursuit and achievement of personal goals as well as reasons for pursuing these goals.

Findings point to the importance of studying perceived partner responsiveness in adult relationships. Perceived partner responsiveness is characterized by the belief that relationship partners care about, understand, validate, and otherwise react supportively to the core, defining feature of the individual’s needs, wishes, and desires. Perceiving responsiveness may be influenced by many factors such as individual differences in personality, expectations, and relationship history. Research measuring both the recipient’s perceived partner responsiveness and the provider’s or observer’s report of responsiveness show differences in reporting of responsiveness. This may occur because the provider’s efforts at providing responsive behaviors often fall short of the needs and expectations of the recipient, fail to be detected by the recipient, or are misinterpreted as being unresponsive. In situations of social support, provider’s intended supportive behaviors may sometimes be experienced as being unresponsive because it may have reduced the recipient’s feelings of competence or induced feelings of interpersonal debt. In such cases of divergence, usually, perceived partner responsiveness is a better predictor of positive outcomes than actual responsiveness. Of course, there are some agreements between the two, suggesting that objective responsive behaviors contribute to perceptions of responsiveness.

Personal and Relational Consequences

Perceiving responsiveness from a relationship partner has many important implications for enhancing both personal and relational outcomes. For example, the availability of supportive relationship partners is associated with enhanced physiological and emotional well-being. Responsive listening can facilitate effective communication and development of relational closeness. Perceived responsiveness plays a larger role in strengthening intimacy than self-disclosure does. Intimacy is enhanced when relationship partners respond to important self-disclosures in such a manner to induce feelings of having been understood, validated, and cared for. In turn, perceiving responsiveness promotes feeling connected and encourages further self-disclosure. Moreover, in contrast to less satisfying relationships characterized by norms of equity, or tit-for-tat, more satisfying communal relationships are characterized by mutual responsiveness to each other's needs and welfare without keeping track of benefits given and received. Accordingly, increasing responsive communication and behavior are key goals of many couple-based therapies. Even in nonromantic relationships, responsiveness plays a large role in promoting effective teaching, mentoring, and leadership styles.

In addition, perceiving responsiveness is critical to the formation of secure attachment, from infant-parent relationships to adult close relationships. Security of attachment is an important predictor of many personal and interpersonal processes—compared with insecure children, secure children are more likely to be socially competent and are more likely to initiate exploration of their environment. Mental models of attachment formed in early childhood have important consequences for adulthood. Secure adults are more likely to have intimate, satisfying relationships than insecure adults, and they are better at receiving and providing responsive support and caregiving. A responsive partner also can serve as a secure base, on whom adults can rely to enrich their careers, hobbies, and personal growth.

Although research tends to emphasize negative events requiring support, personal and relational outcomes have been shown to be enhanced by having a responsive partner who celebrates the person's successes. Responsive partners are more

likely to bring out the best in each other by perceiving and supporting each person's ideals and aspirations. Moreover, responsive interaction may strengthen feelings of security in relationships, leading to enhanced satisfaction and well-being. Such perceived security has other benefits—research also shows that, compared with thinking about an unsupportive or nonclose relationships, people who are asked to think about the supportiveness of a close partner are more likely to seek out unfavorable but useful information that will aid self-improvement.

Other Determinants of Responsiveness

Several factors facilitate or impede the provision of actual responsiveness and the perception of responsiveness. First, some people are better than others at detecting emotional states in others, drawing out more self-disclosure, and communicating responsive behaviors. For example, being female or having high general empathy, self-esteem, or secure attachment all seem to predict actually enacting more responsive behaviors than being male or having low empathy, self-esteem, and insecure attachment.

Second, people may unknowingly foster a reality that matches their general expectations about their social relationships. Individuals whose self-concept includes beliefs that others are unlikely to provide support, who expect rejection, or who are depressed may indeed undermine their relationships by engaging in neglectful, hostile, or excessive reassurance-seeking behaviors and thereby inducing unresponsiveness from their partners. Compared with reports of independent observers, people with low self-esteem sometimes perceive their partners' behaviors as being more unresponsive than they actually are. Such low self-esteem individuals may even regard partners who confirm their low self-views as being responsive and feel that their partners understand them. An ironic consequence of this is that when partners of low self-esteem individuals express high regard, it can increase fear of abandonment on the assumption that sooner or later the partner will begin to see oneself through the same prism of unworthiness. In contrast, individuals with high self-esteem perceive and report more supportive behaviors

from their partners, often more than is judged by outside observers.

Consequently, it is important to consider the interactive nature of dyadic interaction and whether responsive behaviors are mutual and reciprocal. The perception of responsiveness is a function of each partner's needs and motives, expectations of the other's responsiveness, and the nature of the existing relationship. People with insecure attachment may pick as a partner another insecure person who, during their ongoing interaction, may not only confirm the expectation of unresponsiveness, but make the unresponsive interaction a reality. In contrast, secure individuals tend to pick partners who are more likely to be responsive and, in addition, may be able to increase their partners' responsive behaviors through their own responsive behaviors. Even in child-parent relationships, children's temperament and responsiveness to parental behaviors may contribute to responsive or unresponsive parenting styles: Infants who maintain eye contact, smile often, and have calm temperaments may induce more responsive caregiving from parents than infants who fail to exhibit these behaviors. Furthermore, the situation must be taken into account. Levels of responsiveness expected from a specific person or role may influence the process; generally, people expect more responsive behaviors from close partners, but may perceive same behaviors by a colleague to be inappropriate. For example, partners who call several times a day during a sick day may be perceived as being responsive, whereas the same behavior by a colleague may be considered excessive or intrusive. Thus, research on responsiveness often takes into account the complexity of the interactive, dynamic nature of responsiveness, as well as the motives and behaviors of both interaction partners and situational circumstances.

RETIREMENT, EFFECTS ON RELATIONSHIPS

Retirement heralds a new stage in the life cycle. It marks the end of paid employment and the start of life as a senior citizen. Relationships with coworkers are important during a career, but how does retirement affect them? Relationships with coworkers are apt to change, and so are relationships at home, with the extended family and with nonkin. This entry discusses the extent to which personal relationships are affected by retirement.

Social relationships at the workplace enhance enjoyment, creativity, and career development and

are thus meaningful. They also contribute to one's sense of personal worth and importance. In addition, the support provided in these relationships may diminish the effects of work-related stress and often contributes to well-being. However, most relationships with coworkers are not preserved beyond the workplace and do not become personal relationships. Work relationships are more likely to become personal if people work in the vicinity of their home or when coworkers have common interests. If coworkers have shared activities beyond the working environment, the likelihood of coworker relationships continuing after retirement increases.

Three theoretical perspectives predict a retirement-related loss of personal relationships. Holding that old age is a stage of life with limited social expectations about the roles that older adults play, disengagement theory notes that older people tend to withdraw from society. Not only work-related but also other types of relationships deteriorate. For disengaged retirees, loss of the work role places constraints on them, and they are forced to withdraw from certain activities and relationships. In particular, people who have no control over when and how they stop working face greater disruptions in their relationships than people whose retirement occurs as anticipated.

Socioemotional Selectivity Theory predicts that older people disengage from relatively superficial relationships, such as with former coworkers, because they find their emotional engagement with network members such as close kin and close friends more effective for maintaining their social identity and sharing their joys and sorrows. Reengaged retirees also identify retirement with disengagement, but are selective and content with it. If the partner or other significant others in the personal network no longer have a job or never did, the new retiree may be absorbed into a post-retirement world. The retiree typically spends a great deal of time at home, focusing on kin relationships and leisure activities with significant others. It is unlikely that relationships with former coworkers would be continued in a situation of this kind.

According to Social Convoy Theory, networks consist of close relationships determined by attachments and peripheral relationships determined by role requirements. Role-guided relationships (e.g.,

with coworkers) can be important and affectionate, but are primarily linked to the role setting, which generally limits their duration and content. Realigned retirees may look forward to retirement to release them from the pressures of their work role. Retirement decreases the likelihood of coworker relationships continuing. These retirees see retirement as a time for extending their lives in different and more meaningful directions. The initial period after retirement is full of positive changes. Retirees may explore and enjoy new possibilities. Retirees may take new social roles, and people from other role settings such as volunteer work, leisure activities, or grandparenting might replace coworker relationships, although sometimes still some contact is maintained with former coworkers.

Few researchers have studied the retirement effect on relationships. A general finding is that the number of relationships does not decrease contrary to the disengagement perspective. Two studies particularly showed that an estimated average of half the personal relationships with coworkers end shortly after retirement. Network members with whom job-related relationships are continued are now tagged as *former coworkers* or *friends*. These continued relationships are not necessarily part of the persistent core of ties maintained across time and might be ended later. Intensive social interaction with the spouse, local kin, and other people in the neighborhood replaces ties with former coworkers. Retired people also may initiate or renew relationships linked to postretirement activities. Consistent with the social convoy perspective, retirees' total number of personal relationships thus equals the preretirement number, and retirement mainly affects the network composition.

Changes after retirement are not always positive. It is not easy for everyone to preserve a positive mood. After a number of years, the retiree's satisfaction and well-being can decrease, and relationships, in particular job-related ones, tend to deteriorate. Also marriage quality may be affected as older studies show. Marriage may improve because there is more time and energy to devote to the spouse. However, and more important, husbands spending more time at home or in the immediate vicinity can generate spousal tension because the home has traditionally been the wife's territory. As a result of increased female employment and

men's greater involvement in domestic tasks in contemporary Western society, the situation might be different for future cohorts.

No person's biography is one-dimensional, focused only on employment. Retirement may coincide with changes in other life domains. It can, for example, trigger changes in health, and poor health or being a caregiver for others may trigger early retirement. Retirement may be followed by a move to a more pleasant environment. This multidimensionality in personal biographies contributes to individual differences in relationship changes. For some people, retirement might be the start of a third stage of life with opportunities to develop and intensify relationships, whereas for others it leads to a constrained situation with limited chances to maintain existing relationships.

REVENGE

Definitions of *revenge* in the scholarly literature vary, but there is considerable agreement that the phenomenon these definitions are intended to describe is both ubiquitous and universal, appearing repeatedly and frequently throughout human history and across diverse cultures and relationship forms. Indeed, so common are acts of revenge in literature, historical records, and current events

that some experts have concluded that the desire for vengeance ranks among the most powerful of human passions.

For purposes of this entry, *revenge* is defined generically as action that repays harm with harm. Consistent with this definition, Roy Baumeister has argued that, at its core, revenge entails a reversal of roles in which the original perpetrator becomes the victim. Revenge can thus be seen as a perversion of the maxim “do unto others as you would have them do unto you,” in which an individual does unto others what has been done to him or her.

Revenge is often treated in the scholarly literature as if it is the polar opposite of forgiving. There may be reasons to question this viewpoint, however. For example, Everett Worthington has argued that there are a variety of ways to reduce the complexity of negative emotions (which he calls *unforgiveness*) that often arises when we experience offense or injury at the hands of another and that forgiving and taking revenge are just two of these. From this perspective, revenge and forgiving share a common identity as responses to interpersonal harm or strategies for reducing unforgiveness. In actuality, research suggests that desires for revenge and the inclination to forgive tend to be inversely related to each other, but that, in itself, does not imply that they need be antithetical to each other. Indeed, under certain circumstances—such as when forgiving is used to demonstrate one's moral superiority over an offender—forgiving may in fact serve vengeful purposes.

Empirical research on revenge is rather limited at this time despite that much has been written about the topic from philosophical and theoretical perspectives. In part, the lack of research in this area may stem from a tendency among scholars to focus their attention on acts of revenge that are extreme and violent. Not only are such extreme acts of revenge less amenable to systematic investigation, but existing research suggests that they may reflect just “the tip of the iceberg.” In everyday life, milder, more mundane acts of revenge may be far more numerous and frequent than extreme acts of revenge.

Revenge in Organizational Settings

At present, the literature on revenge in organizations offers the richest descriptive base for understanding

when and how people take revenge and the kinds of consequences that accompany a decision to retaliate in response to perceived provocation. For example, the work of Thomas Tripp and Robert Bies and their colleagues indicates that (a) the desire for revenge is typically triggered by provocations involving the obstruction of goals, violation of rules or norms, and/or threats to social status or power; (b) acts of revenge can take diverse forms that vary in severity, kind, and relation to the initial offense; and (c) revenge may achieve a variety of outcomes such as eliminating injustice; restoring a threatened sense of self-esteem, self-image, or reputation; equalizing power; deterring future acts of harm; and teaching the harmdoer a lesson.

Revenge in Romantic Relationships

Based on the findings of their research, Tripp and Bies have argued that scholarly discussions tend to portray revenge in a biased fashion that emphasizes its destructive, antisocial potential while rejecting the possibility that revenge can sometimes be used for and actually achieve constructive and prosocial ends. Recent research on revenge in romantic relationships corroborates this viewpoint to some extent. For example, participants in a study by Susan Boon, Alishia Alibhai, and Vicki Deveau were interviewed about an episode in which they “got even” with a current or former romantic partner. As part of the interview, participants were asked to consider the consequences that followed their decision to repay harm with harm. Most participants indicated that their vengeful actions had both positive and negative consequences (e.g., redressed the negative feelings they experienced in the aftermath of the provocations that fueled their desires for revenge, elicited empathy in their partners, taught their partners a lesson, gave their partners a taste of their own medicine, etc.; made them feel guilty or bad, compromised their images of themselves as good, moral people, failed to resolve the original problem with the relationship). It was less clear, however, that the positive or constructive consequences they reported were also prosocial in nature (i.e., likely to benefit others, rather than themselves). Participants only rarely described constructive outcomes that benefited other people, although a

small proportion of the sample did claim that their actions benefited their relationships with their partners.

Finally, several scholars have argued that people’s attitudes toward revenge are morally ambivalent. The results of research on revenge in relationships appear to support such arguments. On the one hand, the considerable majority of participants in Boon and colleagues’ interview study asserted that revenge is morally wrong, arguing, for example, that getting even is unethical and immoral, a childish and immature response to wrongdoing, and that better (i.e., nonvengeful) responses to wrongdoing exist. On the other hand, participants in another of Boon and Deveau’s studies were no happier with the situation when an aggrieved individual (the victim in a hypothetical love triangle) decided not to retaliate against his partner than when his retaliatory gesture went to excess. This latter finding is consistent with arguments in the literature that people often perceive those who do not retaliate for harms committed against them as weak and ineffectual.

REWARDS AND COSTS IN RELATIONSHIPS

Among general social-psychological theories that have been applied to social and personal relationship

processes, reinforcement-based theories have been most explicit in addressing rewards and costs in relationships. Reinforcement-based theories owe a considerable debt to B. F. Skinner's operant reinforcement theory, which emphasizes the impact of the physical and social environments on individuals' behavior. Reinforcement-based theories can be classified into three major categories: (1) social exchange perspectives (George Homans's social exchange theory, Uriel and Edna Foa's Resource-Exchange Theory), (2) equity perspectives (J. Stacey Adams's Equity Theory, Elaine Hatfield and G. William Walster's Equity Theory), and (3) interdependence perspectives (John Thibaut and Harold Kelley's Interdependence Theory, Caryl Rusbult's Investment Model). This entry defines the concepts of rewards and costs, and it compares and contrasts theoretical perspectives on rewards and costs. Also, drawing on research by Constantine Sedikides, Mary Beth Oliver, and Keith Campbell, this entry provides a critique of reinforcement-based theories of rewards and costs.

Social Exchange Perspectives on Rewards and Costs

According to Homans's social exchange theory, a reward is anything that an individual considers agreeable, whereas a cost is anything that an individual considers disagreeable. For example, the receipt of money constitutes a reward for the individual, whereas the giving of money constitutes a cost for the individual. Likewise, the receipt of esteem constitutes a reward for the individual, whereas the giving of esteem constitutes a cost for the individual. In Homans's social exchange theory, principles of economic transactions govern social interactions in general (e.g., in order for one person to obtain a reward, another person must incur a cost). To the extent that an individual perceives a relationship as more rewarding than costly over time, the individual is likely to remain involved in that relationship.

Foa and Foa's Resource-Exchange Theory retains the concepts of rewards and costs as defined in Homans's social exchange theory. However, Foa and Foa's Resource-Exchange Theory builds on Homans's social exchange theory by defining a commodity or resource as anything that the individual perceives as rewarding when gained and costly when lost. Moreover, Foa and Foa's

Resource-Exchange Theory not only distinguishes between social and personal relationships, but also distinguishes between tangible and intangible commodities or resources. Social and personal relationships alike are characterized by the give and take of tangible resources (e.g., money, information, services), but personal relationships are unique in that they also are characterized by the give and take of intangible resources (e.g., love, support, esteem). Unlike tangible resources, intangible resources may be given without necessarily entailing a loss for either partner (e.g., by giving love to her or his spouse, an individual may experience greater self-love).

Equity Perspectives on Rewards and Costs

In Adams's Equity Theory, rewards are renamed as positive outcomes, whereas costs are renamed as negative outcomes. However, the premise that rewards/positive outcomes can be distinguished from costs/negative outcomes on the basis of the individual's perception of social interactions as agreeable versus disagreeable remains unchanged. Adams's Equity Theory builds on Homans's original version of social exchange theory by making it clear that ongoing social and personal relationships are not necessarily based on equal investments by partners. In both Adams's Equity Theory and Homans's original version of social exchange theory, an investment is anything that individuals have put into the relationship that subsequently entitles them to rewards. In response to Adams's Equity Theory, Homans's revised version of social exchange theory likewise acknowledges that investments by partners need not be equal. According to Adams's Equity Theory and Homans's revised version of social exchange theory, as long as partners agree in advance regarding inequality of investments, both partners will be inclined to remain in their relationships to the extent that they receive a fair return on their investments.

Hatfield and Walster's Equity Theory builds on Adams's Equity Theory by noting that individuals may experience chronic overbenefits or chronic underbenefits in social and (especially) personal relationships. An overbenefit represents a level of profit (i.e., rewards minus costs or positive minus negative outcomes) that is higher than the individual

deserves given his or her initial investment (compared with the partner's investment). In contrast, an underbenefit represents a level of profit that is lower than the individual deserves given his or her initial investment (again compared with the partner's investment). An individual may be unhappy with overbenefits (due to shame or guilt) as well as with underbenefits (due to anger or resentment), although underbenefits are more likely to lead the individual to end the relationship than are overbenefits.

Interdependence Perspectives on Rewards and Costs

According to Thibaut and Kelley's interdependence theory, a reward is anything that increases an individual's relationship satisfaction or happiness, whereas a cost is anything that decreases an individual's relationship satisfaction. In turn, relationship satisfaction strengthens an individual's relationship commitment or decision to remain in his or her relationship. Thus, rewards and costs indirectly influence an individual's relationship commitment. Also, because commitment directly affects a variety of relationship outcomes (e.g., marriage, divorce), rewards and costs indirectly influence those relationship outcomes as well.

Rusbult's original Investment Model builds on Thibaut and Kelley's Interdependence Theory by including investment, along with satisfaction and perceived alternatives, in predicting individuals' commitment. Like satisfaction, but unlike perceived alternatives, investment is a positive predictor of commitment. In subsequent versions of the Investment Model, Rusbult has added several relationship maintenance strategies that are used as consequences of greater commitment (e.g., decision to remain in the relationship, tendencies to accommodate, derogation of alternatives, willingness to sacrifice, and perceived superiority), as well as consequences of those maintenance strategies (e.g., relationship stability).

Critique of Reinforcement-Based Theories of Rewards and Costs in Relationships

Reinforcement-based theories have gone a long way toward clarifying the give and take of relationship

processes. However, as Sedikides, Oliver, and Campbell noted, such theories are not without weaknesses. To begin with, reinforcement-based theories focus mostly on rules and expectations that regulate the giving and receiving of benefits or costs, rather than the content of benefits or costs as seen from the perspective of the individual. That is, such theories overlook subjective or idiosyncratic construals of benefits and costs when such construals are powerful determinants of partner choice. Partners, for example, give high ranks to such benefits as companionship, feeling loved or loving another, feeling happy or elated, exclusivity, and self-growth and understanding, whereas they give low ranks to such benefits as social support from partner's friends or relatives, learning about other sex, and expertise in relationships. Conversely, partners give high ranks to such costs as stress and worry about the relationship, increased dependence on partner, and social sacrifices (e.g., lack of freedom to socialize), whereas they give low ranks to such costs as monetary losses, loss of innocence about relationships and love, and loss of privacy. Relatedly, reinforcement-based theories do not account for divergent perceptions of benefits and costs: What a relational partner perceives as a benefit may not be received as such by the other.

Moreover, reinforcement-based theories do not pay adequate attention to subjective perceptions of the relative importance of benefits and costs as they apply to different kinds of relationships such as friendship versus romance, communal sharing, authority ranking, equality matching, and market placing. Also, such theories do not account for changes in the relative importance of benefits and costs at different stages in the relationship. Indeed, perceptions of what is rewarding and costly are to a substantial degree in the eye of the beholder, and thus they will change as a function of novelty, satiation, or the availability of alternative partners.

Furthermore, reinforcement-based theories do not provide a compelling account of gender differences in subjective construals of benefits and costs. Women, for example, regard the benefits of intimacy and self-growth as more important than men do, whereas men regard the benefit of sexual gratification as more important than women do. Conversely, women regard the costs of loss of identity and loss of innocence about relationships as more serious than men do, whereas men regard

the cost of monetary losses as more serious than women do. Finally, women regard good partner earning potential as a more important benefit than men do, whereas men regard partner physical attractiveness as a more important benefit than women do. In addition, reinforcement-based theories do not account for age and cultural differences in perceptions of relational benefits and costs.

Understanding of the subjective construals of benefits and costs may increase understanding of the expectations that individuals bring to the relationship, of how these expectations change at different relationship stages, and of how they differ and evolve for women and men. Although the road from stated benefits and costs to real-life partner choices is rocky, in the end, enrichment of the conceptual dimensions of idiosyncratically perceived benefits and costs may contribute to a better understanding of why individuals enter a relationship, why they stay in it, and why they terminate it.

Conclusion

Due to space limitations, the literature review in the present entry is highly selective. For example, among general social-psychological theories that have been applied to social and personal relationship processes, cognitive consistency theories (e.g., Fritz Heider's Balance Theory, Theodore Newcomb's Strain-Toward-Symmetry Theory) are not reviewed because those theories at best are indirectly concerned with rewards and costs. Also, theories that are focused exclusively on interpersonal attraction (e.g., Bernice and Albert Lott's theory of the role of reward in the acquisition of positive interpersonal attitudes, Elliot Aronson's Gain-Loss Theory of attraction) are not reviewed because those theories historically have been applied primarily to laboratory situations rather than to real-life relationships. In contrast, the reinforcement-based theories covered in the present entry have been especially influential throughout the history of relationship research.

RISK IN RELATIONSHIPS

Risk in relationships can be considered in two distinct ways. From a psychological perspective, *risk* can be defined as a way of thinking about relationships (a cognitive schema) where choices to form and maintain intimate relationships are thought to involve unusually high levels of psychological/emotional investment combined with high uncertainty about outcomes and accompanied by a heightened anxiety about forming and maintaining relationships. These thoughts are likely to be the product of life-course experiences (e.g., divorce) that generate an increased desire for intimacy, but also a fear of negative consequences should a relationship become too close. From this perspective, risk is largely indistinguishable from other concepts such as anxious-ambivalent or fearful attachment styles, trust, and fear of intimacy.

Alternatively, *risk* can be defined in sociological terms as a perceived and/or actual characteristic of the social context within which relationships are formed and maintained. Rather than the outcome

of earlier life-course experiences of individuals, risk is conceptualized as a product of changing structural and cultural conditions experienced by all individuals sharing a common social environment—specifically, a context of late modernity (e.g., contemporary North America and Northern Europe). In such a context, social institutions (e.g., families, communities, and churches) no longer control or provide guidelines for forming and maintaining relationships, individuals take on more responsibility for shaping their own identity and life outcomes, and there is an increased reliance on rational decision making and technology for controlling the physical and social environment, as well as individuals' personal lives. As a result, individuals must make relationship choices that were largely made for them in previous generations and must do so under conditions of expanded options, increased uncertainty, and a greater reliance on logical means–end reasoning about what they believe should be an inherently emotional experience. In addition, these relationship decisions have greater consequence for their identity, and individuals bear more personal responsibility for negative outcomes should their relationships fail. It is in this sense that risk is considered here.

Theoretical Context

Risk in relationships is derivative of the concept of risk more broadly applied to life in modern societies. Ulrich Beck was first to develop the idea of “risk society” as a condition of “late modernity.” In this historical period, life outcomes and conditions are no longer determined by chance, fate, kinship, or divine intervention, and individuals no longer base their actions on tradition—the way things were done before—nor the dictates of family or community authorities. Instead, individuals are expected to control their own destinies by making rational decisions about the best means for achieving their personal goals without clear guidelines and with more significant and unknown consequences.

With choice comes the possibility of risk. Risk, as used in this theoretical framework, is inherently about a link between choices and their potential outcomes. Without choice, our outcomes may be

uncertain or potentially negative, but we lack responsibility for those outcomes and therefore risk is not involved. If our actions are predetermined for us or based on precedent or community control, then there is little or no risk involved. If we did what we were told to do, then any negative outcomes were not our fault. However, when, as in modern societies, we are left to weigh the merits of alternative actions for achieving our goals and then make a decision based on that calculation, we are confronted with the possibility of risk.

Beck and Elizabeth Beck-Gernsheim in *The Normal Chaos of Love* further developed this idea as applied to intimate relationships. They note the demise of traditional institutions responsible for regulating intimate relationships. In highly developed modern societies such as contemporary North America, institutional norms and practices are substantially weakened. For example, there are no longer clear “rules” for dating, it is no longer necessary to make a formal commitment (marriage) before residing with a partner, and legal constraints on marital partners are greatly reduced. This is a process Andrew Cherlin calls *deinstitutionalization*. Individuals are responsible for developing their own criteria for what constitutes a desirable partner, finding ways to meet and get to know potential partners, negotiating the rules of appropriate behavior within relationships with those potential partners, determining the levels of commitment involved in their evolving relationships, and maintaining personal commitment levels that can sustain a rewarding relationship in the absence of community and other institutional constraints.

Making the choice even more risky are the disembedding of social relations that occurs in late modernity, the increased significance of expressive versus instrumental traits in defining the self, and the increased reliance on rationality as a means for managing the risks involved.

The concept of disembeddedness, as developed by Anthony Giddens, refers to the fact that social relationships in modern societies extend beyond traditional social status boundaries and beyond the local community. As a result, the selection process is less regulated by social norms; less informed by having a lengthy history of interaction with potential partners; individuals will feel less justified in settling for someone other than an optimal partner; and the person chosen is more likely to

possess social and personal characteristics that are different from one's own, resulting in greater pressures on the relationship to negotiate those differences. In addition, there will be less community support during the process and a less developed support network to help maintain a relationship once it is formed.

The emergence of what Marlis Buchmann calls the *expressive self* refers to a growing importance of psychological/emotional traits in defining identity and a diminished importance of ascribed traits. For example, traits such as extraversion and empathy take on greater importance than one's kinship or social status (ascribed traits). As a result, our relationship choices depend on our ability to discern more amorphous personality traits and to make uncertain judgments about how our traits fit with those of a potential partner. In addition, the outcomes of those choices take on greater significance in defining who we are because the person we choose will be one of the few people who really sees our deeper psychological/emotional qualities. Thus, the identity stakes involved in choice are raised at the same time that uncertainty about the choice is increased.

Finally, the tendency in modern societies to rely on technological and rational means for managing risks may paradoxically elevate the risks of forming a less authentic and meaningful relationship. Choices become based on artificial and somewhat arbitrary categorizations of the self and others. Furthermore, Eva Illouz notes that relationship experiences and sentiments become commodities in modern capitalistic societies. They are advertised, bought, and sold. In a modern consumer society, we purchase greeting cards to express sentiments that are not our own, show our love for one another through the purchase of symbols of romance or romantic experiences (e.g., a cruise), and demonstrate the quality of our relationship through the purchase of material goods. As a result, it becomes difficult to know whether our relationships are authentic or simply the outcome of consumption.

Conceptual Definition and Measurement

Objectively, risk increases when choice increases, when investments in the decision are greater

(increasing the potential for negative outcomes), and when the potential gains and losses to be realized from the decision are uncertain and significant. Thus, any social conditions that increase the choices, investments, uncertainties, and significance of outcomes during the process of relationship formation/maintenance will increase risks. Choice occurs in the absence of constraints and with the expansion of options. Investments increase when they become more psychologically and emotionally significant. Uncertainty occurs when the probabilities of positive outcomes are offset by the probabilities of negative outcomes or when the probabilities are unknown.

Although it would be convenient if we could quantify changes in each of these dimensions of risk at the societal level and calculate the level of risk involved in relationships in any given social context, this is not realistic. Instead, to assess the dimension of expanded choice, we might rely on broad social indicators such as reduced partner similarity in partner selection (both geographic and social similarity). To assess increased investments, we might analyze cultural narratives for expressions of concern about investments or demographic data on the physical and psychological health benefits of relationships. Finally, to determine levels of uncertainty and significance of outcomes, we could rely on an analysis of cultural narratives or on reported levels of marital distress, violence in intimate relationships, levels of sexually transmitted diseases in the population, and divorce rates. Taken together, such changes would signify increased risk.

It is also possible to assess risk at the individual level by collecting information about individuals' perceptions that there is much to gain and lose in relationship decisions and that the outcomes have high levels of uncertainty attached to them. As a perception, however, it is important to distinguish between risks in one's own relationships and risks involved in the marketplace of relationships. The level of risk that one feels in one's own relationships may be considerably less than they perceive to exist in the world of relationships within which they make relationship decisions. Societies develop cultural mechanisms for dealing with risks and uncertainties through the development and promotion of belief systems (e.g., religion, romanticism, a belief that risk can be managed through

rational decision making, technology and science) and validating rituals (e.g., weddings, honeymoons, anniversaries). In addition, individuals engage in cognitive maintenance activities (self-serving changes in how they think about their situation and reconstruct their pasts) as a means for deflecting potential negatives in their own relationships. As a result, we tend to underplay the risks in our own relationships, but may still feel a sense of risk with respect to the relationship market.

Dimensions of Risk in Relationships

There are several dimensions of the relationship formation/maintenance process where uncertainties have increased and thereby increase risk.

First, risk is increased by an expanded and deregulated marketplace. Those seeking a partner today lack institutional settings for their search, are confronted with the dilemma of whether to use technological search tools that may seem artificial and insincere, and must make a decision to pursue a specific relationship from a larger pool knowing that doing so too early could preclude later options that might be a better fit and waiting too long could lead one to miss out on the best-fitting alternative.

Second, risk is increased by the lack of clear guidelines for making the right choice and the increased emphasis on expressive traits and emotional fulfillment in relationships. As a result, uncertainties arise with respect to how to determine partner compatibility, how to fulfill our own needs and those of our partner, and whether we will be able to find and maintain long-term agreement about our life goals and expectations.

Third, risk is increased by uncertainty with regards to appropriate actions/behavior in searching for and maintaining relationships. In particular, the cultural shift away from gender-specific traits (e.g., masculinity, femininity) has made it increasingly difficult to avoid misinterpretations between heterosexual partners regarding the gender appropriateness of behaviors. The potential for negative outcomes as a result of such misinterpretations extends beyond the search process and is ever present because couples can no longer rely on institutional constraints to maintain their relationships.

Fourth, risk enters into the relationship process as a result of unclear markers of relationship progression (e.g., “going steady,” “engaged”), mixed motives among those in the “market,” and uncertainties about commitment levels of partners. With the lack of clear cultural markers, it becomes difficult to determine appropriate timing for relationship progression and to know whether a given relationship warrants an increase in the levels of investments and sacrifice. Without assurances that a potential partner is also seeking a long-term commitment, the potential for exploitation or wasting time/money on a given relationship increases.

Finally, there are risks associated with the decision to maintain a relationship once established and having to manage breakups should they occur. With increased choice in the relationship marketplace, there is uncertainty around knowing when to hang on or let go of a given relationship (e.g., when does a relationship become too much work to continue, how do we avoid or at least not fear multiple breakups, and how do we avoid being trapped in exploited or abusive relationships?). In addition, with so much diversity in individual lives, it becomes difficult to determine how to keep a relationship vital over time, deal with growth and change within a relationship, manage boundaries and unrealistic expectations, and deal constructively with conflict.

Conclusion

Risk in relationships is a relatively new concept. As a product of modernity, risk arises in relationships as a function of increased choice, psychological/emotional investments, and uncertainties in all stages of relationship process from searching for the best partner, to developing mutual commitment and trust, to maintaining commitment and trust over time. Although a characteristic of the social context, it may provide us with a greater understanding of why problems of trust, intimacy, and commitment at the individual level arise in modern societies.

ROCHESTER INTERACTION RECORD

The time people spend with each other is often described as *social interaction*, and understanding human relationships requires understanding social interaction. Social interaction can be studied using various methods, and an important distinction among these methods is the extent to which a method concerns naturally occurring social interaction or social interaction in controlled settings such as the laboratory. Both types of methods have advantages, and in this entry, a popular (almost the standard) method of studying naturally occurring social interaction, the Rochester Interaction Record (RIR), is described.

The RIR was developed by a group of scholars at the University of Rochester (hence the name) in the 1970s. The primary impetus for developing the RIR was a sense of dissatisfaction with the state of the art of studying social interaction. At the time, much of the research on social interaction was laboratory based. Although such studies provided controlled settings in which specific (and often elaborate) hypotheses could be tested, laboratory studies were and remain, by definition, controlled and limited in their focus. For example, in the laboratory, it is not

possible to study how socially active people are in their daily lives and how they distribute their interactions (with friends vs. lovers vs. strangers, etc.). Moreover, even when an interpersonal process can be studied in the laboratory (e.g., intimacy), the artificial context of the laboratory may alter the phenomenon being studied. Another popular method, global surveys, also have limitations such as the undue influence of recent events on responses, difficulties in remembering past events, response bias, and so forth.

The RIR was developed to provide scientifically valid and useful descriptions of naturally occurring social interactions. Participants in RIR studies use a standardized form to describe their social interactions each day, and studies usually last for 1 to 3 weeks. A *social interaction* is usually defined as “any encounter with another person (or people) in which people attend to one another and adjust their behavior in response to one another.” Moreover, because there is broad cross-cultural agreement about what constitutes a social interaction, such a definition has been used successfully worldwide. To avoid overburdening participants by asking them to describe literally every social contact, in most RIR studies, participants are asked to describe interactions that last 10 minutes or longer. The 10-minute limit eliminates few (if any) important interactions. To avoid problems and biases associated with recalling events over long periods of time, participants are required to update their diaries as soon as possible after the interaction. Originally, participants used paper forms, but recent studies have used electronic data collection (e.g., Web-based, Palm pilots). It is important to note that, as revealed by poststudy interviews and questionnaires, participants typically find that maintaining an RIR diary is relatively easy and does not interfere with their daily lives.

Within this framework, the specific data collected about each social interaction can vary and has varied across studies. It is useful to think of these data as describing two broad aspects of interaction: quantitative and qualitative. Quantitative aspects include where the interaction occurred, how long it lasted, who was there, what was going on during the interaction, and so forth. Qualitative aspects refer to people’s reactions to the interactions: how much they enjoyed the interaction, how intimate they felt the interaction was, the emotions

they experienced during the interaction, and so forth. In this regard, it is important to note that the RIR is more an approach than an etched-in-stone specific method. That is, different researchers may collect different data about social interactions depending on their interests.

Data provided by the RIR can be used to answer two broad types of questions: differences among types of interactions and relationships between measures of interaction and other individual differences. Examples of the first type of question include comparisons of interactions with friends and romantic partners and comparisons of interactions with ingroup and outgroup members (e.g., cross- vs. same-race interactions). The second type of question could concern relationships between social interaction and individual differences, such as personality, racist attitudes, attachment style, and so forth. The data produced by RIR studies constitute multilevel data structures in that interactions are nested within persons; because of this, they need to be analyzed using appropriate (multilevel) techniques.

Given that social interaction is ubiquitous and individual differences in social interaction probably reflect myriad influences ranging from the intrapersonal to the interpersonal to the cultural, it is difficult to make broad summary statements about patterns of interaction. Nevertheless, the available data provide the basis for a few such statements. First, there is tremendous variability among individuals in terms of virtually any measure produced by the RIR. Some people are very active, whereas some are not. Some people find considerable enjoyment in their interactions, whereas others do not. Second, there is considerable variability within individuals in how they feel during and how they react to different interactions. For example, some interactions are very intimate, whereas others are not. Third, people tend to have a relatively small set of close friends (certainly fewer than 5) who account for (or appear in) more than a majority of their interactions. Fourth, markedly unpleasant interactions are uncommon. Certainly, not all interactions are viewed as very enjoyable or very pleasant; however, very few interactions are viewed as very unpleasant or not at all enjoyable.

Broadly speaking, quantity of interaction and quality of (reactions to) interaction are distinct,

unrelated aspects of interaction. This conclusion is based on the fact that quantity and quality of interaction tend to be unrelated and have been found to be related to different individual difference variables. For example, depression is negatively related to people's reactions to and feelings during interactions (e.g., enjoyment, intimacy, control), whereas it appears to be unrelated to social activity per se.

In terms of understanding human relationships, studies using the RIR complement laboratory-based studies, providing in vivo measures of important constructs. Understanding the subtleties of human relationships will require different types of studies using different methods, and the descriptions of social interactions provided by the RIR are a valuable part of this effort.

ROLE THEORY AND RELATIONSHIPS

Role theory is an attempt to understand human relationships as a set of blueprints for interacting. The basic idea is that, in any encounter, individuals are never dealing with the whole person, but with the person in a “status” or social position. As the interaction unfolds, each person is constrained

by existing cultural scripts that specify typical scenarios for each type of encounter. For example, students approaching their teachers, parents encouraging their children, doctors attending to their patients, and friends getting together are all guided by a template of rules they have learned as members in good standing of their culture or subculture. These templates implicitly structure the interaction, including the types of “business” that get transacted and the patterns of deference and demeanor that get displayed. This entry outlines some basic issues of role theory, including conceptual background, the close link between role and identity, and the problems of agency, power, and role transformation.

Beginning with the anthropologist Ralph Linton’s influential formulation in 1936, *status* and *role* became linked to each other as two sides of the same conceptual coin. Unfortunately, consensus over the exact meaning of this conceptual distinction has been lacking, and many analysts forego conceptual purity and use the terms *status* and *role* interchangeably. Because of this muddiness, it is useful to lay out the assumptions that underlie the present definition.

Role Theory and the Culture–Behavior Dualism

Most contemporary social science rests on a dualism that separates meanings from actions or culture from behavior. Cultural meanings are what we think, whereas behavioral actions are what we do. Together the interweaving of observable actions (behavior) and unobservable interpretive “sense-making” (culture) produce the miracle of coordination within human relationships.

The concepts of status and role in Linton’s formulation are best seen as mobilizing the two sides of this culture–behavior dualism (some analysts use the hyphenated term *status-role* as a stretch toward unification). A status is a unit of culture, whereas a role is a corresponding unit of behavior that gives expression to the status. It is useful to think of a status as both a job title and a job description. The job *title* is simply the name of the social position—citizen, friend, lover, Democrat, female, lesbian, mother, gardener, jogger, professor, shopper, moviegoer, and so on. The job *description*

is the unique set of social definitions that distinguish one position from another. These definitions establish the norms and expectations (e.g., rights and duties) that will guide any person who enters that particular position.

In this formulation role (sometimes termed *role performance*) is not the status holder’s *expected* behavior, but his or her *actual* behavior in the position. The actual behavior may or may not conform to the expectations contained in the job description—this is always an empirical question. For instance, people do not expect someone called a friend to speak ill of them to other people, but in their actual behavior, friends sometimes betray one another. They may then be held accountable for violating the “job description” of a friend, even to the point of getting “fired” from the job.

Role Theory and the Self

George Herbert Mead’s classic distinction between the *me* and the *I* is closely parallel to Linton’s *status* and *role*. For Mead, the *me* is a set of organized attitudes of the community, or called-for responses, internalized through what is sometimes termed a *role-taking* process. Much as a status is what I *should* do in a given position and my role is what I *actually* do, the *me* is the self offered to me via other people’s expectations, and the *I* is my response to it (the *I* is the “living act,” as Mead once put it). Ralph Turner’s distinction between *role-taking* and *role-making* is quite similar.

Mead’s me–I distinction not only upheld Linton’s culture–behavior dualism, but it also transformed role theory into a sociological perspective on identity. Indeed, some symbolic interactionists in sociology use the hyphenated term *role-identity* to give expression to this connection between role and self. Each status offers a different me or self to the person who steps into it. The job descriptions that constrain my performances as spouse, teacher, friend, or grandfather are all quite different from each other. They prescribe different kinds of actions, resulting in different self-experiences as I play out my various roles. My *teacher-me* feels quite different from my *spouse-me*, for example. Students in a large classroom expect their teachers to be authorities, and teachers often feel far more authoritative in these situations than they do

anywhere else. In contrast, modern companionable spouses may feel far more affectionate, solicitous, intimate, and relaxed with their spouses than they do in any other role relationship.

Because different roles engender different self-experiences, it is often the case that a person may favor some self-experiences more than others and therefore privilege the roles that make those experiences possible. *Role attachment* is the tendency to select a particular status and invest one's identity in its ongoing deployment, as if this is the true self, the one that really matters. Losing such a status may be devastating—a process of “self-destruction of the self,” as Erving Goffman once put it. Lost statuses that are highly valued both culturally and personally are frequent candidates for this kind of personal crisis. Examples are losing a spouse or partner relationship because of divorce, death, physical separation, or breakup; losing a job because of retirement, cutbacks, or getting fired; and losing a child because of a death or simply because the child leaves home. In all these instances, the person loses a set of regular behaviors and interactions, as well as a set of self-experiences and, hence, selves.

Roles, Selves, and the Issue of Agency

The fact that people may attach themselves to some roles and not to others suggests a certain freedom in the relationship between person and role. Goffman remains the unrivaled master in demonstrating the variability and flexibility of the person–role connection. He suggested a continuum of possibility from role embracement to role distance regarding the standpoint of the person toward any of his or her roles. To embrace a role is to disappear fully and eagerly into its performance and the attendant self-experience it makes possible. To distance from it is to withdraw all of one's inner identification from what one is doing, as if to say, “What you see me doing here is not really who I am.” Complaining, mocking, muttering, sneering, smirking, and moving with exaggerated slowness are all examples that suggest that one is role distancing, or disaffected from the performance that she or he is caught up in. For example, a young adolescent may greet an unwanted parental command with sneering and

muttering compliance and then move through the requested task with an exaggerated show of half-heartedness, leaving little doubt that the self he thinks he is has been violated by this parent–child interaction and its outcome.

As always, however, human agency may run up against structures of accountability regarding the adequacy of a person's role performances. To be sure, no one can force me to embrace my role. If I feel stuck in a status that I cannot imagine getting out of soon, I may use my agency to turn sour and distant from the role through whatever expressive devices or internal machinations I might muster. Nevertheless, if I am to continue a given role relationship, the penalties for distancing and the rewards for embracing the role may be considerable. Many statuses come in pairs, such as wife and husband, friend and friend, teacher and student, parent and child, colleague and colleague, and so on (we sometimes speak of the occupants of paired statuses as *role partners*). Any marriage, for example, is a complex set of reciprocities mapped out in the job description, and highly valued goods and services are typically at stake. If there are no other reliable sources of supply, then both partners may have considerable latitude to hold one another accountable for any signs of half-hearted role performance.

Multiple Roles, Role Strain, and the Work–Family Interface

All people occupy multiple statuses and enact multiple roles, and therefore the question of the impact of one role on another becomes salient. Some theorists such as William Goode have suggested that, in modern societies, role strain—any “felt difficulty” in performing a role—is normal and inevitable. He argued that individuals' total systems of roles are overdemanding simply because time and energy are too scarce for people to meet the myriad demands of their various role partners. Other analysts such as Stephen Marks have argued that time and energy are flexible and expansible and that role strain should be treated as a variable rather than an *a priori* assumption. A great deal of empirical work has focused on the impact of various roles and role combinations on the person's well-being. Many studies have explored the spillover

effects—both positive and negative—of the quality of one role on the quality of another role. Work–family research has occupied the lion’s share of these inquiries, and in recent years, the interest in balance—variously framed as work–family balance, role balance, and life balance—has emerged as a central concern.

Role Theory, Power Dynamics, and Role Transformation

Because roles so often throw the person into a network of relationships, issues of power dynamics are interwoven with how statuses are defined and roles played out. To continue the metaphor, if a status is a job description, then someone must have written it. In a friendship relationship in which the friends are equals, power dynamics may appear to be absent, but they are merely hidden: Each friend has an equal chance of writing the rules, including how and where they should get together, how much contact is appropriate, and what kinds of interchanges should occur. Each friend therefore has the power to hold the other accountable for slacking in their responsibilities. However, many role relationships are hierarchical, as is typically the case with teacher–student, parent–child, coach–athlete, employer–employee, and intimate-partner relationships in which one partner is typically dominant. Where role hierarchy is present, the person at the top of the hierarchy may have the power to create or destroy lower status positions, add and remove people from them, promote or demote people, write and revise their job descriptions, control the use of the physical territory, create the mood or atmosphere of the setting, and mete out the rewards and punishments for good or bad role performances.

It is difficult to transform roles that are hierarchically regulated. Even in role relationships that feel oppressive to lower status persons, they may be dependent on whatever scant resources they get. In turn, the people in the more powerful and privileged statuses may have a vested interest in maintaining the status quo. They may revert to physical violence or other coercive mechanisms to generate compliance.

Nevertheless, even potentially violent repercussions may not stem the tide of resistance on the

part of unhappy status holders. The I is unpredictable, as Mead pointed out. Role performances may take some surprisingly rebellious or innovative turns, contributing to new rules that then reconstitute the status. Moreover, any social arrangement may go through periods of upheaval, and social movements sometimes promote power struggles that are instrumental in creating waves of change. Resurgent feminism in the 1960s helped to rewrite the status of *woman* and *girl*, affecting typical role performances within social institutions such as marriage, family, work, athletics, and education. Hierarchy can be undone, but it most often requires an organized and concerted refusal to do role business as usual.

It is possible, however, for individuals to restructure their statuses and roles without a social movement standing behind them. In literature, some of our favorite stories feature individual underlings who manage, against all odds, to launch successful power struggles. In Ken Kesey’s *One Flew Over the Cuckoo’s Nest*, a mental patient named McMurphy systematically undermines the “good-mental-patient-me” that the autocratic Nurse Ratched has crafted for the men on the ward. By slow degrees, he succeeds in rewriting the job description of mental patient to include the right to gamble, smoke without permission, go big-game fishing, and have sex with women. In the end, most of the men reject the role of mental patient altogether. They leave the ward to embrace the alternate role of “real men”—men who do manly activities and are not under the thumb of any woman.

ROMANTICISM

Romanticism refers to a set of beliefs about the nature of love and romantic relationships, and more specifically about the characteristics of, or criteria for, an ideal relationship. These beliefs tend to emphasize the affective components of relationships and minimize or even discredit the importance of other components; as such, they are often characterized as overly idealistic, unrealistic, or even dysfunctional in nature. Romantic beliefs act as cognitive schema that are believed to be relatively persistent and form a frame of reference for attending to, interpreting, and responding to information and experiences in romantic relationships.

Romanticism commonly involves the idealization of the partner and relationship, or the idea that in true love the relationship will be perfect and the partner will meet all of the individual's needs, and that such a relationship will be easy to maintain. A second common theme involves the idea that there is one perfect person in the world for everyone and/or that individuals have only one true love in their lives. Related to this theme is the idea that you will know this love at first sight, and that true love, as opposed to lesser forms of love, will last forever. A romantic view of love also seems to entail a belief that true love can find a way to overcome all obstacles; that obstacles such as cultural differences, financial instability, or parental opposition should not exert a significant influence on the success or stability of such relationships; and that overcoming such obstacles will help to strengthen the relationship. Romanticism also tends to involve the belief that love is the only

legitimate basis for mate selection. Romantic beliefs often involve the intentional rejection of reason in terms of beliefs that love is a strange and incomprehensible phenomenon that cannot be scientifically understood or predicted, and that we should reject reason and rationality and “follow our hearts” in making these decisions. Romanticism may also involve the idea that you should experience a significant physiological response when in the presence of, or even just thinking about, the love object (e.g., heart racing, chills), and that this relationship should occupy a significant amount of your cognitive and emotional energy (e.g., through daydreaming, obsessive thoughts about the partner, or jealousy). In summary, there is a diverse constellation of beliefs associated with romanticism, many of which involve unrealistic or even dysfunctional components.

Romantic beliefs are proposed to develop through a variety of factors, both micro- and macrolevel. At the microlevel, romantic beliefs develop through the observation of others' romantic experiences (e.g., parents, peers, media representations) and through personal romantic experiences (e.g., romantic relationships, learning about relationships in classes). For example, individuals who watch more visual media (i.e., television and movies) tend to be more romantic, and those who take courses that teach students about the true nature of romantic relationships tend to be less romantic. The effects of these experiences on romanticism are thought to be strongly influenced by more macrolevel socializing agents, such as gender and culture. For example, consistent gender differences are found in romanticism, such that men tend to be more idealistic and romantic in their perspectives on love and relationships than women. There also appear to be cultural differences in romanticism, such that Americans tend to be more romantic than individuals in many other cultures examined (e.g., Korean, Chinese, Indian). It is proposed that these differences are the result of differences in broad cultural features such as the extent of individualism and gender-role norms.

As cognitive schema, romantic beliefs can influence many aspects of our romantic experiences, including our goals and motivations in relationships, attitudes about the partner and the relationship, behaviors in relationships, and interpretations of self or partner behaviors. Research has found

romantic beliefs to exert an important influence on initial attraction and in the early stages of relationship development. Additionally, romantic beliefs have been found to be associated with levels of love, satisfaction, and commitment in relationships.

The data are somewhat more complicated, however, on the specific nature of this influence on relationships. One approach to the study of romantic beliefs defines them as implicit theories about relationships and focuses on beliefs about growth (i.e., that relationship success is a function of cultivation and develops over a period of time through working together to grow closer, conquer obstacles, etc.) or destiny (i.e., that partners are either right for each other or are not) in romantic relationships. High adherence to growth beliefs is associated with attempts to improve the quality of the relationship and longer dating relationships, whereas high adherence to destiny beliefs is associated with a greater tendency to end a relationship when problems arise and a stronger association between satisfaction and relationship length.

However, some perspectives on romanticism see it as inherently problematic for relationships and suggest that the reality of the relationship will often not live up to idealized beliefs about what such relationships should be like, which will lead to more negative evaluations of, or disillusionment with, the relationship. There is evidence to support this perspective because more idealistic and unrealistic relationship beliefs or standards are related to more negative assessments of the ability to improve a relationship's quality and predict greater relationship dissatisfaction and marital distress. Additionally, the greater the perceived distance between the characteristics of an individual's actual partner and their ideal, the less satisfied they tend to be with that relationship. However, there is also evidence that a romanticized perception of a particular romantic relationship, especially premaritally, may promote relational development and satisfaction. Some suggest that this type of relationship-specific romanticism may act to promote commitment by minimizing attention to the negative aspects of the relationship or that a healthy degree of romantic idealization may promote relationship health in much the same way as general idealized beliefs seem to promote general mental health.

RULES OF RELATIONSHIPS

“Tell the truth to the people you love.” “Don’t say hurtful things to the people you love.” If these somewhat contradictory directives appear to have a common theme and a familiar ring, it is because they are both rules governing human relationships. One can hardly be involved in a relationship without having some idea about the rules that regulate it. This entry defines relationships and rules, briefly discusses types of rules and relationships, and describes the reciprocal relationship between the two.

Defining Relationships and Rules

Defining *relationships* is difficult because of the complexity of the concept. Nonetheless, a reasonable definition is that a relationship is a series of communicative interactions over time between two individuals who agree that those interactions constitute a relationship and who jointly believe that there will be interactions in the future.

The contention that relationships and rules go hand in hand can be traced back to Aristotle. A more recent expert on rules and relationships, Susan B. Shimanoff, defines a *rule* as a followable prescription that designates what behaviors are prohibited, obligated, or preferred in what contexts and in what type(s) of relationship(s).

Much of the literature on rules pertains to verbal and nonverbal *interpersonal communication* behaviors such as being polite. Interpersonal communication, unlike behaviors without communicator intent, refers to the *management of meaning* between relational partners, including what the rules are and what they mean, what the partners' relationship means, and how their relationship and the rules that regulate it are connected.

Contending that a rule is *followable* minimally means that an individual must be aware of the rule and have the linguistic and behavioral skills to follow it. For example, a guest who is unaware of a family rule of not discussing politics at dinner would be excused for breaking the rule because she or he was not aware of it. Additionally, there is no rule that people traveling abroad on vacation must talk to others in their native language because such a rule would be, for most, not followable.

Defining a rule as *prescriptive* means that a person *should* follow the rules of a particular relationship and be willing to suffer the consequences if he or she does not. For example, if a person breaks the friendship rule that one should thank a friend for a significant favor, then that person should not be surprised if the friend is less willing to perform the favor the next time around.

Describing a rule as *contextual* means that the situation needs to be considered when applying the rule. For instance, romantic partners may have a rule specifying that either one should immediately speak up if the other says or does something the partner finds offensive. However, the situation within which something offensive is said (e.g., a public context as opposed to a private one) would influence how the rule is applied. Contextual considerations also encompass situational factors such as type of relationship (e.g., family vs. friends), the formality of the situation (e.g., the bedroom vs. the boardroom), and the cultural and/or geographical context.

Types of Rules and Types of Relationships

Rules governing relationships may be *implicit*, meaning that the rule is not orally communicated but parties are aware of its existence, or *explicit*, in which the rule is verbally communicated. An example of an implicit friendship rule is that friends do not reveal each other's secrets. An openly communicated explicit rule in parent-teenager relationships might be "No yelling." There are also rules about rules, referred to as *metarules*. For example, one member of a quarrelling couple might say to the other, "I know we have a rule not to go to bed when we are angry, but can we make an exception in situations in which we are both exhausted and unable to think clearly?"

There are also rules regulating nonverbal communication. Colloquially referred to as body language, nonverbal communication includes such things as physical contact, tone of voice, and facial expressions. For example, a rule of workplace relationships is that physical contact between workers should not be sexual in nature.

Although different types of relationships, such as family and friendship, share common features, each type of relationship, indeed, each specific relationship within types, has unique properties of its own that can lead to special relationship rules. For instance, friendship and family relationships are similar in that emotional support is expected in each. However, when contrasted to family relationships, friendships are voluntary, whereas family relationships are not, as revealed in the often-stated axiom, "You can choose your friends but not your family."

Relationships may be personal or professional in nature or be a combination of the two that might lead to a conflict of rules. For example, an individual may consider his or her boss to also be his or her friend, but the friendship rule of not telling each other what to do would be trumped by the workplace rule that an employee should follow the directives of her or his boss.

Reciprocal Nature of Rules and Human Relationships

Rules and relationships are reciprocal in the sense that they complement and mutually influence each

other. Relationships in general and specific types of relationships in particular require rules in order to function with some degree of predictability and success. Rules, in a similar fashion, require relationships to determine their form and function. They coexist in a correlational rather than a cause–effect association, meaning that neither causes the other, and yet changes in one invariably bring about changes in the other. Rules influence the properties of relationships just as the properties of relationships give rise to the rules that regulate them.

One way to examine the reciprocal basis of rules and relationships is to briefly inspect an actual set of rules that apply to an actual type of relationship. In a classic article, Michael Argyle and Monica Henderson conducted a study designed to identify fundamental rules of friendships. Note that most or all of these rules would also be applicable to other types of close personal relationships such as family and romantic relationships, but would not be appropriate for casual, spur-of-the-moment, or newly formed relationships, in which there is no desire to form close ties, such as many professional relationships, relationships with friends of friends with whom one has little in common, and relationships in which getting close is against the rules.

In closing, an invitation is offered to the reader to think of a specific friend that he or she has and to go down this list of rules and decide which ones might be implicit or explicit or both, which ones

might regulate verbal or nonverbal communication or both, and which ones might require meta-rules to help in their application. Finally, spend just a moment reflecting on whether these rules existed prior to the formation of your friendship or whether they were mutually established and agreed on as the friendship developed. In no particular order, the rules are:

- Stand up for the other in his or her absence.
- Share news of success with him or her.
- Show emotional support.
- Trust and confide in each other.
- Volunteer help in time of need.
- Strive to make him or her happy while in each other's company.

S

SAFE SEX

For sexually active individuals, the likelihood of contracting a sexually transmitted disease (STD) is best viewed as linked to behavior that varies on a continuum from risky to safer. Safe (or safer) sex is defined as taking precautions to reduce the likelihood of negative consequences of sex—including both STDs and unintended pregnancy. Safer sex is typically thought of in terms of barrier protection methods such as male or female condoms (i.e., protected sex), and a majority of studies on safer sex focus on the use of condoms. There are, however, a variety of strategies that one can use to reduce risk of STDs and unwanted pregnancy. These include engaging in lower risk sexual behaviors (e.g., oral sex rather than anal sex), reducing numbers of sexual partners, refusing unwanted sex, not drinking or using drugs in combination with sex, and not having sex with partners that one knows or suspects may be risky (e.g., injecting drug user, sex worker). Thus, rather than a single behavior, safer sex is perhaps best viewed as a set of behaviors and practices that have the ultimate effect of reducing one's risk. Although the only means to eliminate risk is complete abstinence, for most individuals abstinence is neither realistic nor desirable.

Relationships and Safer Sex

Although defining safer sex is an important starting point, sexual behavior (and thus safer sexual

behavior) does not occur in a vacuum. Rather, it takes place in the context of a relationship—be it intimate or casual. Given that this is the case, a large literature demonstrates that the choice of whether to have protected sex (i.e., sex with a condom) is driven largely by relationship dynamics. For instance, many studies of both heterosexual and gay couples show that couples are more likely to use condoms during sex with casual as compared with main or steady sexual partners. This is presumed to be the case because more casual, lesser known sexual partners are perceived to potentially be a threat or risky whereas better known partners are perceived as safe. In addition, a variety of processes appear to play into these dynamics, depending on the type of relationship.

Main-Steady Relationships

Studies suggest that the most likely time for steady heterosexual and gay couples to use condoms is at the start of a relationship. At that point, the relationship is still new, partners may not know one another well, and the relationship itself may be casual in nature and not serious or monogamous. Over time, however, many gay couples will discontinue condom use, while heterosexual couples replace condom use with hormonal birth control. How much time does this take? One study of heterosexual adolescents and young adults found that typical couples dropped condom use in favor of hormonal birth control only 3 weeks after initiating sexual intercourse. From a safer sex perspective, these young people clearly believe that they

are substituting one type of safer sex (condom use with casual partner) with another type (hormonal birth control use with steady partner). The problem for heterosexual couples, of course, is that hormonal methods only protect from unwanted pregnancy and do not protect against STDs. In the case of gay couples, discontinuing condom use leaves them unprotected from STDs. Given that STDs are very common in young people, as are serial monogamy and multiple sexual partners, it quickly becomes clear how STDs are passed within the context of close, steady relationships. In fact, this is thought to be a contributor to the rising rates of HIV/AIDS among African-American and Latina women, who often have their guard down in the context of close relationships. In some cases, such women are unaware of significant risk factors of their male partners, such as bisexuality, multiple partners, and/or injection drug use.

In addition, research has illuminated the relational dynamics that play a role in the reduction of condom use within close relationships. Why would heterosexual couples swap condom use for hormonal birth control when condoms protect from both disease and unwanted pregnancy? Studies in this area have revealed several answers to this question. First, switching from condoms to contraceptives is seen by many couples as a trust and commitment building step, and condoms themselves are sometimes viewed as a symbol of infidelity. In fact, studies have found that talking about STD risk or asking a partner to use a condom in the context of a close relationship is sometimes perceived as implying that one has been unfaithful. Studies also find that higher relationship quality and investment (e.g., having a child together) are related to lower levels of condom use, again suggesting increased commitment equals less protected sex. Such phenomena exist not only among heterosexual couples but also among gay couples as well.

In addition, many studies suggest that relational concerns often take precedence over health concerns within close relationships. Although health professionals' primary concern for a couple may be STDs and unwanted pregnancy, couples' primary concerns may be focused on social and interpersonal issues. For instance, an individual who is feeling pressured by his or her partner to discontinue condom use may do so simply to please his or her partner, to avoid an argument, and to keep

the relationship moving in a positive direction. Given that males have been consistently found to have more negative attitudes about condoms than females, it may (in the heterosexual case) more often be the male who applies such pressure. Finally, individuals (particularly youth) often have an underappreciation for the concept of risk within relationships. Many studies show that young people believe that because they are in a relationship, that this in and of itself renders them safe from STDs. What is not recognized is the cumulative risk that may have been posed by recent sexual partners that one or both members of the couple may have had.

Casual Relationships

The safer sex dynamics within casual relationships are quite different than in closer, steady relationships. Casual relationships include brief, sexual encounters (e.g., one-night stands) and other types of relationships that are casual or new. Compared with steady relationships, trust, commitment, infidelity, and other relational issues are generally not of concern in brief sexual encounters and are of less importance in new relationships where fidelity may not be established. Instead, the health threat posed by a partner that is not known well is likely to be much more salient as compared to a close, steady partner. This results in condoms being much more likely to be used within a variety of new and casual sexual relationships and interactions in both heterosexual and gay couples. This does not mean, however, that condoms are always used in such relationships. Given that condom use still varies in this context, the following question has been posed: What factors affect the decision of whether or not to use a condom within the context of a new or casual sexual relationship?

Despite evidence to the contrary, many studies reveal that both heterosexual and gay individuals think they can tell whether someone is infected with an STD or is "clean." Thus, many individuals appear to use such judgments in making decisions about sex with casual partners. Studies show that misperceptions that have been attributed to individuals who are perceived as clean include (a) attractiveness and health—one is very attractive and/or the person appears healthy; (b) liking—one really likes the person; (c) familiarity—one has

some knowledge or familiarity with the person, often learned through friends and social networks; (d) association—person is not known to associate themselves with those traditionally at risk for HIV (e.g., drug users, bisexuals, etc.); (e) waiting—a partner wants to wait to have first sex, leaving the impression that he or she tends not to be promiscuous; (f) among men, dress-clothing has been found to be a factor (e.g., overly revealing clothing suggests that a woman is a higher STD risk); and (g) just knowing—one just knows intuitively that a partner is safe. Gay men have also been found to endorse additional factors—such as the kinds of clubs one frequents, the types of sex one prefers, and one's dress and occupation—as cues that are perceived as potentially distinguishing HIV-infected from uninfected men.

In addition, there are other reasons why unprotected sex sometimes takes place in casual relationships. In some cases, partners do not want to bring up or talk about the often uncomfortable topic of STDs and safer sex and/or do not have the communication or assertiveness skills to have such discussions and negotiations. Also, given that sex is not a rational act, research suggests that condoms are sometimes not used in casual situations because couples get caught up in the act and never even think to use protection. This may be particularly true when sexual arousal and/or alcohol or other substances cloud one's judgment. In addition, certain personality types such as high sensation seekers have been shown to be more likely to engage in unprotected sex and other risky sexual activities as compared to low sensation seekers.

Concluding Remarks

Owing to the importance of context in decisions about safer sexual behavior, the study of the role of relationship types in STD/HIV risk behavior has emerged as a major area of study in recent years. As has been demonstrated, relationship dynamics play a key role in safer sexual behavior, and understanding such dynamics is thus key to understanding the STD and HIV/AIDS epidemics. Given the complexity of this area, much remains to be understood. For instance, although most studies rely on reports from just a single member of a couple, little is known about how perceptions of sexual relationships

differ when both members of the couple are considered. The few studies on this topic suggest some important differences. In addition, studies that have taken an even broader perspective, studying entire sexual networks, remind researchers that sexually active individuals are actually part of a broader sexual network. When someone with an STD enters the network, that disease can spread quickly, particularly when unprotected sex is taking place in the context of concurrent sexual partnerships. Understanding the perceptions within relationships that lead to unprotected sex is thus key to prevention efforts that ultimately seek to reduce the spread of STDs, including HIV/AIDS.

SATISFACTION IN RELATIONSHIPS

Relationship satisfaction is of interest to researchers, theorists, and practitioners. What follows in this entry is an examination of the issues related to the conceptualization of relationship satisfaction. This discussion of the conceptualization of satisfaction is followed by a summary of the relationship patterns that contribute to the experience of satisfaction within intimate relationships.

Conceptualization

Historically, in the relationship sciences, the term satisfaction has been used to refer to a person's attitudes toward his or her partner and the relationship. People who are satisfied with their relationships feel good about their relationships and believe the relationships and their partners have many good qualities. Satisfaction is thought of as existing on a continuum from highly satisfied to highly dissatisfied. Those who are highly dissatisfied with their relationships are often referred to within the close relationship literature as experiencing relationship distress. Those with extremely negative attitudes towards their partners and relationships are likely, over time, to believe that the relationship suffers from serious problems that threaten the viability of the relationship. Once individuals have reached this level of distress, relationship termination is likely.

Theoretical Underpinnings

Theoretical insights into the factors that define and contribute to relationship satisfaction are found

within two prevailing sociological and/or psychological frameworks—namely, the social exchange and the symbolic interactionist frameworks.

Social Exchange Perspective

The basic tenets of exchange theory suggest that people choose to participate in a particular relationship because of the relationship's ability to provide a satisfactory level of outcomes. Outcomes are defined as the rewards derived from the relationship minus the costs of participating in the relationship. The level of outcomes perceived to be available from a relationship is based on a person's perception of his or her partner's attributes (e.g., sense of humor, physical appearance, etc.) and on the perception of the quality of the interaction between the partners (affection expressed, support experienced, etc.).

The exchange framework offers insights into the factors that define and influence the positive and/or negative attitudes that form around a relationship by focusing attention on the processes people use when evaluating the outcomes derived from their relationships. According to the exchange framework, partners continuously evaluate their relationships by comparing their experiences to their expectations. These expectations are thought to comprise what exchange theorists have come to refer to as each participant's comparison level (CL). The CL is defined as the outcomes that a person has come to expect as a result of past and vicarious experiences. When the outcomes received in a relationship tend to consistently fall above the CL, individuals are apt to be satisfied with their relationships. Conversely, when outcomes tend to fall consistently below this baseline of expectations, individuals then are likely to feel dissatisfied with the relationship.

In that the CL is based in part on relationship norms generally held within society, most participants in intimate relationships have somewhat similar expectations for what is expected and felt deserving. These culturally supported expectations are further refined and shaped, however, by the unique developmental and relationship experiences of individuals. Consequently, expectations should be viewed as reflecting a broad array of contextual and developmental factors. As a result, there exists considerable variability in terms of

what people come to realistically expect is deserved within an intimate, ongoing relationship. This variability makes it difficult to predict with certainty what will generate satisfaction or distress within a particular relationship because these attitudes revolve around the subjectively held and individually constructed expectations of each partner within the relationship.

To add further complexity, exchange perspectives highlight the fact that individuals will differ with respect to the salience of different aspects of their relationships. One individual might attribute a great deal of significance to whether his or her partner helps out around the house. Another individual might attribute greater significance to the quality and frequency of sex. This means that some characteristics of relationships weigh more heavily into the overall feelings of satisfaction or dissatisfaction experienced. When a relationship fails to meet important expectations, this failure is likely to override the satisfaction that might result from less salient expectations being met.

In addition, the exchange perspective highlights the fact that expectations are not fixed—they can and will change over the course of a relationship. For example, changes in expectations are often tied to changes in investments—increased investments are thought to result in somewhat higher expectations for returns. This means that over time, because of changes in life circumstances, it is possible that partners' relationship expectations might fluctuate upwards when they perceive themselves to be investing more than before in their particular relationships. This change in investments and the accompanying change in expectations can result in shifts in the experience of satisfaction because patterns of behavior that were acceptable in the past now fail to measure up to these new, emergent expectations.

Symbolic Interactionism and Relationship Satisfaction

Symbolic interactionist (SI) perspectives focus, as well, on the relationship between expectations and satisfaction. Individuals in an intimate partnership occupy reciprocal and interdependent roles. Individuals carry into their relationships constructions of how they should enact their roles as partners.

And because of the reciprocal nature of roles, each individual's construction of his or her role imposes a set of expectations on the individual who occupies the counterrole position as well. For example, if a wife believes that she should be responsible for only half of the housework, her construction of this role carries with it implications for how she believes her husband should construct his role. That is, she believes that he should be willing to be responsible for his half of the housework.

This partnering of expectations and counterexpectations is important to the understanding of satisfaction in that as long as there are congruent expectations, participants are apt to be satisfied with the relationship. When expectations are not shared, when constructions of roles differ, individuals are more apt to become increasingly dissatisfied with their relationships. This experience of satisfaction or dissatisfaction is explained within the SI tradition by the focus on the interdependent nature of role constructions and identity.

SI theorists view identity and role constructions as linked. People are satisfied when partners act in ways that are consistent with their constructions of roles because the partners' behavior confirms their views of themselves. Conversely, the violation of role expectations is apt to be experienced as an identity disruption. If the violated role expectation is particularly salient or central to the individual's identity, it would be expected that the felt injustice and sense of being discounted would be all the more extreme.

In other words, it is difficult for individuals to not feel as if their identities have been discounted in some significant way when their partners fail to conform to their role expectations. Of course not all role expectations are centrally connected to the sense of self. This is why some issues are more volatile within relationships than others. For example, a partner's messiness may not contribute greatly to dissatisfaction as long as this violation is not experienced as identity disrupting. Under these circumstances, an individual might complain periodically about the messiness, but the messiness does not necessarily detract from the overall feelings of satisfaction with the partner and the relationship.

In contrast, the tendency of a wife to wash the dishes a second time after her partner has already washed them and to revacuum the floors after he has recently cleaned them could become a major

source of tension in the relationship. Such tensions will result only if her behaviors are experienced by him as discounting his view of himself as a caring and responsible spouse and a competent male (at least competent enough to wash dishes and vacuum floors!). In other words, if these identities are central to his view of himself, his partner's seemingly discordant views of his role performance will be likely to result in feeling hurt and defensive.

In sum, within the SI tradition, satisfaction and dissatisfaction are understood as being centrally connected to the dynamic interrelationships among roles, expectations, and identities. Incongruent role expectations are likely to result in an erosion of satisfaction, particularly when the role expectations that are being violated are core to one's identity. The violation of highly identity-salient role expectations generates interpersonal tensions that are not easily managed because of the emotional reactivity and defensiveness that can accompany their negotiation. These identity-driven tensions become the foundation for cascading degrees of marital distress.

Interaction Patterns Leading to Relationship Satisfaction or Failure

A vast amount of research has focused on the predictors, moderators, and mediators of relationship satisfaction. The assumption within this research tradition is that patterns of interaction result in individuals developing positive or negative attitudes towards their partners and relationships. It is important to consider, however, that levels of satisfaction experienced within the relationship also influence the patterns of interaction.

By far the most extensive examination of the patterns of interaction associated with satisfaction and dissatisfaction within ongoing and intimate relationships has been conducted by John Gottman and his colleagues. According to Gottman, how couples manage ordinary difficulties and conflicts are central to the experience of relationship satisfaction. The most important and consistent of the findings of this line of research are summarized below.

Conflict Management and Cascading Negativity

Gottman's research makes it clear that relationship distress is associated with patterns of conflict

management that promote cascading negativity. Specifically, four negativity processes, labeled the *Four Horsemen of the Apocalypse*, characterize the management of conflict in distressed couples. Although most couples engage in these negative communication patterns some of the time, distressed couples do them more, and couples who do them a lot are on the fast track to divorce. These patterns include the following:

Criticism: "You are such a slob!"

Contempt: "I would never be so low as to do something like that!"

Defensiveness: "Yeah? Well what about what you did?"

Stonewalling: Shutting down, associated with high physiological arousal and efforts to self-soothe with thoughts such as "I can't believe she's saying this!"

Emotional Disengagement: Gottman's research goes on to note that emotional disengagement is common within distressed relationships. Emotional disengagement can be viewed as both a cause and consequence of relationship dissatisfaction. Emotionally disengaged couples generally demonstrate little of the interest, affection, humor, and concern that characterize happy couples. Emotionally disengaged couples appear fine on the surface but are actually highly distressed as they try to keep their problems from poisoning the entire relationship. However, the cost of this avoidance is the erosion of intimacy and absence of shared positive feelings in their interactions. These relationships slowly atrophy as the partners become more and more distant.

Emotional Flooding: Emotional flooding is an emergency state that can occur during conflict. Although it is more common in men than in women, flooding can happen to either partner. Flooding occurs when individuals are emotionally and physically overwhelmed by the negative emotions experienced within their relationships. At the point of flooding, individuals' palms begin to sweat, their heart rate increases to over 90 beats per minute, and their breathing becomes shallow or irregular. With these physiological symptoms, the partner is unable to think clearly or participate in constructive conversation. The primary focus of the flooded individual is self-preservation, accompanied by thoughts such as "I can't stand this anymore" or "Why is she attacking me?" At the point of

flooding, it becomes extremely difficult for individuals to take in information or respond to others.

Negative Reciprocity: Negativity is not necessarily damaging to relationships. All individuals within intimate relationships occasionally react in negative ways towards their partners. Research makes it clear, however, that a pattern of negative escalation in which negativity is responded to with increased negativity is harmful to relationships. These reciprocally negative patterns are characterized by each partner using a more destructive response to the other.

Conflict Styles of Satisfied Couples

Couples within more successful relationships do not always resolve their conflicts in what relationships experts would characterize as ideal ways. What is clear, however, is that satisfied couples maintain a relatively high (i.e., greater than five to one) ratio of positive to negative comments within their interactions. Maintaining a sufficiently high balance between positive and negative interactions allows relationships to overcome the times when destructive and ineffective conflict management threatens the overall well-being of the relationship. In other words, successful couples manage to resolve a sufficient number of their critical conflicts in positive ways, even if they do not always do it perfectly.

Solvable Versus Unsolvable Problems

A myth about satisfied couples is that they are able to resolve all disagreements. Both happy and unhappy couples have unsolvable as well as solvable problems. Solvable problems have a solution, whereas unsolvable problems are ongoing issues that may never be resolved resulting from fundamental personality, cultural, or religious differences or essential needs of each spouse.

What differentiates successful from unsuccessful relationships is that couples within successful relationships seem to understand and respect the distinctions between the two types of problems, and they handle them differently. Successful couples deal with perpetual problems by learning to accept them. The aim in discussing a perpetual problem is to create an atmosphere of acceptance of the partner's viewpoint rather than to create a condition of gridlock.

Accepting Influence

One way that successful couples deal with conflict is by accepting influence from each other. This term is used to describe each partner's willingness to defer to the other during an argument. Deferring to the other's needs, however, should not be mistaken as surrendering to the other's whims. Instead, accepting influence is the ability to find a point of agreement in the other's position. It is reflected in the ability to see the partner's point of view, to understand the partner's position, or to understand why the partner might feel the way that he or she does. Although accepting influence is difficult at times, it has a positive impact on the relationship, as partners feel validated and secure and realize that they can cooperate and work together as a couple.

Repair Attempts

Satisfied couples also manage conflict and miscommunication with what communication theorists refer to as repair attempts. Examples of repair attempts include apologies, humor, affection, and changing the subject. These interactions are not necessarily related to the content of the argument but may simply provide a brief reprieve from it.

It is interesting to note that successful couples use repair attempts more often throughout conflicts and earlier in conflict situations than do unhappy couples. Using the repair attempt earlier is one way of preventing a conflict from becoming too negative. In contrast, unhappy couples may wait until the argument is heated and divisive before making any attempt at a repair. In addition, unhappy couples frequently respond to attempts at repair by interpreting the overture in a negative way.

Turning Toward

Everyday interactions between intimate partners are characterized by what Gottman and his colleagues call *emotional bids*. An emotional bid occurs when a member of a couple initiates contact with the partner through ordinary conversation. The partner can respond to these emotional bids by either turning toward the partner, turning away from the partner, or turning against the partner. These conversational bids create opportunities to interact and help to define the couple as a couple. When these conversational bids are responded to

positively, the resulting interactions reinforce the sense of connection between the members of the couple. When such bids are not responded to or are negatively reacted to, they undermine the experience of intimacy.

Needless to say, happy couples rarely ignore their partner's bids. Having an eagerness to interact creates more interactions and increases a sense of connection and friendship. In particular, playful bidding is a characteristic of happy couples—this takes the form of good-natured teasing or physically sparring. For example, a husband might throw a crumpled napkin at his wife in response to her teasing him about an improper use of grammar. In many respects, these daily interactions can contribute to the level of positive affect in the relationship.

Positive Sentiment Override

The relationships of successful couples are characterized by what relationship researchers have termed positive sentiment override (PSO). This refers to the emotional climate created by successful and happy couples that enables them to override the negative effects that conflict creates in the relationship. PSO is built on a foundation of fondness and admiration and a good knowledge of the partner's life and world. PSO can be thought of as a filter that colors how couples remember past events and view new issues.

It is important to point out that PSO and conflict management reciprocally influence each other. As such, the effective management of conflict creates an emotional climate that fosters PSO. In turn, the presence of PSO results in couples approaching conflicts in a more constructive way. They are more likely to soften the startup of a conflict by bringing up issues tactfully and more likely to accept influence and to make repair attempts. It is not possible for researchers to determine if the effective management of conflict over time creates PSO or if PSO results in successful couples effectively managing conflict over time. Both factors are present in successful couples and are clearly interconnected.

SECRET RELATIONSHIPS

A secret relationship is a type of romance in which the partners involved make deliberate attempts to hide some aspect of their relationship from one or more other persons. Most partners who keep their relationships secret do so because they anticipate some type of negative response if others were to discover it. Examples of relationships that are often subject to secrecy include (but are not limited to) same-sex romances, interracial or interethnic partnerships, interoffice loves, and extradyadic involvements. These relationships can vary on a number of dimensions, such as why the partnership is being kept secret, from whom the secret is being kept, and what the perceived consequences of others discovering the relationship might be.

Surprisingly, although a vast number of studies have been conducted on secret keeping in general, relatively little research has specifically addressed the effects of keeping a romantic relationship secret and how this might affect a partnership.

Early research on secret relationships seemed to suggest that the partners involved might experience greater attraction to one another. However, more recent research has found that this does not appear to be the case. In fact, secret romances actually tend to fare worse than do nonsecret relationships. This entry summarizes the existing research on secret relationships and suggests directions for future work in this area.

Attractive Side of Secret Relationships

The earliest theorizing and research on secret romantic relationships was conducted by Dan Wegner and his colleagues. Wegner theorized that secret relationships are characterized by obsessive preoccupation (i.e., a cycle involving thought suppression followed by thought intrusion). In other words, people who are keeping secrets (not only about their relationships but also about anything else for that matter) want to avoid disclosing that information to others. As one means of doing so, those holding a secret may suppress relevant thoughts in the hopes that this will prevent them from accidentally talking about the secret. However, maintaining secrecy by suppressing thoughts is not ideal because extensive social psychological research has found that thought suppression has ironic effects. Specifically, suppressing thoughts may actually increase the later cognitive intrusiveness of those thoughts. Thus, with regard to secret relationships, intentionally suppressing relationship-specific thoughts actually makes those thoughts more likely to intrude, or pop into mind later on.

Wegner further theorized that this obsessive preoccupation will actually enhance attraction to a romantic relationship. Why might this be? This answer to this lies in psychological research showing that greater thought about any object or concept will result in attitude polarization. This means that one's feelings about the relationship will become more intense with greater thought about one's partner. Because people generally feel positively about their relationships to begin with, thinking about them more typically serves to make this positivity more extreme, and as a result, romantic attraction should increase. Consistent with this reasoning, several researchers have found that greater thought about one's relationship is

associated with greater love for one's partner and enhanced commitment to the relationship.

Support for this theoretical rationale (i.e., that secret relationships facilitate romantic attraction by means of obsessive preoccupation) was found in a series of studies conducted by Wegner and his colleagues. In their first study, undergraduate participants were asked to recall several romantic relationships that they had previously had and report how often they thought about each of these relationships after they had ended. They found that the relationships participants remembered and thought about most frequently were characterized by higher levels of secrecy than those that were thought about less frequently. Similar to this finding, in a second study, undergraduate participants were asked to recall one specific relationship from their past and report on their current level of obsessive preoccupation with that relationship. They found that levels of obsessive preoccupation were higher for past romances that were secret in nature compared to those that were not secret.

Their third and final study was an experiment in which mixed-sex pairs were instructed to play footsie underneath a table while playing a card game against other mixed-sex teams (i.e., participants were instructed to play the game while their feet and their partner's feet were touching). Some of the pairs received instructions to play footsie secretly, while the others were told to do so with the full knowledge of the opposing team. Those pairs who received the secrecy instructions reported greater attraction to their footsie partners than those who did not have to keep it secret. Also, among those pairs who received the secrecy instructions, levels of obsessive preoccupation regarding their footsie partner tended to be higher as well.

One might infer from this theoretical rationale and the supporting set of studies that secrecy will lead only to positive consequences for romantic relationships. However, there are some very important limitations to this research that prevent such a generalization from being made. Specifically, the first two studies reviewed here refer only to people's retrospective self-reports of past relationships. Researchers know that such reports are often biased and thus might not be completely accurate (e.g., people might forget or leave out certain pieces of information about their past romances). In addition, the manipulation of secrecy in the

experimental study, which involved playing footsie secretly underneath a table, does not approximate real-world romantic secrecy for a number of reasons. First, the secret was not being kept from valued others, such as family members or close friends—it was being kept from strangers in a lab setting. Romantic secrecy is likely to be more stressful and consequential when relationships are kept secret from persons who are very important to the partners and/or persons the partners see on a regular basis, as opposed to persons they do not know and/or may never see again. Second, the secret was not being kept for a particularly long time—the secrecy ended once the study ended. Long-term secret keeping (for months or years) is likely to be much more difficult to do and thus more stressful. Finally, there were no serious consequences to be had if others discovered the secret. In real life, people who are hiding their relationships may fear physical assault, loss of income or earning potential, social ostracism, and/or ridicule if others were to discover their romance. Thus, for these and other reasons, this set of studies may not be a completely accurate reflection of the effects of romantic secrecy.

Burdensome Side of Secret Relationships

In contrast to earlier research touting the positive side of romantic secrecy, Craig Foster and Keith Campbell theorized that secret romantic involvements should actually be less rewarding than non-secret relationships. They proposed that keeping a romance secret is a burdensome endeavor due to the host of behaviors that is required to prevent others from finding out about the relationship. For example, persons in secret relationships may be forced to meet only at inopportune times and/or inconvenient places in order to be together. This might mean only meeting late at night or in out-of-the-way locations. Moreover, they may find that they need to change their behaviors when in front of other persons who do not know of their relationship. Thus, they may have to pretend to be just friends and avoid public displays of affection when others are around. Partners will be less interdependent with one another to the extent that they must engage in more of these burdensome behaviors. That is, the partners will have

reduced opportunities to integrate each other into their lives (e.g., by sharing quality time together). Also, if fewer people are aware of the relationship, then there will be fewer people who can provide social support for the partners involved, and previous research has demonstrated that such support is vital to relationship well-being. In short, greater secrecy will make it more difficult to maintain the relationship over time because it requires partners to engage in burdensome behaviors that interfere with relational interdependence.

Foster and Campbell conducted a series of studies to examine secrecy as it occurs in actual, ongoing romantic relationships (as opposed to the previous secrecy research, which only examined past relationships and relationships created in a lab setting). Consistent with their reasoning, the findings indicated that greater secrecy is associated with reduced relationship quality (i.e., less love for and attraction to one's partner, as well as less anticipated distress if the relationship were to end) and with a stronger perception that the relationship is burdensome. In these studies, the effect of secrecy on relationship quality was indirect, with secrecy exerting its influence through relationship burden. In other words, secrecy seems to lower relationship quality by virtue of putting a significant burden on the couple members. In social exchange terms, such burden should increase the perceived costs of remaining in the relationship and hence should reduce partners' satisfaction with and desire to remain in the involvement.

These findings are probably more reflective of the nature of real-world secret romances because the data were derived from participants currently involved in actual relationships. However, these data are not without their limitations. For instance, all participants were college undergraduates. Thus, it is unclear whether their results would generalize to different types of relationships and relationships of longer duration.

Summary and Future Directions

Based upon the research conducted to date, keeping a romantic relationship secret seems to be associated with more negative than positive relational outcomes. However, this is not to say that secrecy will always damage romantic relationships. It is easy to

find instances of secret romances that have lasted for years in which couple members have found their relationship to be deeply satisfying and fulfilling. Thus, an important direction for future research is to examine the types of relationships or circumstances under which secrecy is likely to be more or less harmful to a romance. Factors that might play a role in determining secrecy's effects include from whom the secret is being kept, how long the partners have been involved with each other, how often the partners need to engage in cover-up behaviors, and whether the couple members have a choice with regard to secrecy (i.e., Have they made an active choice to conceal the relationship from others, or has the situation dictated that they have no other option but to hide the romance?).

There are also a number of other important questions with regard to romantic secrecy that have yet to be addressed. For instance, is keeping a relationship secret different from hiding any other aspect of the self? Researchers know that hiding important things about the self is so cognitively taxing and stressful that it can actually harm people's physical and psychological well-being. Given that people's romantic relationships often become defining features of the self (a phenomenon known as cognitive interdependence—people come to view themselves and their partners as one collective representation), it may be that hiding a romantic relationship would be just as detrimental to one's health as hiding any other aspect of the self.

Another important question concerns changes in secrecy across time. Specifically, when secrecy diminishes over time (e.g., when other people find out about the relationship), do relationship outcomes improve? A variety of studies have found that revealing important secrets about the self (e.g., gay and lesbian individuals disclosing their sexual orientation) enhances a person's well-being. Would disclosure of a secret romance lead to similar enhancement in relationship well-being?

In short, there is much to be addressed in future research on romantic secrecy. However, the real key will be further exploring the opposing effects already documented in the literature and delimiting the conditions under which secrecy tends to enhance romantic attraction versus the conditions that ultimately hamper relationship functioning.

SECRETS

What counts as a secret is sometimes contested. An adolescent who keeps information from a father might consider that information to be private, but the father might accuse the adolescent of keeping a secret. Despite such disagreements, secrets are defined in this entry as information that one person purposefully keeps from another person.

People often keep secrets in close relationships. Almost everyone keeps at least one secret from somebody in his or her family, and in one study, roughly 40 percent of college students admitted keeping aspects of their dating history from their current boyfriend or girlfriend. Given the prevalence of secrets in relationships, it is important to understand them. This entry summarizes some common assumptions about secrets, people's reasons for keeping secrets, and the consequences of secret keeping in relationships.

Common Assumptions

People often assume that secrets are inherently shameful. The phrase “keeping secrets” connotes

something negative. However, not all secrets are negative: A person planning a surprise birthday party keeps secrets. Moreover, keeping secrets often involves following conventions; for instance, most people would find it unseemly if colleagues divulged details about their family finances.

It is also commonly assumed that secrets represent failures to disclose. In North American culture, people value openness, and keeping secrets seems inconsistent with that value. However (as discussed below), people often have many apparently sound reasons for keeping secrets. Thus, keeping a secret is more of a purposeful choice than a failure. Moreover, some research suggests that people can be very committed to the ideal of open communication but not see keeping secrets as impediments to that ideal; for instance, some people want to be able to feel like they could talk about anything with their relational partners, but in reality they keep secrets from them.

Another assumption is that secrets are always deceptive. Certainly, one can lie to keep a secret. However, people also keep secrets by other means, such as simply not bringing up a topic that might be related to the secret. Sometimes the level of deception is so low that others are aware that somebody is keeping information secret. Many people who ask about someone's honeymoon, for example, will be happy to hear about the travel without pressing for the omitted details.

Why People Keep Secrets

There probably are an infinite number of specific reasons for keeping secrets, depending on the particular secret and circumstances. Nevertheless, there are some broad themes that are widely relevant to people's decisions to keep secrets. Perhaps the most commonly cited reason for keeping a secret is that people are concerned about what others might think. If the secret is something that is often stigmatized (e.g., sexual abuse, having HIV), secret keepers may worry about being judged negatively. They also might believe that whomever they tell will subsequently tell other people, a result which would further complicate their desire to manage how others see them.

There are also various relationship-oriented reasons for keeping secrets. Sometimes people

believe that divulging a secret will lead to conflict. Other times, people believe they must keep a secret to preserve their relationship; for example, some college students have reported hiding the extent of their sexual history because they fear their current partner would not want to stay with them if they knew everything.

People also keep secrets to protect others from stressors. Parents might keep financial difficulties from their children; young adults may keep dating troubles from their parents; a family member who is very ill may guard the severity of his or her prognosis. Secrets can also promote closeness; keeping a secret together from others can make people feel a special bond.

Consequences of Keeping Secrets

Despite the negative connotation of secret keeping, the effects of keeping secrets in relationships are multifaceted. Keeping secrets can have many different effects, sometimes both good and bad ones at the same time.

One potential cost of secret keeping is that it can lead people to think about the secret excessively, which can be psychologically distressful. There are also interpersonal risks of keeping secrets. Overall, the more secrets individuals report keeping in their relationships, the less happy they are. However, the absolute number of secrets is probably less important than one's perceptions of secret keeping; for instance, even people with a lot of secrets can be quite satisfied if they see that as normal.

Balanced against such risks are some potential benefits for keeping secrets. Research has shown, for instance, that people's reasons for keeping secrets are not unfounded. Revealing secrets can lead others to experience stress and can damage relationships. Moreover, sometimes others do judge harshly a person who reveals a secret; keeping a secret can therefore protect a person from the risk of being judged.

Given that there are both costs and benefits for keeping secrets, any claims about the universal desirability of revealing (or concealing) secrets should be viewed with skepticism. Whether it is a good idea to reveal a secret in a relationship depends on factors such as the relative value one

places on the various costs and benefits. It also depends on contingencies that the secret keeper cannot completely predict or control. For example, although people deciding whether to reveal a secret may consider whether the confidant would be supportive, they cannot always predict the confidant's response. This complicates decisions about revealing because the confidant's response is a major determinant of how beneficial (and how costly) revealing a secret turns out to be.

SECRET TESTS OF RELATIONSHIP STATUS

Secret tests of relationship status are calculated strategies that individuals use to learn, often without asking, how another person feels about their friendship or romantic relationship. They are opportunities for an individual to intuit by the other person's reaction whether that person wants to continue or deepen the relationship. Leslie Baxter and William Wilmot, who coined the term *secret tests*, identified seven different ways in which people assess how important a relationship is to the other person involved. From the most commonly used categories to the least, the tests are as follows: endurance tests, triangle tests, indirect suggestion tests, separation tests, directness

tests, asking third party tests, and public presentation tests.

When individuals use endurance tests, they get the other person to help or compliment them (particularly at a cost) or they get the other person to accept a certain amount of mistreatment without complaint (e.g., by being rude to that person). Triangle tests involve putting the other person in situations with others that test his or her fidelity and jealousy. Indirect suggestion tests involve interpreting the other person's reaction to minor attempts at more intimacy through touch, jokes, and hints. Separation tests involve evaluating the effort the other person goes through to reinitiate contact after separation. Directness tests, which are not actually secret, involve asking the other person directly how they feel about the relationship. Third party tests involve asking someone outside of the relationship how the other person feels. Finally, public presentation tests involve monitoring the other person's reaction to defining the relationship for others publicly.

Secret tests of relationship status are used when individuals are uncertain about their relationships. Sometimes uncertainty comes from individuals' own personalities or characteristics; sometimes it comes from the situation. Personality-derived uncertainty may be likened to insecurity. Individuals who most rely on secret tests are those who have low self-esteem, have an anxious attachment style, and are less trusting of others. Women use secret tests more than men, particularly triangle tests and separation tests. However, their reasons for using such tests may stem from their social roles or lack of power in society.

In terms of situation-based uncertainty, circumstances within the relationship are largely responsible for creating instability. Typically, individuals are uncertain when the relationship is new, when it seems to be changing (e.g., from friendship to romance), and when it is threatened by another person or by outside circumstances (e.g., a new good friend or more time spent at work). Individuals involved in cross-sex relationships that may be transitioning from friendship to romance use secret tests more than individuals in stable cross-sex friendships and romantic relationships. Specifically, they rely on separation tests and indirect suggestions to determine how their relationship partners feel about the relationship.

Theories that explain why individuals use secret tests of relationship status were developed from research on decision making, attributions, and personal relationships. They describe individuals' motivation for dealing with uncertainty related to all aspects of their lives, from health care to relationships. Several theories continue to be popular. These can be summarized into three main perspectives: those that assume that uncertainty reduction is a goal, those that assume that uncertainty reduction facilitates further decision making, and those that assume that uncertainty may be reduced, maintained, or enhanced according to the individual and the specific circumstances involved. For simplicity's sake, only the most common theory from each perspective will be summarized.

The Uncertainty Reduction Theory (URT), developed to describe how uncertainty affects communication, presumes that individuals have a need for a stable understanding of their worlds. According to this theory, individuals use secret tests to reduce uncertainty because people are uncomfortable with feeling as though they do not have a full understanding of their relationships. URT describes three basic ways that individuals manage uncertainty: information seeking, planning, and hedging. In the context of secret tests, individuals decide what tests to use during planning; they use active (e.g., third party tests), passive (e.g., observation), and interactive strategies (e.g., endurance tests) to gain information about their relationships; and they hedge (e.g., indirect suggestion tests) to avoid embarrassment or inadvertently threatening their relationships.

The Predicted Outcome Value Theory takes a social exchange perspective on communication, emphasizing individuals' desire to maximize the rewards they incur and minimize the costs. According to this theory, secret tests reduce the uncertainty that keeps individuals from adequately weighing the costs and benefits of their relationships. Secret tests help to define relationships so that they can be compared to similar relationships. This helps individuals determine what level of commitment (if any) they should allocate to the relationship.

The Theory of Motivated Information Management (TMIM) tries to take into account both situational and personality factors to predict when individuals will utilize information-seeking strategies, such as secret tests. This theory presumes

that under some circumstances individuals will want to maintain or even enhance their uncertainty. Further, it suggests that decisions about how to handle uncertainty are influenced by individuals' personalities and their expectations about the knowledge they seek and how they plan to obtain it. The logic of TMIM suggests that secret tests are used when individuals think that by using a specific secret test (e.g., joking), they will be able to find out information that they need (and want) without threatening their relationship.

Overall, secret tests of relationship status help individuals manage their relationships. They provide opportunities for diagnostic information without threatening individuals' own self-esteem or their relationships. Although personal characteristics and circumstances within relationships affect which strategy is selected, uncertainty is the driving force behind the motivation to use secret tests.

SECURITY IN RELATIONSHIPS

From mothers to mentors, friends to lovers, people have a fundamental need to believe that their

significant others will be responsive in times of need. According to John Bowlby, the father of Attachment Theory, the result of this belief, when fulfilled, is a sense of security—a feeling that the world is generally a safe place and that one can find support in difficult times. As this definition implies, the key ingredient of felt security—security in oneself and one’s social world—is the perceived responsiveness of significant others. For instance, if Jenny is upset after a poor performance review at work, when she gets home and finds Rupert in a bad mood, she will want to assess whether he is likely to respond supportively to her because if he rejects her, she risks feeling worse. At a time when one is looking for social support, “Will others be responsive?” is the pertinent question.

Bowlby described felt security as a key psychological construct, basic to human cognition. Indeed, evolutionary theorists contend that gauging the extent to which significant others will be responsive is critical for human survival. The importance of the concept is also evident in its centrality to three major theories of interpersonal relations, albeit framed in different ways. This entry will deal with the treatment of felt security by Attachment, Sociometer, and Interdependence theories. Although the three theories take different approaches to the concept of felt security, importantly, each views it as rooted in an individual’s mental representations of their experiences with significant others.

Attachment Theory

Attachment Theory, the most extensively articulated of the major relationship theories, posits that adult relationships are shaped by chronic, dispositional relationship orientations first developed in infancy with primary caregivers, or attachment figures. Attachment theorists contend that adult relationships in which romantic partners or significant others take on the attachment figure role are influenced by attitudes toward the self as well as expectations about the responsiveness of attachment figures in general. To continue the example, if Jenny, as an infant, was well cared for by a responsive, emotionally available parent, she is likely to have learned that attachment figures are available in times of need and that she is worthy of

their support and love. Thus, it is likely that she will not be hesitant to turn to Rupert for support when she gets home from a stressful day at work.

Although many attachment theorists acknowledge that people may sometimes develop relationship-specific attachment styles, the theory takes a predominantly trait-like approach to felt security: It is assumed that if Jenny developed a secure (or insecure) attachment style early in life, that orientation will stay with her and strongly influence her adult relationship with Rupert and others.

According to Attachment Theory, a secure attachment style will develop only when the infant learns that attachment figures are emotionally available to them, that is, when they receive an affirmative answer to the question, “Will others be responsive?” If, instead, Jenny’s experiences indicate that the answer is at least in part negative, attachment theorists predict that Jenny will turn to a coping strategy associated with one of two different insecure attachment styles characterized by a trait-like, chronic lack of felt security. These coping strategies are designed to provide optimal safety in the less than perfect circumstance of dealing with unresponsive attachment figures. The seriousness of concerns about partner responsiveness cues the individual to engage in one of two coping responses, hyperactivation or deactivation.

People who react to concerns about rejection with hyperactivation of the attachment system are called anxiously attached. Their relationship patterns may be gleaned from the following items from a popular measurement tool, the Experiences in Close Relationships Questionnaire: Anxious people are relatively likely to agree with statements such as “I often worry that my partner doesn’t really love me” and “I often worry that my partner will not want to stay with me.” This kind of insecurity is typically associated with inconsistent caregiver behavior toward the child, alternately responsive and neglecting. The anxiety reflects residual concerns that the self may not be worthy of caring (a negative self model), resulting from the feelings of uncertainty associated with inconsistent caring. The coping strategy promotes, among other features, a disposition toward vigilance and sensitivity to signs of potential rejection. Though vigilance reduces the risk of missing potential signs of rejection, the hypersensitivity results in ambiguous evidence being interpreted in negative ways

and, ultimately, in unwarranted insecurities about others' caring.

By contrast, others cope with rejection by deactivating the attachment system and are called avoidantly attached. Avoidant people tend to agree with items such as "I prefer not to be too close to romantic partners" and "I find it difficult to allow myself to depend on romantic partners." Avoidant attachment is typically associated with childhood caregivers who are largely unavailable in times of distress. It reflects serious concerns about the generosity and benevolence of others (a negative model of other). As the label implies, the main strategy associated with this form of insecurity is to avoid situations in which one must depend on the good nature of others. Whereas an avoidant style indeed decreases the risk of being let down by significant others, the increased distance and lack of deeper interdependence that results mean that many of the most important benefits of closeness are forfeited. Further, such a style is likely to be self-perpetuating because trust can only be established by taking the risk of relying on others and discovering that they are responsive in times of need.

These two forms of insecurity have been shown to shape perceptions and behavior in close relationships in important ways. As an example, Jeffry Simpson and his colleagues studied the effects of anxious attachment on social interactions between dating partners. Couples discussed either a major relationship conflict or a minor one. Difficult conflicts raise the issue in people's minds about whether a partner will largely look out for himself or herself or will be responsive to the person's needs at some personal cost. Thus, relative to minor conflicts, major conflicts provide much more information about the value the partner places on the self, and therefore function as diagnostic situations for anxious individuals who are not confident of their partner's affections. Indeed, anxious people interpreted their partner's behavior in the major conflict, but not the minor one, as rejecting and unkind. They then reciprocated the behavior they perceived and acted in a more hostile, less accommodating way. However, trained observers rating the videotapes could see no evidence that the partners had actually behaved in a rejecting, selfish way. This disposition to be oversensitive to signs of potential rejection is the very basis of this style, and the study impressively illustrates how anxious

individuals can perpetuate their own fears in a self-fulfilling prophecy.

Attachment theorists have gone further in demonstrating the importance of felt security. Mario Mikulincer and Phillip Shaver have presented impressive evidence for its beneficial effects on mental health, prosocial behavior, and intergroup relations. By priming a secure relationship—that is, by bringing mental representations of a secure attachment figure to the forefront of the mind without conscious awareness of the process—they demonstrated that a sense of security, even temporarily induced, can help a person maintain emotional stability and adaptability in times of stress, reduce the likelihood of post-traumatic stress disorder, increase compassion toward needy others, and reduce aggression toward members of disliked groups.

For example, in one study assessing the effects of security priming on intergroup hostility, Israeli Jews and Arabs came to the lab and completed a 30-trial word-relation task. During each trial, the name of a security-enhancing attachment figure they had previously provided was flashed very briefly (20 milliseconds) on the screen. Control participants were exposed to names of nonattachment figure acquaintances or friends. The exposure time was so short that participants were unaware of having seen the name. In the second part of the study, participants decided how much of an unpleasant hot sauce to assign to either a member of their own racial group or a member of the negatively perceived outgroup. Participants who were primed with nonattachment figures allotted more hot sauce to the outgroup person (i.e., an Arab, if the participant was Jewish, and vice versa) than to the ingroup person. However, when participants had received security primes, the difference was erased: Arabs and Jews were treated the same. Although the aggression measure used in this study was mild, the positive effects of felt security priming are clear. In light of these findings, Bowlby's characterization of felt security as a key cognitive construct appears quite justified.

Felt security clearly plays a pivotal role in Attachment Theory and in the characterization of hyperactivation and deactivation of the attachment system as coping strategies points to its unique framing. Interestingly, attachment theorists have typically studied felt security (a secure attachment

style) largely as the absence of anxiety and avoidance rather than as a concept in its own right. This is rather a different approach from that taken by Interdependence and Sociometer theories, as is explored in subsequent sections.

Sociometer Theory

Mark Leary and Roy Baumeister have proposed that the root of felt security, which they equate with self-esteem, is a summary of people's past, present, and likely future standing with significant others in their social network: It is an aggregate of their perceived social value. That is, from a sociometer perspective, global self-esteem is a barometer of one's perceived relational value. Individuals with higher chronic self-esteem (HSEs) feel that they are generally valued by others and thus experience a sense of social security, whereas individuals with lower self-esteem (LSEs) generally doubt their value as relational partners and are chronically insecure. People rely on these social beliefs to predict future social outcomes and to select interpersonal strategies.

How does this perspective on felt security relate to the attachment theory concept of perceived responsiveness, which is seen as the basis of felt security? Harry Reis, Margaret Clark, and John Holmes suggest that high perceived relational value leads people to strongly expect both caring and responsiveness from significant others. Research has indeed shown that the three concepts are very strongly related and that they essentially overlap with the construct of interpersonal trust. In contrast to Attachment Theory, however, Sociometer Theory does not distinguish beliefs that the self may not be worthy (anxiety) from beliefs about others as unresponsive (avoidance). Instead, it posits a summative evaluation of one's social worth to be used in an interpersonal guidance system. In this context, the term *sociometer* implies a gauge that indicates to people the overall extent to which their social needs are likely to be met.

People rely on the expectations about their relational value embodied in their sociometers to select safe interpersonal strategies. HSEs' strong sense of their relational value leads them to anticipate acceptance from future relational partners, whereas LSEs' interpersonal doubts cause them to anticipate

a chillier interpersonal reception. To cope with this sense of vulnerability, LSEs tend to adopt a self-protective interpersonal style aimed at avoiding rejection, whereas HSEs adopt a riskier, more relationship-enhancing style, aimed at fostering social bonds. For example, HSEs' social confidence causes them to eagerly seek new social opportunities, whereas LSEs' interpersonal doubts make them less willing to enter novel social situations unless acceptance is more or less guaranteed. LSEs also manage the risk of rejection in part by self-protectively underdetecting actual acceptance cues, a perceptual bias that leads them to avoid the risk of trying to draw closer unless the evidence is overwhelmingly positive and clear.

Though people have a chronic or average sense of security or insecurity, they also monitor and interpret current social experiences for information about their ongoing level of acceptance. This state of self-esteem is part of what is called the sociometer's acceptance signaling system, which is attuned to answering the question, "Am I valued?" If the sociometer detects acceptance, it signals this desirable state of affairs with increases in state self-esteem, that is, with positive feelings about the self. This momentary sense of security facilitates efforts to forge social bonds and take the risk of creating closeness. If the sociometer detects rejection, it signals this undesirable state of affairs with decreases in state self-esteem and self-affect. Decreases in state self-esteem alert the individual that his or her social bonds may be in jeopardy and encourage a person to either make reparative efforts or to seek new social acquaintances who might be more accepting.

Interdependence Theory

Interdependence theorists have also described felt security as rooted in perceptions of being valued by others. Felt security has typically been seen as directly linked to perceived regard, the extent to which the self is seen to be valued and cared for by a specific partner. Although theorists in this tradition reinforce the idea that dispositions like anxious and avoidant attachment and self-esteem strongly affect one's perceptions of being valued by, for instance, a romantic partner, they also have demonstrated that feelings of security are partly

determined by experiences with and beliefs about that particular partner, a more social psychological point of view. Rupert and Jenny, for instance, may each have had experiences in their relationship that persuasively demonstrated the other's responsiveness to their needs, over and above their chronic dispositions to trust others.

Consistent with the view of Sociometer Theory, perceived regard is seen as having a chronic, more stable level and a state or context-bound value. That is, confidence that a partner will be responsive will be influenced by current relationship circumstances, such as whether the partner must make a costly sacrifice in order to act responsively, whether a conflict has been recently experienced, whether the person is in a good mood, and so on.

Murray and her colleagues have shown that having high perceived regard in close relationships results in a relationship promoting orientation because closeness is seen as a minimal risk. High perceived regard and the sense of security it fosters reduces people's sensitivity to rejection, reduces social pain when feelings of rejection do occur, and promotes efforts to increase closeness even in the face of concerns about rejection. All three tendencies predict increased satisfaction in marriage over time. In contrast, serious concerns about how one is regarded and loved by a partner result in a sense of vulnerability, which causes the risk regulation system to activate a preventive, cautious approach. Low perceived regard people show an increased sensitivity to signs of potential rejection, report stronger hurt feelings in the face of perceived rejection, and are much more likely to emotionally distance themselves from partners and be less charitable toward them. All three tendencies predict declines in satisfaction over time for both partners.

A sense of security, in the Interdependence Theory perspective, controls everyday decisions to take the risk of creating intimacy and depending on another to be responsive to one's needs. People secure in the belief that their partner values them feel safer taking the risk of disclosing their failures, problems at work, and so on. They feel confident that their partner will help them even when it is costly and that they can turn to their partner for support in difficult times. Such reactions are likely to create a self-perpetuating cycle if such trust is warranted. Not only does the increased interdependence increase the

mutual benefits in the relationship, but evidence that a partner was responsive to one's needs will further strengthen one's sense of security. Conversely, people insecure in their belief that a partner values them may miss the very opportunities that offer the most potential for growth in relationships.

Conclusion

There is impressive evidence to support the claim that the construct of security in relationships is perhaps the most central and critical of any concept. Expectations of responsiveness are pivotal in shaping people's emotions, cognitions, and behavioral strategies in their close relationships. Theories may differ in their explanations for how these expectations develop, but all agree that how secure people feel in their relationships controls people's most basic orientations toward their significant others. A sense of security creates a platform of safety that encourages people to deepen their interdependence with others, despite the risks, to act in a promotive way in their relationships that will realize the most profound benefits. In contrast, a sense of insecurity often leaves people at the margins of their relationships, unwilling or unable to enjoy the benefits of being truly close to significant others because of a self-protective sense of caution rooted in their pessimistic expectations about others.

SELF-CONCEPT AND RELATIONSHIPS

Scientists and laypeople alike would agree that human relationships have an enormous impact on people's inner lives—such as on their emotional well-being and judgments of life satisfaction. Most people would also agree that relationships can shape how people define and evaluate themselves. For example, a relationship might influence whether a person sees him or herself as patient, whether a person considers having a high-status job to be an important goal, or whether a person views him- or herself as worthy of being loved. This entry discusses how the self-concept is influenced by relationships. The self-concept refers to a wide array of people's perceptions and feelings about themselves, including their views of their physical and personality characteristics, their goals and values, and their positive and negative evaluations of themselves. To define the self-concept and relationships, this entry will first provide some historical background and then describe three recent conceptualizations of the link between the self-concept and relationships, including examples of research spawned by each. Finally, relationship-related aspects of the self-concept will be distinguished from other aspects of the self-concept.

Historical Background

In psychology, the link between the self-concept and relationships is a longstanding one, traceable

to the 1890s in William James's theorizing on the self. James distinguished between the I-self, or the self as subject, whereas the me-self captures the self as object. James further delineated three components of the me-self—namely, the material me, social me, and spiritual me. A link between the self-concept and relationships can be found in the social me, which refers to aspects of the self that are associated with and experienced in relation to individuals and groups whose opinions are valued. In contemporary terms, individuals whose opinions are valued are essentially significant others, or people's close relationship partners, such as spouses, parents, close friends, boyfriends, or siblings or other relatives.

Subsequent to James's early writings, psychologists and other social scientists continued to theorize about the link between the self-concept and relationships. A key example is the work of symbolic interactionists, who believe that the person and society are mutually constructed in the course of social interaction. Charles Horton Cooley, a prominent early symbolic interactionist, coined the term *looking-glass self* to capture the idea that people's views of themselves are based on their perceptions of how others see them. To illustrate, Jane's views of herself as a singer are based on her perceptions of her family's and friends' responses to her singing. If her family and friends cheer her on at the local karaoke bar, encouraging her to sing another song, Jane may interpret these reactions as indicative of their favorable impressions of her singing abilities. Accordingly, she is likely to develop an image of herself as a talented singer. In the same vein, George Herbert Mead, another famous symbolic interactionist, argued that conceptions of the self emerge through perspective taking, whereby people take on the perspective of others on themselves. Finally, an important example outside of the symbolic interactionist tradition is the theorizing of Harry Stack Sullivan, who posited that encounters with significant others provide the forum for personality development and by implication, the formation of people's conceptions of themselves.

Interest in the self-concept and relationships diminished in the mid-20th century as part of the waning of attention to the self in the wake of behaviorism. However, by the late 1900s, the self reemerged as an important topic of psychological

inquiry, and with it came renewed attention to social influences on the self-concept. In fact, tremendous advances have been made on the topic of the self-concept and relationships in the past two decades in particular. This entry turns now to a description of three recent conceptualizations of the link between the self-concept and relationships that emerged during this time.

Recent Conceptualizations

Relational Selves

Relational selves is a term used to refer to aspects of the self that come into play in the context of interactions with relationship partners. Researchers assume that relational selves are represented in people's memories in the form of self-other linkages. More specifically, this conceptualization of the link between the self-concept and relationships assumes that people possess separate schemas—that is, bundles of knowledge stored in memory—of themselves and of each of their significant others. A person's self-concept schemas and each of his or her significant-other schemas are thought to be linked by knowledge reflecting the typical patterns of interaction that the person experiences with each significant other. This is what is meant by self-other linkages. To illustrate, Jason possesses a schema that designates his self-concept as well as a schema that designates his mother. Jason's self-concept and mother schemas are linked by knowledge reflecting the interaction patterns that Jason usually experiences with his mother. For example, if Jason typically submits to the wishes of his domineering mother, the linkages that connect his self-concept schema to his mother schema will embody this interaction dynamic. In other words, the person that Jason is with his mother—or Jason's relational self with his mother—includes the trait submissiveness.

To examine the nature of people's relational selves, researchers often prime, or in other words experimentally activate, research participants' significant-other schemas. That is, they ask participants to engage in some kind of task that temporarily brings their significant others to mind. For example, researchers might ask participants to spend a few minutes visualizing a significant other. Interestingly, significant-other schemas can be

brought to mind even without participants' awareness that this has happened. For instance, researchers might expose participants to the name of a significant other on a computer screen, but the exposure may occur so quickly that participants do not consciously recognize the name. Regardless of how a significant-other schema is activated, when this happens, it is assumed that the relational self associated with the significant other is also temporarily brought to mind since self-concept and significant-other schemas are connected by self-other linkages. As a result, participants' thoughts, feelings, and behaviors reflect the activated relational self. In essence, people think, feel, and behave as they typically do with their significant other.

In one concrete example of research on relational selves, Mark Baldwin and his colleagues exposed psychology graduate students to the face of their graduate advisor, who was presumably a significant other, or the face of someone who was not a significant other. Both faces were shown subliminally, that is, so quickly that the students were not aware of their exposure to them. Importantly, the graduate advisor's face had a disapproving expression while the other person's facial expression was approving. The hypothesis was that exposure to their graduate advisor's disapproving face would activate the students' schema of their advisor, along with the associated relational self. As a result, the students would evaluate themselves as they typically do with their advisor—namely, negatively when their advisor shows disapproval. Indeed, students exposed to their graduate advisor's face subsequently evaluated their research ideas more harshly compared to participants exposed to the face of a nonsignificant other.

In a second research example, Susan Andersen and her colleagues activated significant-other schemas by telling participants they were going to have an interaction with a supposed other participant. This upcoming interaction partner was described in a manner somewhat similar to participants' own significant other, based on descriptions that participants had provided about their significant other in a pretest session. The descriptions of the partner were meant to activate participants' schema of their significant other without participants being aware that this was happening. The researchers hypothesized and found that after the significant other was activated, participants described and

evaluated themselves in-line with how they had characterized their relational self with the significant other earlier in the pretest session. In other words, the relational self associated with the significant other was activated. Applied to everyday social interactions, this study suggests that when people meet someone new who reminds them of a significant other, they come to see and evaluate themselves as they do in their relationship with the significant other. In turn, such changes in the self-concept have implications for the nature of people's social interactions. For example, if Amanda is fun loving and feels good about herself when she is with her best friend, when she meets someone new who reminds her of this friend, she will tend to see herself as fun loving and to evaluate herself positively just as she does with her friend. In turn, she is likely to approach the interaction with the new person in a fun-loving and positive manner.

Inclusion of Other in the Self

Another recent conceptualization of the link between the self-concept and relationships also assumes that people have schemas of themselves and their significant others stored in memory. However, instead of linkages between them, this conceptualization posits that these schemas may overlap with one another. More specifically, it proposes that, to varying degrees, people may include or take on aspects of their significant others as their own. One theory that proposes this kind of conceptualization is the inclusion-of-other-in-the-self approach. Arthur Aron and his colleagues developed this approach to understand closeness in relationships. According to this approach, the closer one's relationship is, the more one's relationship partner has been included in the self—or in schema terms, the more self-concept and significant-other schemas overlap. Research indicates that people may include a variety of aspects of their relationship partners into their self-concepts, including their partners' resources, perspectives, and personality attributes. As an example of the last of these, the closer Samantha's relationship with her boyfriend is, the more her view of herself may come to include her boyfriend's optimistic outlook and love of adventure.

To assess the degree to which people have included relationship partners in the self, researchers

have used both direct and indirect measures. The most commonly used direct measure is a single-item scale composed of seven pairs of circles. In each pair, one circle designates the self-concept and the other, one's relationship partner. The seven pairs vary in terms of how overlapping the two circles are with greater overlap meant to imply greater closeness in the relationship. Respondents are asked to choose the pair of circles that best represents their relationship.

A common indirect measure of inclusion of other in the self involves participants' reaction times on a computer task (i.e., how quickly participants respond to stimuli presented to them on a computer). Before this task, participants are asked to rate themselves and their relationship partner on various personality traits (e.g., outgoing, helpful, assertive, polite). Based on these ratings, researchers identify traits that participants think describe or do not describe both themselves and their partner, as well as traits that participants think describe only themselves or only their partner. After a delay, participants do the computer task, which involves once again indicating whether the traits they rated earlier describe themselves. The computer records how quickly participants make their self-ratings. The logic of this task is that if relationship partners are included in the self, it should be quicker for people to respond to traits that are descriptive or nondescriptive of both themselves and their partners and slower for them to respond to traits that are descriptive of only one of them because the latter requires people to momentarily separate themselves from their partners. To illustrate, if Jack is included in Linda's self-concept to a large degree, Linda should be quick at responding to the trait outgoing, which describes both her and Jack, but slow at responding to the trait punctual, which describes her but not Jack.

Self-Discrepancy Theory is another theory that assumes that aspects of significant others may be included in the self-concept. According to this theory, people hold beliefs about what they are actually like (actual self), as well as beliefs about what they would ideally like to be (ideal self) and what they think they ought to be (ought self). Ideal selves represent people's hopes and wishes (e.g., Steve hopes to be a rock star), whereas ought selves represent people's duties and obligations

(e.g., Steve feels obligated to become a doctor). Ideal and ought beliefs can be thought of as self-guides that people are trying to meet. Research indicates that when people are made aware of discrepancies between their actual self (i.e., who they are) and their self-guides (i.e., who they hope or feel obligated to be), they experience specific emotions. Discrepancies between actual and ideal selves produce dejection-related affect (e.g., disappointment), whereas actual-ought discrepancies elicit agitation-related affect (e.g., anxiety). To illustrate, when the casting director disparages Allen's acting ability, the discrepancy between his actual self (a poor actor) and his ideal self (a movie star) arouses disappointment but not fear.

Where do people's ideal and ought self-guides come from? Children are exposed to parents and other significant others who convey ideal and ought self-guides directly or indirectly through their reactions. Oftentimes, children come to take on their parents' ideals and oughts as their own. However, as people mature, they develop independent standpoints on their self-guides. Thus, people know what significant others hope they become and what significant others think it is their duty to be, but they may not necessarily share these ideals and oughts. Introjected self-guides are significant-other self-guides that people do not themselves endorse. In contrast, identified self-guides are significant-other self-guides that people do endorse. These latter guides are essentially included in people's own self-concepts, and thus, in this sense, they exemplify a link between the self-concept and relationships.

Cross-Cultural Differences

A third conceptualization of the link between the self-concept and relationships assumes that significant others and relationships are more self-defining for some people than for others. In other words, it assumes that there are personality or individual differences in the degree to which the self-concept and relationships are linked. One well-known example of this kind of conceptualization comes from theorizing on cross-cultural differences in the nature of the self-concept. Hazel Markus and Shinobu Kitayama argue that the traditions, institutions, and practices of Western cultures promote an independent self-construal, a

view of the self as a unique, separate, and autonomous entity. For example, children in the United States are encouraged to express their individual preferences from an early age, and to stand out among their peers. This is less true in East-Asian cultures, where children are taught to be attentive to others' preferences and adjust to their peers. The traditions, institutions, and practices of these cultures are thought to foster an interdependent self-construal, a view of the self as interconnected with others, such as one's relationship partners. Thus, from this theoretical perspective, there is a stronger link between the self-concept and relationships for people from East Asian relative to Western cultures.

Research examining this conceptualization has typically compared the responses of people from Western cultures (e.g., United States) to those from East-Asian cultures (e.g., Japan). Consistent with the idea that relationships play a bigger role in the East-Asian self-concept, people from East-Asian cultures tend to refer to their relationship partners more when describing themselves ("I am Amy's best friend") than do Westerners. More indirect evidence of cross-cultural differences in the self-concept has also been found. For example, East Asians tend to take into account the social context more in their explanations than do Westerners. To illustrate, to explain a coworker's silence at a company meeting, East Asians, who presumably hold an interdependent self-construal, would be especially likely to notice and make reference to social considerations such as the coworker's concern over offending others by being too vocal.

Distinguishing Relationship-Related Versus Other Aspects of the Self-Concept

Finally, it may be useful to distinguish aspects of the self-concept that are linked to relationships from those that are not. The self-concept is complex and multifaceted. Indeed, many psychologists consider the self-concept to be composed of three core components: the personal component, the relational component, and the collective component. This entry has focused on the relational component—those parts of the self-concept that are influenced by relationships. The personal component, by contrast, refers to those parts of the

self-concept that reflect who people are as unique, separate, and autonomous individuals. Finally, the collective component of the self-concept embodies those aspects of the self-concept that are derived from the social groups to which people belong—for example, one's ethnic or racial group. In the course of everyday life, different components of the self-concept are activated, thereby shaping people's cognitive, emotional, and behavioral responses. In other words, who people are at any given moment depends in part on the particular component of the self-concept that is active in the immediate situation.

SELF-DISCLOSURE

Self-disclosure is a process of revealing oneself to others. It is described as what individuals voluntarily say about themselves to others, including their thoughts, feelings, and experiences. Self-disclosure may involve personal information about facts or feelings; it may be about the past, the future, or the present; it may be related or unrelated to the listener. Self-disclosure is key to the development and maintenance of relationships whether it focuses on issues associated with the self, the listener, the relationship, or all three. It can be viewed as a personality trait related to other traits or as an interpersonal process; either way, the extent to which people engage in self-disclosure affects and is affected by social interaction.

Theoretical and Conceptual Foundations

One of the first researchers to examine self-disclosure was Sidney Jourard. Jourard, who was a psychotherapist, described self-disclosure and claimed that it was positively associated with individuals' health and well-being. He argued that being able to share feelings, thoughts, and experiences with another person often serves as a relief to individuals and may elicit support and validation from listeners.

The importance of self-disclosure to the development of interpersonal relationships was initially highlighted by Irwin Altman and Dalmas Taylor. In fact, Altman and Taylor's Social Penetration Theory describes self-disclosure as inextricably tied to relational development. The theory suggests that increases in relational intimacy are a result of individuals sharing increasingly personal information about themselves with each other. When people first meet and do not know each other well, they tend to exchange information that is impersonal and talk about a limited range of topics.

As they come to know and trust each other, they begin to disclose more personal information and talk about a relatively broad range of topics. According to the theory, sharing information is not only a means for individuals to become more intimate with each other, it also is a way for them to evaluate the rewards and costs that may be associated with their relationships. Altman and Taylor suggested that as long as the rewards partners perceive as associated with their relationship are greater than the costs they believe they will incur, relational development will continue.

Altman also argued that relational partners experience an ongoing struggle about how much information to disclose and how much to conceal. In-line with this idea, more recent theory and research suggest that people utilize self-disclosure to regulate and define their relationship boundaries. Thus, self-disclosure may be employed strategically as a means to get closer to someone or it may be avoided in order to preserve relational distance.

In addition to examining the links between self-disclosure and relationship development, researchers and theorists have studied the degree to which individuals reciprocate self-disclosure. Reciprocity occurs when a person discloses to a listener, and the listener discloses in response. Reciprocity has been studied in experiments where a confederate, who disclosed at various levels, was introduced into small groups. Members of the groups responded to the confederate by matching the degree to which the confederate disclosed. Although self-disclosure often is reciprocated within a single situation, it also can be reciprocated at some other time in a different situation. Indeed, in long-standing relationships, reciprocity may take place over relatively long periods of time. For example, research has demonstrated that although husbands and wives may not reciprocate each other's disclosures immediately, they tend to match how much they disclose to each other over time. Reciprocity may be viewed as an expression of trust between partners, as a tendency of individuals to model or mimic each other's behavior, or as a relational norm.

Measures and Methods

The most common measures of self-disclosure are questionnaires that are used to elicit participants'

reports of their self-disclosing behavior. Participants typically are asked either to report what they have disclosed or what they would be willing to disclose to certain people. For example, Jourard's original questionnaire consists of 60 items (a later version had 25) where each of six content areas is represented by 10 items. The six content areas are attitudes and opinions, tastes and interests, work and study, money, personality, and body. Participants' responses are framed in terms of the person to whom the information is revealed, such as the respondents' mother, friend, best friend, and so on.

Another method of measuring self-disclosure is by asking participants to keep diaries in which they report interactions with others, how much they disclosed, and how revealing or intimate their self-disclosures were. Diaries also may be used to obtain written descriptions of disclosures which then are rated by experts.

When researchers want to observe self-disclosure, they often do so by manipulating the degree of disclosure in experiments. For example, an experimenter or a confederate can disclose to a participant at different rates, and the degree of the participant's self-disclosure can be coded.

Self-disclosure can be measured from several perspectives. For example, researchers have assessed how much disclosure occurs because of the discloser's, or the listener's, characteristics. A relatively novel approach is measuring the degree of disclosure in a dyad's interaction that occurs as a product of the relationship itself and the interacting partners together, above and beyond the degree of self-disclosure of each individual. The introduction of psycho-physiological indices such as blood pressure, muscle tension, and skin conductance has likewise expanded the possibilities for interpreting the process and impact of self-disclosure. These indices enable researchers to measure self-reported degree of self-disclosure or anxiety and compare that assessment with some physiological response. Discrepancies between self-reports and physiological measures may indicate ongoing distress that is not self-reported.

Outcomes Associated With Self-Disclosure

Although disclosing information about oneself to others can be risky, self-disclosure has been linked

to a number of positive psychological and physiological outcomes. Some of the psychological benefits of self-disclosure include enhanced self-worth and self-validation. Self-disclosure can protect people from intrusive thoughts, free up cognitive resources, and facilitate insights. People who tend to disclose information about themselves to others typically are less anxious, less depressed, and less lonely and have less problematic interpersonal relationships than do others. Self-disclosure is related to commitment, love, and satisfaction in close relationships. Disclosure shows trust and confidence in others and often creates a positive cycle in relationships.

The physiological benefits of self-disclosure also are striking. Research on self-expression and disclosure of emotional experiences has demonstrated that both can be associated with better physical health. Various health indicators, such as markers of the immune system, blood chemistry related to liver functioning, cardiovascular functioning, physical symptoms, morbidity, and even mortality rates, are related to a range of measures and levels of self-disclosure. In the laboratory, talking about traumas has caused immediate and striking reductions in disclosers' blood pressure level, muscle tension, and skin conductance. The mechanism that researchers believe may be at work here is that repressing negative experiences such as traumas, disappointments, rejection, and losses requires a physiological effort that impairs normal biological functions. Some researchers have argued that there is a curvilinear relationship between degree of self-disclosure and degree of health—that those who disclose in moderation are mostly better adjusted—but this argument has remained intuitive so far.

It is important to acknowledge that because disclosing information about oneself involves vulnerability and risk, it is not always associated with positive outcomes. In fact, a number of motivations work against disclosing. People may perceive the costs of disclosure as too high, or they may fear that their partner will not respond positively to the disclosure. Protecting the partner from being hurt or upset by the information is another restraining motivation. Partners also may fear that the self-disclosure will cause loss of assumed similarity and thus create social distance. They may fear losing their relationship altogether because of the content of what they reveal.

People also may have negative experiences when they disclose. They may feel shame for deviating from expected norms or conversely, may experience regret for not revealing the relevant information sooner. Those who disclose can create undesirable impressions of themselves in their listeners. Self-disclosure that is not well received can carry several costs. These include loss of privacy, being judged, losing face and status, instigating conflict, being deemed to have poor judgment, and so on. Likewise, there may be costs to the listener, such as feeling hurt, being misunderstood, and so on.

Development of Self-Disclosure Among Children and Adolescents

Little is known about self-disclosure with regard to human development. People tend to assume that children express themselves genuinely, in earnest, and therefore that they self-disclose at higher rates than adults. It is reasonable to think that children are relatively naïve and that their judgment of appropriateness is still developing. However, the distinct features of children's self-disclosure have not been investigated systematically. Research suggests that children's willingness to disclose to their parents tends to be higher when their relationship with their parents is warm. Disclosure to mothers and siblings tends to be higher than to fathers. Where relationships with parents are marked by distrust, the children's tendency is to avoid disclosing to parents altogether.

During adolescence, self-disclosure to friends and then to romantic partners tends to increase, as young people seek validation and support more from peers than from parents. This tendency seems to continue through the college years: College seniors were found to disclose to best friends more than did freshmen.

Sex Differences

In North America, women disclose more to other women than men disclose to other men. Women more than men disclose particularly to intimate persons such as their mother, romantic partner, close female friends, and siblings. In contrast, a few studies show that men disclose more than

women to distant targets like coworkers, neighbors, and strangers. Women tend more than men to disclose about intimate topics such as emotions, personal development, and personal relationships. Normative patterns of relating to intimate others may discourage men from self-disclosing. Interestingly, men who avoid disclosing particularly in the context of close relationships regard self-disclosure as a sign of neediness, dependency, and weakness. In contrast, women may see self-disclosing as a desirable process by which they acquire sympathy and support, so it is a source of strength.

Relationships

Research generally suggests that self-disclosure is an important part of close relationships. For instance, there is a positive association between self-disclosure and variables such as liking and relational satisfaction. Experiments where levels of self-disclosure were manipulated have demonstrated that when people disclose to someone, they have a greater tendency to like that person. The reverse also is true: When individuals like someone, they are more likely to disclose to that person. Studies further indicate that in ongoing relationships there is a positive association between disclosure and the tendency of partners to be emotionally involved with each other. Partners who disclose more to each other tend to report greater relational satisfaction and relational stability.

Although self-disclosure appears to be positively linked to happy, close relationships, it is important to note that the association between disclosure and intimacy is not necessarily linear. Some theorists argue that relational partners experience dialectical tensions between being open and closed about what they discuss with each other. Others similarly suggest that partners work together to establish a balance between what they disclose to each other and what they keep private. Scholars also note that, after partners come to know each other well, their need to disclose personal information declines. Further, although self-disclosure among married couples is related to greater marital satisfaction, couples' self-disclosure can depend on the type of relationship they maintain. For instance, researchers have noted that couples can

be characterized as evincing one of three relationship types: traditional, where the partners use regular and traditional daily schedules and stress stability rather than satisfaction; independent, where couples maintain a high level of companionship and are assertive in their relationship; and separate, where partners are disengaged and control psychological and physical accessibility to each other. Studies of couples interacting in a laboratory setting showed that independents disclosed more than traditionals who, in turn, disclosed more than separates. Further, separates and traditionals disclosed a significantly higher proportion of factual information to one another, twice as much as independents.

Context: Cultural Differences, Social Class, Setting

Self-disclosure is influenced by norms and social rules that pertain to what is appropriate, depending on each situation and relationship. Cultures regulate differently the degree to which people self-disclose, the content of their disclosure (defining certain topics as taboo), and the individuals to whom they disclose—parents, siblings, spouse, acquaintances, and strangers. For instance in one comparative study, young African Americans of both genders were found to disclose less than young European men and women. Men of lower income, regardless of origin, tended to report less self-disclosure to intimate persons—family, close friends, partners—and more to distant targets. Women, regardless of social class and origin, tended to disclose more to intimates.

Like culture, physical settings can affect self-disclosure. It is particularly complicated to regulate self-disclosure and privacy in a context where there is reduced physical space and crowding, where privacy is limited, and where much about each person is exposed. A context of this kind is the Israeli kibbutzim. In these very small, modern collective communities self-disclosure is inhibited, although relationships among the members are generally positive and cooperative. One of the explanations for the relative inhibited self-disclosure in the kibbutz is that communal life is based on intense contact most of the day. Until about 15 years ago, children also slept in separate children's houses,

thus experiencing almost around the clock contact. As a result of this intense contact, people may feel the need to guard their psychological privacy and their individuality.

The most common participants in self-disclosure research have been students and married couples. Research on special groups and their special contexts, such as individuals with HIV, gay men and lesbian women, sexual abuse survivors, and so on, will enable scholars to test the extent to which previous research findings valid under these special circumstances.

Self-Disclosure and Psychotherapy

Self-disclosure is important in psychotherapy to clarify the sense of self, to explore inner thoughts and feelings, and to enable people to make choices in their relationships outside the therapy. People who undergo psychotherapy tend to feel more open and to self-disclose more in other contexts (e.g., in their personal relationships) than people who have not had therapy.

Individual psychotherapy usually involves two persons, the therapist and the client-patient. Self-disclosure by the latter is a cornerstone of psychotherapy. By disclosing thoughts and feelings that they see as unacceptable and having those thoughts and feelings accepted by the therapist, client-patients are likely to experience greater internal peace. Greater disclosure by client-patients during therapy is associated with better therapeutic outcomes.

There are two extreme positions concerning self-disclosure by the therapist to the client-patient, as well as a recent position that is more moderate. Jourard who was among the first to coin the term self-disclosure within psychology, regarded it as essential for the therapist to disclose to the client about himself or herself. In contrast, Freud, who laid the foundation for most current psychotherapies, advocated the total absence of any disclosure by the therapist (although in practice he engaged in disclosure). For decades, self-disclosure by therapists was discouraged. Jourard's original sweeping suggestion about its value was ignored. It was considered likely to interfere with the nature of responses from the client and to change the direction of the therapy. The therapist's refraining from verbal self-disclosure was part of an effort not to

contaminate the directions that patients chose to go. It meant belittling the effect of all the non-verbal and indirect information available to the patient about the therapist. In recent years as part of a novel relational-psychodynamic therapy, a degree of self-disclosure by the therapist is considered essential to the psychotherapeutic relationships. The place of disclosure from therapists to clients has been conceived as positive, provided that the disclosure is intentional and planned by the therapist to suit the patient's specific needs. Research indicates that self-disclosure by therapists, when appropriate, and especially in response to similar client self-disclosure, may increase positive, rewarding, and reciprocal self-disclosure by the client.

SELF-ESTEEM, EFFECTS ON RELATIONSHIPS

A widespread belief in popular culture is that to truly love others, one must first love oneself. That is, global self-esteem—one's overall evaluation of and liking for oneself—must be high and secure. This entry examines research relevant to this belief. It concerns, first, the concept of self-esteem; then it addresses evidence concerning self-esteem and the initiation of new relationships and the quality of close relationships. Finally, it concerns mechanisms that may link self-esteem and relationship quality.

Typically, self-esteem is measured through a self-report questionnaire with items such as, "I am a worthy person." This entry focuses on such traditionally measured self-esteem rather than on implicit self-esteem—feelings about the self that are beyond full awareness. This entry also focuses on (a) global self-esteem rather than on self-evaluations in specific domains (e.g., academic, social) and on (b) dispositional self-esteem, which has been shown to be quite stable over time rather than state self-esteem, which involves one's feelings about oneself at a particular moment. In most research on self-esteem, people classified as having low self-esteem (LSEs) do not truly dislike themselves; they view themselves positively, just less positively than do people with high self-esteem (HSEs). This entry also assumes that HSEs' positive self-views are genuine and secure—not falsely inflated or narcissistic—which probably would have different consequences for relationships.

Self-Esteem and Relationship Initiation

Although only a few studies have addressed self-esteem differences in relationship initiation,

evidence has emerged that is consistent with Mark Leary's Sociometer Theory. According to Sociometer Theory, self-esteem is a barometer of one's perceptions of one's relational value: HSEs are confident that others value them, whereas LSEs are doubtful. In-line with Sociometer Theory, LSEs compared to HSEs express less confidence that being friendly will bring about affiliative responses from others, tend to underestimate the degree to which new acquaintances like them, worry more about rejection, and according to some studies, are more hurt by rejection when it does occur.

Such differences in confidence about others' acceptance may well contribute to self-esteem differences in relationship-initiating behaviors. HSEs rate themselves, and are rated by others, as being better than other people at initiating relationships. They also report dating more than do LSEs. In contrast, LSEs appear to pass up opportunities for gaining new friendships if those opportunities carry even a slight risk of rejection.

In the case of initiating new relationships, then, popular wisdom appears to be correct: It helps to love oneself.

Self-Esteem and Relationship Quality

Many studies show that HSEs view their interpersonal relationships favorably. Compared to LSEs, HSEs describe themselves as more socially skilled, more popular, less lonely, more socially supported, more accepted by other people in general and by specific people in their lives, more satisfied in both their friendships and romantic relationships, more secure in their attachments, and more optimistic about the future of their romantic relationships.

Such findings may not indicate that HSEs actually do have higher-quality relationships, however. HSEs are more happy and cheerful than LSEs, so they may have more favorable views of everything; they may even see the sky as bluer. Correlations between any two self-report measures—including measures of self-esteem and the quality of one's relationships—may be inflated by such positivity biases, as well as by social desirability concerns and shared method variance. Researchers can use three methods to avoid these problems with self-ratings: assess relationship

dissolution, use relationship partners' ratings (e.g., friend, romantic partner), and attempt to control for the problems associated with self-ratings.

The objective measure of relationship dissolution—whether the friendship has ended or the couple has split or not—would seem to provide an incontrovertible index of relationship quality. Yet very few studies involving self-esteem have employed such measures, and those that have contradict each other. More importantly, relationship dissolution may not be an unambiguous index of relationship quality after all. People often stay in unsatisfactory friendships and marriages, yet some relatively happy relationships dissolve. Decisions about whether to seek a divorce, for example, may be influenced by factors other than relationship quality, such as financial resources. The ambiguity of a breakup as a measure of relationship quality is particularly acute when it comes to examining self-esteem. LSEs tend to stay in relationships even when they are unhappy, probably fearing that they have relatively poor alternatives to their partner.

A second way of avoiding the pitfalls of self-report measures is to examine whether relationship partners share HSEs' rosy views. Although vastly outnumbered by studies of self-rated satisfaction, a few studies have measured the association between one partner's self-esteem and the other's satisfaction. These studies confirm that the higher one's self-esteem, the better the relationship (as viewed by one's partner).

A third approach to the problems of self-report is to retain self-report measures but to attempt to control for the problems that such measures create. An example involves a study by Sandra Murray, John Holmes, and their colleagues in which the dependent variable was perceived regard—for example, Nora's perceptions of her partner Nick's regard for her—rather than relationship satisfaction. These researchers examined the association between (Nora's) self-esteem and perceived regard while controlling for (Nora's) ratings of relationship satisfaction. Results showed that HSEs thought that their partners regarded them more favorably than did LSEs. Because Nora's satisfaction ratings should have been influenced by any tendency on her part to be positively biased or concerned about social desirability, controlling such ratings should control for those problems. Hence, the results strongly suggest that the

self-esteem-perceived regard association is not due to these nettlesome issues.

In sum, studies of relationship quality—involving self-reports, partner reports, and self-reports with controls for positivity biases—suggest that HSEs enjoy happier, more satisfying relationships than do LSEs. But what is the direction of causality? Although it is plausible that self-esteem influences relationship quality, it is also plausible that relationship outcomes influence self-esteem. For example, being happily married could well raise one's self-esteem. It is also possible that a third variable, such as high income or robust physical health, promotes both high self-esteem and happy relationships.

Stronger conclusions about causality are afforded by longitudinal designs that measure self-esteem at time 1 and relationship quality at time 2 (and that control for time 1 relationship quality and time 2 self-esteem, which should control positivity biases). Only a few studies of this design have been reported. Three studies, again coming from Murray's laboratory, suggest that HSEs not only find their relationships more satisfying, but they also experience greater increases in satisfaction over time. In contrast, LSEs not only start out less satisfied with their relationships, but also their satisfaction tends to decline. Self-esteem also predicts corresponding changes in partners' satisfaction over time.

Many more longitudinal studies have examined the role of neuroticism, which is the tendency to view the world as threatening and to experience negative emotions. Such studies are pertinent here because neuroticism is typically conceptualized as including low self-esteem, and measures of neuroticism and self-esteem are moderately to strongly correlated (inversely). Longitudinal studies have shown convincingly that neuroticism is the strongest personality predictor of relationship quality: Couples that include a partner high in neuroticism are less harmonious than those that do not. It is possible that self-esteem may be the true cause underlying these effects. Although it is also possible that any association between self-esteem and relationship quality may be due to the third variable of neuroticism, the possibility that low self-esteem is the active ingredient in neuroticism seems at least equally plausible, as described in the next section.

Mechanisms Underlying the Self-Esteem–Relationship Quality Link

Research has indicated that within their close relationships, LSEs differ from HSEs in a variety of beliefs and behaviors. The following summary focuses only on the beliefs and behaviors that have been shown in other research to be associated with relationship quality. Relative to LSEs, (a) HSEs more openly express their thoughts and feelings with people they are close to, (b) HSEs are more secure in their attachment styles (i.e., they are more willing to get close to and depend on others), and (c) when their partners behave badly, HSEs make attributions for those behaviors that are more charitable. In turn, these three characteristics—self-disclosure, secure attachment style, and benign attributions—positively predict relationship quality.

Some of these associations can be understood within the risk regulation model of Murray, Holmes, and their colleagues. According to this model, people in romantic relationships must balance their desire for closeness against their desire to protect themselves from the pain of possible disapproval or rejection by their partner. Hence, people estimate their partner's regard for them and regulate their closeness accordingly. Self-esteem enters into this model because it is a strong predictor of perceptions of the partner's regard. Murray and her colleagues have shown across many studies that LSEs underestimate how much their partners love them. When judging their partner's regard for them, they seem to project their own self-doubts. An LSE, George for example, assumes, without supporting evidence, that Gracie shares his unfavorable view of himself. LSEs' perceptions of their partner's regard also seem to be readily contaminated by how they feel about themselves in other spheres of life. On days when they have succeeded in some way at work, for example, LSEs feel more loved and accepted by their partner, whereas when they fail, they feel less loved. HSEs do not display the same pattern. Murray and colleagues' studies also show that people with LSE seem ready to interpret ambiguous cues from their romantic partner as signs of rejection. For example, when their partners are in a bad mood, LSEs tend to take it personally and to feel hurt. When they believe that their partner sees a problem in their relationship,

they are more likely than HSEs to fear losing their partner's love and commitment.

The risk regulation model also predicts what happens when people have the insecurities exhibited by LSEs: They attempt to reduce closeness and interdependence with their partner. In several studies, Murray and her colleagues have shown that when their insecurities are heightened in the ways just described, LSEs self-protectively withdraw, derogate their partners, or otherwise behave badly toward their partners on subsequent days. In contrast, HSEs behave in the opposite way: When their insecurities are heightened, they perceive greater love from their partners, have more generous perceptions of them, and draw closer. As one would expect, LSEs' customary reactions are more destructive to the relationship than are HSEs'. In several studies, such patterns predicted declines in the partner's satisfaction with the relationship. LSEs may bring about, then, the very rejection that they fear. In contrast, HSEs' more constructive responses are more likely to resolve the issues that gave rise to their insecurities in the first place.

In summary, although few studies have directly and rigorously examined the effects of self-esteem on relationship quality, many rigorous studies have identified self-esteem differences in important perceptions and behaviors—perceptions and behaviors that have been shown to predict relationship quality. These findings strongly point to several ways in which high self-esteem can contribute to happy relationships and low self-esteem can contribute to unhappy ones. As was true for relationship initiation, then, the popular wisdom that loving oneself helps one to love others seems highly plausible.

SELF-EVALUATION MAINTENANCE MODEL

How do people know who they are? Social psychologists have long noted that self-knowledge derives from social comparison processes. That is, people define their attributes based on how they perform relative to others. This perspective informs how self-identity is developed. Taken alone, social comparison perspectives might lead to the assumption that people strive to outperform others. This contrasts with research investigating an alternative perspective, the need to belong. How do self-identity and belongingness needs coexist? This entry reviews Abraham Tesser's self-evaluation maintenance (SEM) model, a framework for understanding the interaction of these two fundamental drives.

The SEM model holds that individuals are interested in upholding a positive self-evaluation. People want to feel good about themselves. According to the model, three mechanisms interact to predict self-evaluation. These mechanisms are performance, relevance (or importance) of the domain to the person, and closeness. Generally, people feel good when they outperform others and feel poorly when outperformed. This reaction is not always true. How people react depends on the relevance of the domain they are competing on, or how important the domain is to them.

In the first example, Lilly and Oliver have a dinner party. Both cook. The guests seem to like

Oliver's food but do not respond as positively to Lilly's. Lilly is outperformed on a dimension important to her. She feels bad. In the SEM model, this is an example of negative comparison. Oliver has outperformed Lilly on a dimension important to him. He feels positive, or has positive comparison.

Suppose that Oliver, a technology consultant, gets a contract for the development of a new gadget. He has outperformed Lilly. Technology is not highly relevant to Lilly. She is unlikely to feel bad. In fact, she might feel pleased to be associated with Oliver and his good performance or positive reflection. In contrast, imagine if Lilly, a medical doctor, received an award for implementing a new computer-based patient monitoring system at work. She has outperformed Oliver in a domain that is not relevant to her but is to Oliver. Her self-evaluation would be negatively affected by this knowledge.

The outcomes of these scenarios depend on how close Lilly and Oliver are. According to the SEM model, closeness intensifies reactions. Research supports this theory. Reactions are stronger when people are put in performance situations with close others versus distant others.

What do these results mean for close relationships? For instance, are people more likely to have intense emotional reactions in close relationships? Research on the SEM Model has shown that people are more likely to report negative affect when outperformed by a close other compared to a distant other and when the domain is important to the person. Negative communication in close relationships also follows SEM model predictions. One study looked at both partners' perspectives. The first condition was the most positive. The domain was relevant to the outperforming partner but not relevant to the outperformed partner. Both felt positively about the performance outcome. In the intermediate condition, the domain was relevant to both partners. The outperforming one felt positively; the outperformed individual felt poorly. In the third condition, the domain was relevant to the outperformed partner and was not relevant to the outperforming partner. Both partners experienced negative self-evaluation. Couples in the third condition expressed the highest levels of negative communication, intermediate levels of negative communication in the second condition, and low levels in the first condition.

Clearly, SEM processes can destabilize relationship balance and happiness. Negative outcomes are not inevitable, however. The SEM model posits that people can make adjustments on any of the three domains in an attempt to uphold a positive self-evaluation. An individual may reduce a negative affective reaction by changing the perceived relevance of the domain in question (“Oh well, that particular kind of technological adaptation isn’t that important to me”), by making downward distortions of the other’s performance (“Anybody could implement those kinds of simple technology programs”), or by changing closeness (“I didn’t really want to stay in this relationship anyway”). These adjustments reduce the threat of the performance outcome and reinstate a stable emotional state.

In close relationships, the SEM model suggests that people will make increasingly complex adjustments in an effort to sustain both closeness and positive self-evaluation. In one study, following performance feedback, partners made adjustments in the relevance of relationship-enhancing domains. When outperformed, people increased the perceived relevance of the domain to the partner and decreased the relevance of the domain to themselves. For example, if Lilly was outperformed by Oliver on cooking, she might have said, “Oh well, cooking has always been extremely important to Oliver. I like to do it, but wouldn’t say it’s the most important thing I do.” As relationships become more committed, these types of adjustments become increasingly and iteratively refined so that people create specific niches within the relationship where they can both perform well and sustain their self-identities while also maintaining closeness. Oliver and Lilly, for instance, may come to a point where Lilly defines herself as an excellent baker and Oliver defines himself as a great chef.

These refined adjustments also influence affect. It might be rude to gloat if outperforming a partner on a dimension relevant to both persons. Likewise, if a partner outperformed the other on a dimension relevant to the other person and that person became bitter, this might pose problems for the relationship. Research shows that in committed relationships, people attenuate their responses in relationship-enhancing ways. They are more empathic and less bitter. These patterns occur only

in committed relationships and not in early, dating relationships, suggesting that these reactions develop over time.

In sum, SEM processes provide a useful framework for understanding how it is possible to simultaneously honor both self-identity and belongingness needs. As relationships increase in commitment, the SEM model predicts that partners will make increasingly refined adjustments in their self-definitions as they negotiate how to retain closeness and relationship happiness while upholding self-identity.

SELF-EXPANSION MODEL

The Self-Expansion Model is a conceptual framework that attempts to describe how people think, feel, and act in close relationships. Originally proposed in 1986 by Arthur Aron and Elaine N. Aron, it was inspired by an integration of Eastern psychology’s views (mostly Vedanta) on the evolution of the self and the nature of love with contemporary Western psychological work on motivation and cognition. In the years since, it has generated a large body of research while undergoing continued theoretical refinement.

The Self-Expansion Model is based on two fundamental ideas:

1. *Self-expansion motivation*: People seek to expand themselves by expanding their ability to accomplish their goals, leading to ever greater goals or life purposes. This basic motive has been described in Western psychology as exploration, effectance, curiosity, competence, or self-improvement.
2. *Inclusion of close others in the self*: One way in which people expand themselves is by including others in themselves through close relationships in which inevitably the other's resources, perspectives, and identities are experienced, to some extent, as one's own.

This entry describes each of these two ideas in more detail along with representative research related to each in the context of close relationships; it briefly concludes with examples of research and applications generated by the model in areas other than close relationships.

Self-Expansion Motivation

According to the model, a central human motive is the desire to expand the self—to acquire whatever skills or resources that will enhance one's ability to accomplish one's always evolving goals. Rapid expansion of the self, as often occurs when forming a new romantic relationship (or learning a sport or exploring a new, interesting place), results in high levels of excited positive feelings. Rapid de-expansion of the self, as might occur with the sudden death of a spouse (or the onset of a physical handicap or being imprisoned), leads to intense negative feelings.

For a more concrete idea of what is meant by self-expansion in a close relationship, consider three items on a questionnaire developed by Gary Lewandowski and A. Aron: "How much does your partner provide a source of exciting experiences?" "How much has knowing your partner made you a better person?" and "How much do you see your partner as a way to expand your own capabilities?"

On the surface, a self-expansion that involves including the other's resources in one's self may sound like the height of selfishness, as if one is taking resources from the other in order to accomplish one's own goals. But it is not, for several reasons. First, the motivation is usually not conscious. Second, when one is self-expanding by

including another in the self, the other is generally having the same experience so that, as discussed below, their identities come to overlap. Thus, third, one is not taking from another, or even sharing resources with another, but rather in an important sense the other's resources are experienced as one's own because there is no longer an other person. The two persons are expanding to include each other so that they are becoming the same identity, with the same needs. For many purposes, they do act as separate persons and view each other that way, but they can also act as if they have fused their identities.

Self-expansion motivation affects initial attraction in interesting ways. It is well established that in the context of romantic and friendship relationships similarity attracts. The self-expansion model explains this attraction is due in part to the fact that any relationship expands the self, and people are aware that it is easiest to develop a relationship with someone who is similar. However, the model also proposes what has been supported by recent experiments: If one thinks it is likely that one will be able to develop a relationship with a particular person, one will be most attracted to the person if that person is different from oneself (e.g., different interests or ethnic backgrounds). This is because people who are different offer greater opportunities for self-expansion.

Is there evidence that developing a new relationship does expand one's self? In one study, undergraduates were tested five times over a 10-week period, and at each testing, they answered questions about what had happened since the last testing. Buried among these were questions about whether they had fallen in love. At each testing they also did a 3-minute listing of words or phrases in answer to "Who are you today?" For those who fell in love, there were more words and more different aspects of the self listed after falling in love. Another study found that for those who fell in love there was a substantial increase from before to after in self-efficacy, the sense of being able to accomplish one's goals. Looking at this yet another way, but in reverse, Lewandowski and his colleagues focused on relationship breakup. They found that the more expansion a relationship had provided before the breakup, the greater the contraction of the self after the relationship's dissolution—as indicated by both decreases in the

number of “Who are you today?” listings and by lower scores on a measure of self-efficacy.

Self-expansion motivation also explains the typical decline in satisfaction in a romantic relationship after the honeymoon period—plus it suggests how this decline might be averted. When two people begin a relationship, there is often an initial, exhilarating period in which they spend hours talking, engaging in intense or sometimes risky self-disclosure; thus, the partners are expanding their selves at a rapid rate. But once they know each other fairly well, opportunities for further rapid expansion of this sort inevitably decrease. On the other hand, even in a long-established relationship, if a couple is able to do self-expanding (novel, challenging, exciting) activities together, the resulting rapid self-expansion can become linked with the relationship and thus keep it vigorous.

In one series of laboratory experiments, couples’ marital happiness was assessed before and after doing an interactive task. Some couples were assigned a self-expanding, highly novel and challenging task; others, something more mundane. (In the expanding activity, the two were tied together on one side at wrists and ankles and then had to crawl together on mats and climb over a barrier while pushing a foam cylinder with their heads. This was timed, and the couple received a prize if they beat a time limit, but the situation was rigged so that they almost made it within the time limit on the first two tries and then just barely make it on the third try. The mundane activity was much less challenging and exciting.) Couples in the expanding-activity condition experienced a greater increase in love and relationship satisfaction.

In a study outside the laboratory, one group of married couples was assigned to spend an hour and a half each week doing an activity they chose from a list of highly exciting but only moderately pleasant activities; another group chose from a list of only moderately exciting but highly pleasant activities. The couples doing the highly exciting activities showed a greater increase in marital satisfaction over the 10 weeks of the study.

Yet another line of research emerging from the self-expansion model focuses on passionate love as a goal-oriented motivational state, an intense desire to expand the self by forming a close relationship with a particular other person, rather than on love as a specific emotion in its own right,

such as sadness or happiness. In a series of 10 studies, Bianca Acevedo and her colleagues found that, as with other goal-oriented states such as hunger, people report diverse emotions when they experience the drive state of romantic love. Also, when they do not spontaneously feel the spark of passionate love for someone, they have a much harder time producing this desire than they do producing specific emotions.

Using a brain-scan (functional Magnetic Resonance Imagery [fMRI]) approach to get at this motivation-versus-emotion issue, A. Aron and colleagues recruited participants who were intensely in love. When these participants viewed a picture of their partners, they showed consistent brain activation in regions associated with motivation and reward, consistent with the idea that romantic love is a motivational state. There were also brain activations in areas associated with emotions, but these were in different emotion areas for different participants, consistent with the idea that romantic love is highly emotional, but leads to different emotions according to the particular circumstances.

Inclusion of Close Others in the Self

According to the self-expansion model, the general motivation to expand the self often leads to a desire to enter and maintain a particular close relationship because close relationships are an especially satisfying and human means to self-expansion. Each includes, to some extent, the other’s resources, perspectives, and identities.

Resources

Seeing oneself as including a partner’s resources (e.g., knowledge and material and social assets) means seeing oneself as having access to them, as if to some extent they were one’s own (e.g., as if one were actually thinking “I know I can do this because my partner knows and will show me how”). Similarly, when the other is included in one’s self, as if the identities have merged, to some extent what happens to a close other happens to oneself. Thus, it is not surprising what occurred in a study in which participants made a series of decisions distributing gains and losses of money to self, best friend, or another person, under conditions in

which the friend and other person would not know who was responsible for the decisions. The participants allocated to their best friend about what they allocated to themselves, while they allocated consistently less to the nonclose other. Indeed, many studies have now found that people react to a close other's gains and losses as if they were their own.

Perspectives

Including another in one's self also refers to experiencing the world from the other's point of view. For example, this kind of inclusion shows up as the exception to the well-established tendency of people to see their own actions as being caused by the situation ("I'm generally honest, but in this situation I had to lie"), but another person's as caused by the kind of person he or she is ("He's dishonest"). Studies based on the self-expansion model have shown that people are likely to understand why close others do things in the same way as they understand why they do things themselves (i.e., giving more weight to the situation).

Similarly, seeing the world from a close other's perspective means that if people are asked to form an image of themselves or of someone else interacting with various objects (e.g., riding a donkey, setting a clock), when asked later, they forget more of the objects with which they formed images of themselves interacting; the same forgetting occurred

when they have formed images of close others interacting with objects. This occurs for objects imaged with the self because the self is a background to experience so that images that involve the self are less vivid and memorable. According to the self-expansion model, this also occurs for objects imaged with close others because close others are treated like the self and thus also serve as a background to experience.

Identities

Identity refers to the personal characteristics and memories that make people who they are. The self-expansion model emphasizes that people easily confuse their own characteristics or memories with those of close others because close others are actually part of the very makeup of the self. This has been found in a variety of studies using methods such as reaction time, memory, picture recognition, and brain scanning. One example is a procedure in which people are shown a series of personality traits, one at a time. For each trait, they press either a "Me" button if the trait is true of the self or a "Not-Me" button if it is false of the self. The important finding is that people are consistently slower at pressing these buttons for traits on which what is true or false of the self does not match what is true or false of a close other. The idea is that if something is true of oneself but not of one's partner, because one's partner is part of

Figure 1 The Inclusion of Other in the Self (IOS) Scale

Source: From Aron, A., Aron, E. N., & Smollan, D. (1992). Inclusion of Other in the Self Scale and the structure of interpersonal closeness. *Journal of Personality and Social Psychology*, 63, 596–612. Used by permission of the author.

who one is, then in a sense it is also not true of oneself. Thus it takes people about 65 milliseconds longer to say it is true of oneself. This result has been replicated in many different laboratories and is stronger the closer the two people are.

Finally, an influential methodological development from the self-expansion model is the Inclusion of Other in the Self (IOS) Scale, shown in Figure 1. When people select a pair of circles with a great deal of overlap, it means they feel highly interconnected with the other person. The IOS Scale has been widely used and correlates well with other, less obvious verbal measures of closeness. For example, those who rate a relationship as very overlapping on the scale have a stronger effect on the Me and Not-Me reaction time procedure. As another example, they use more plural pronouns (such as *we* and *us*) when writing about their relationship. Perhaps this measure has been so successful because the metaphor of overlapping circles corresponds to how people actually see themselves in close relationships.

Beyond Close Relationships

The self-expansion model has been applied in a variety of unexpected ways in order to understand the paradox of altruism (why people would ever be motivated to do something that provides no benefits to the self) and to understand people's relationships to their social groups, communities, the environment, God, and even commercial products. It has been especially productive in the context of inter-group relations, where work by the Arons in collaboration with Stephen Wright, Jennifer Eberhardt, Kristin Davies, and others has led to new interventions to reduce prejudice. One example is as a 4-hour procedure that systematically creates closeness between pairs of individuals from different groups (e.g., different ethnic groups, rival political groups, police and community). The result is more positive attitudes towards the group of one's partner. The principle here is that creating a close relationship with a person leads to including the person in the self, and thus to including the person's group identity in the self. This reduces prejudice towards the entire group of the other person—a promising development for a strife-torn world.

SELF-MONITORING AND RELATIONSHIPS

Self-monitoring is a theory of the regulation and control of expressive behaviors and image projection. Certain individuals, high self-monitors, out of a concern for cultivating images and status, are particularly attuned to contextual and social cues. The self-presentational behavior of high self-monitors is flexible and tailored to their situations. A typical high self-monitor would endorse

the following item from the Self-Monitoring Scale: "In different situations and with different people, I often act like very different persons." In contrast, low self-monitors are less responsive to social context and possess smaller repertoires of self-presentational skills. Low self-monitors value consistency between expressive behaviors and inner attitudes and emotions. A typical low self-monitor would endorse the item, "I have trouble changing my behavior to suit different people and different situations." Self-monitoring propensities are related to a wide range of behaviors and life domains, including control of emotional expression, consistency between attitudes and behaviors, organizational behavior, and as discussed in this entry, interpersonal relationships. This entry reviews the general concept of self-monitoring and discusses its relevance to human relationships.

Self-monitoring orientations have profound implications for interpersonal relationships. Just as high self-monitors focus on images and appearances in their enactment of expressive behaviors, they also focus on external qualities of friends and romantic partners, a focus which facilitates the creation of social worlds that allow them to play many roles with complementary casts of characters. Similarly, low self-monitors are not only attuned to their own dispositions and attitudes but are also attuned to internal qualities of others, a sensitivity which facilitates the creation of social worlds that allow them to be themselves.

Friendships

High and low self-monitors approach friendships in very different ways. High self-monitors emphasize shared activities and place little emphasis on nurturance and general compatibility. They have relatively superficial relationships that are limited to specific contexts. In contrast, low self-monitors strive for general compatibility and shared values. They have relatively deep and nurturing relationships that generalize across contexts and activities and are attracted to potential friends with similar attitudes, whereas high self-monitors are attracted to those with similar activity preferences.

Moreover, the social worlds of high self-monitors are more segmented than those of low self-monitors.

That is, high self-monitors are likely to choose specific people for specific activities, and their enjoyment is dependent on matching the right person with the right activity. In contrast, low self-monitors have relatively homogeneous social worlds in which they engage in multiple activities with a few people, and their enjoyment does not depend on matching people with activities. Further, given the choice of doing an activity with either a moderately liked friend who is good at the activity or a highly liked friend who is not good at the activity, high self-monitors choose the skilled partner, whereas low self-monitors choose the liked partner. These findings suggest that high self-monitors desire friends who facilitate the enactment of particular roles and allow them to cultivate desired images, whereas low self-monitors desire friendships based on liking and similarity, allowing them to be who they are with nurturing others.

Romantic Relationships

Self-monitoring is also involved in romantic relationships. In choosing dating partners, high self-monitors pay particular attention to the attractiveness of potential dates and prefer an attractive partner with an undesirable personality to an unattractive partner with a desirable personality. In contrast, low self-monitors attend to personality and attitudinal attributes of potential dates and prefer an unattractive partner with a desirable personality to an attractive partner with an undesirable personality. Moreover, high self-monitors express a greater desire for attractiveness, sex appeal, and social status in potential dating partners, whereas low self-monitors express a greater desire for similar values, honesty, and loyalty in potential dating partners. Thus, just as in friendships, high self-monitors focus on the external qualities, and low self-monitors focus on the internal qualities of romantic partners.

The functioning of low and high self-monitors in romantic relationships reflects two distinct orientations. Low self-monitors have a committed and restricted sociosexual orientation. In exclusive dating relationships, low self-monitors have relatively long relationships, are unwilling to date alternative partners, and report that they have made greater time and emotional investment in

their relationships than their partners. In addition, low self-monitors view love as a psychologically close and emotionally intense undertaking or as a quest to find a compatible life partner; they also believe there is only one person ideally suited to them. High self-monitors, in contrast, have an unrestricted sociosexual orientation. They are more willing to play the field of potential partners and report that their partners typically invest more in their relationships than they do. They have exclusive dating partners for relatively short periods of time and if not involved in an exclusive relationship, date many people. High self-monitors view love as a social game and believe there may be more than one person whom they can love.

These divergent orientations also manifest themselves in marital satisfaction and functioning. Low self-monitors, relative to high self-monitors, report greater consensus in matters such as finances and religion, greater partner engagement in positive activities, greater investment of resources, more commitment, more intimacy, and greater marital satisfaction. Moreover, currently married high self-monitors are more likely than low self-monitors to have been divorced.

Together, these findings show a distinct pattern. High self-monitors, in the service of role enactment and image cultivation, are attuned to the appearances of friends and romantic partners, whereas low self-monitors, in the service of intimacy and authenticity, are attuned to the inner attributes of friends and romantic partners. Although much is known about the impact of self-monitoring in relationships, many areas of interest—relationship maintenance, patterns of influence, the development of relationships over time—remain to be explored.

SELF-PRESENTATION

Self-presentation is the goal-directed activity of controlling information about oneself to influence the impressions conveyed to audiences. Through self-presentation, people construct and maintain identities that allow them to relate to others and accomplish goals that are served by appearing to be a certain type of person. People try to shape impressions of all aspects of their lives (e.g., roles, abilities, personalities, motives, attitudes, histories, relationships). The study of self-presentation involves examining (a) how people, as agents, try to influence how they are regarded and treated by others and (b) how people, as targets, respond to the self-presentations of others. Given the wide range of self-presentation research, this entry highlights implications for relationships.

The idea of self-presentation can be traced to antiquity and was exemplified during Elizabethan times by Shakespeare's conclusion that the world is a stage and people are like actors. In 1959, Erving Goffman discussed the theatrical elements of social behavior; his seminal observations captured the interest of social scientists. Early research, beginning in the 1960s, focused on people's willingness to exaggerate or misrepresent information to accomplish selfish goals such as gaining power and approval, as illustrated by work on ingratiation. Today, the scope of self-presentation research is much broader. Research indicates that self-presentation can be consciously controlled or automatic, deceptive or truthful, and guided by positive or negative motives (e.g., to help or to exploit others). As such, many researchers regard self-presentation as a fundamental characteristic of all social behavior and not just as a specific form of social behavior (e.g., one that is inauthentic, self-conscious, and power oriented).

Dimensions of Self-Presentation

Self-presentation varies in the extent to which it involves automatic versus controlled processes. Much self-presentation reflects habitual action sequences that can be activated outside of awareness and unfold without cognitive effort. Mannerisms, expressions, and affections that prove useful in making desired impressions become habitual with repeated practice and can be triggered by appropriate social cues. Automatic self-presentation predominates in routine situations where little is at stake (e.g., relaxing with friends). Controlled self-presentation, which involves conscious monitoring and regulation, occurs under challenging conditions, as when the other is significant (e.g., an important first date), the situation is important (e.g., a job interview), the desired image is not routine (e.g., differing from self-beliefs), and the actor is uncertain about the type of impression that might be created. On these occasions, people may report feeling on stage and apprehensive about evaluation. Because it can be automatic, controlled, or a mix, self-presentation is relevant at all stages of relationships. Long-term relationships can even be refreshed when people break routines, attend more closely to their partners' preferences, and consciously try to make a good impression, thereby avoiding partners' complaints of being taken for granted.

Self-presentation also varies in how much it corresponds with the actor's private self-beliefs. People often attempt to convey an accurate self-portrait, one that permits self-verifying feedback and a feeling of authenticity. Usually this portrait reflects a slightly glorified self-view but one that is genuinely believed by the actor to be true. On other occasions, people exaggerate or even mislead others to accomplish their goals. People are more likely to try to impress others when (a) the others are more significant (attractive, powerful, expert), (b) there is more to be gained (or lost) by influencing the audience (e.g., job interview), (c) information that is inconsistent with the self-presentation can be hidden from the audience, and (d) relevant prior self-beliefs are weak, inaccessible, or unimportant. People's desire to impress others can even put them at risk for health problems (e.g., eating disorders, sun tanning, risky sex, smoking). Self-presentations

initially intended to create a desired impact on others can change the actor's own self-beliefs, as when people publicly play a new role and later change their self-beliefs to become more consistent with the role. Changes produced by public self-presentations can carry over to new settings with different audiences.

There are individual differences in the willingness and ability to convey an inauthentic self-portrait. Self-monitoring, a frequently researched personality variable, reflects individual differences in tendencies to use, or avoid, activities that involve inauthenticity and social appearances. Inner-directed people are more likely to rely on their private beliefs and values to guide their self-presentations, whereas outer-directed people conform more to the expectations of others and try to be the type of person others prefer. Self-presentational skills (acting and role-taking abilities) are associated with convincing performances regardless of whether the goal is to deceive or be authentic.

Remedying Threats

Self-presentation is also used to protect one's identity and maintain stability in relationships when confronting failures and transgressions. People then engage in remedial activities that fall into three broad categories. Accountability avoidance strategies allow people to postpone, avoid, or escape from threats (e.g., keeping transgressions secret). Accounting strategies are self-serving explanations, which permit the actor to make excuses that try to minimize personal responsibility (e.g., "It wasn't my fault") or justifications that try to change the appearance of the event and its consequences (e.g., "I did it for your own good"). Apology strategies admit blameworthiness and regret, affirm the value of the rules that were violated, and extend promises of better future behavior. Accounts and apologies that seem sincere reduce the negative repercussions for the actor, resulting in less condemnation, negative impressions, and punishment. When hurtful acts occur in relationships, these strategies permit people to try to restore the relationship to its pre-transgression status while seeking understanding or forgiveness.

Mutual Activities

People are not on their own when it comes to constructing and protecting desired identities. People often work as teams, as in the case of husband and wife who act in concert to project their family image. Even when not part of a formal team, people help one another to construct and protect their identities. Norms of politeness prescribe that people have a duty to respect the “faces” of others. Research also indicates that people are especially helpful to those they like by strategically bolstering and protecting the latter’s desired identities. For example, people will strategically help their friends by describing them in ways that are expected to make a good impression on attractive (but not unattractive) others. Self-presentations are performances and are shaped by their expected consequences for self and others.

SELF-REGULATION IN RELATIONSHIPS

Self-regulation refers to the self-exerting control over its own responses. Regulation means change, as in changing one’s thoughts, feelings, or behaviors, but it also involves an effort to bring something into agreement with various standards, such as goals, norms, or expectations.

Human beings engage in many acts and forms of self-regulation. In general, self-regulation is a

potentially powerful and multiple useful set of ways people can alter themselves and their responses so as to improve their relationship outcomes. This entry describes how self-regulation is relevant to close relationships.

Understanding Self-Regulation

Self-regulation is related to familiar concepts such as self-control and self-discipline. It makes behavior considerably more flexible because one does not have to act on just one’s first impulse. Current speculations are that self-regulation evolved to facilitate two important patterns of behavior. First, it permitted improvements in social life because individual animals were able to alter their behavior to the demands and opportunities of the group. Second, it enabled humans to resist temptations in the immediate present so as to pursue delayed but ultimately beneficial outcomes. Clearly, both of these patterns of behavior can be useful for improving relationships. Changing one’s behavior to meet the requirements of others is highly useful for a long-term relationship or marriage. For example, people may seek to live up to the expectations of others or learn to suppress some of their impulses in order to abide by agreements and commitments that are useful for getting along with one’s partner.

By the same token, resisting immediate temptations for the sake of long-term benefits is crucial to the success of long-term relationships. One may, for example, hold one’s tongue rather than giving in to the impulse to say something hurtful. Indeed, relationships may benefit from regulating behavior that is not directed at the partner. Many marriages have suffered conflict and stress over money, for example, and if one person spends money impulsively, both of them may later have to deal with debt or the inability to afford important things.

Self-regulation can involve both states and traits. The trait aspect is reflected in stable, consistent patterns of self-control. For example, some people generally behave in a more controlled, disciplined, consistent manner, while others behave in a more spontaneous, impulsive, uncontrolled manner. State fluctuations in self-control can involve various factors, but one central issue is that each person’s

willpower appears to be limited and so when it is expended on one act of self-regulation, afterward there may be less available to use for other challenges. This so-called state of ego depletion refers to the condition in which the person's willpower is temporarily reduced, usually because the person has expended it recently on other acts. Self-control may also fluctuate with changes in emotional, mood, and motivational states. Alcohol intoxication is a particularly important state that often contributes to relationship problems, and one way that alcohol causes problems is that it impairs self-regulation. Such times present a risk for behavior that could be harmful to relationships.

In particular, modern life often sees relationship partners engaged in careers and coping with many stressors. They may come home exhausted and depleted from these. Research indicates that self-regulation tends to deteriorate as the day wears on, as people use up their resources that they built up from a good night's sleep. If their time together occurs mainly in the evenings when both have depleted their capacity for self-regulation, they may treat each other in less than optimal ways. Some marital therapists advise struggling couples to save energy for each other rather than putting it all into work and other separate challenges.

High Trait Self-Control Strengthens Relationships

People with poor self-control may be charming and attractive because they are spontaneous, impulsive, and fun loving. But what happens in long-term relationships? Should they marry each other or find someone with better self-control? Social psychologists have repeatedly found that similarity leads to attraction and bodes well for long-term relationship success. Yet similarity in self-control is not what produces the best relationship outcomes. Instead, the sum total of the two partners' self-control levels matters: The more total self-control the two partners had between them, the better the relationship fared. The benefits of self-control were evident in current happiness and satisfaction with the relationship as well as in long-term stability (i.e., staying together vs. breaking up).

Why is Self-Control Beneficial?

Multiple studies have investigated why good self-regulation is beneficial for relationships. One important benefit involves accommodating oneself to the partner. Accommodation, by definition, means altering the self to fit better with the partner. If both partners do this, they are likely to get along much better than if either (or both) persists in doing things that the other cannot abide or that are known to have destructive effects on relationships.

A particular focus of accommodation involves how the person responds when the partner does something hurtful or offensive. Research shows that when one person responds destructively to the other's destructive behavior, a vicious circle of escalating antagonism develops that can seriously damage the relationship and that is difficult to reverse. People with good self-control are more able to prevent or break this circle than are people with poor self-control. This applies also to state fluctuations: During the state of ego depletion, people are more likely to respond destructively when the partner does something destructive.

Self-regulation also benefits relationships by helping people resist temptations and stay committed. When self-control is low or resources are depleted, people begin showing more interest in other attractive people they meet, ones who could potentially lure them away from their current relationship. It appears that one contributor to a healthy and strong relationship is that partners regulate their attention so as to avoid paying attention to such external temptations.

Probably all relationships encounter setbacks and stressors at times. When joint efforts meet with failure or frustration, partners may be tempted to blame each other, according to a common tendency known as the self-serving bias. However, blaming each other is likely to be divisive and to put further strain on the relationship. With good self-regulation, people tend to shield their partners from blame, even at the cost of taking extra blame on themselves. However, when self-regulation is impaired, including in the state of ego depletion, people start to blame their partners. Very likely emotional distress and alcohol intoxication contribute to problems in the same way.

Undoubtedly physical violence is an important contributor to some of the worst relationship

outcomes. When frustrated or upset, some people lash out physically (or in other ways) at their partners. Self-regulation helps people resist these destructive impulses. That is because aggressive impulses often arise in the normal and natural course of events, when people are frustrated with each other or conflicts arise. Most people manage quite effectively to restrain themselves and hold back from acting on or expressing these aggressive feelings, but when self-regulation is impaired or low, the restraints are weakened. Therefore, when self-regulation is poor (again, such as during ego depletion), people are more likely to inflict physical violence on their partners.

Effects of Relationships on Self-Regulation

The capacity for self-regulation is not exclusively devoted to relationship behavior in most cases. Because willpower is limited, a person must essentially decide whether to spend more of it on interacting with the partner or on dealing with other events and challenges in life, such as work and study. The limits of willpower suggest that the more one puts into the relationship, the less remains for other activities.

So-called high maintenance relationships are relevant here. The term comes from cars and other machines, some of which require a higher-than-usual amount of care, effort, and expense. Applied to relationships, the category of high-maintenance refers to ones that demand a relatively high amount of effort, attention, and sacrifice in order to be successful. These are not necessarily harmful or problematic relationships. Indeed, some high-maintenance partners may offer a great deal of pleasure and satisfaction, provided they receive the investments they require and that the other person then offers something valuable in return for the investments and efforts.

Recent research suggests that high-maintenance interactions deplete self-regulatory resources. That is, interacting with a partner who is demanding and who presents multiple potential problems can drain a person's willpower, leaving the person less able to perform well in other contexts or meet other challenges. It seems likely that high-maintenance relationships would have similar effects. To illustrate, a high-maintenance relationship

partner might be someone who demands constant attention or praise, who is easily angered and therefore must be spoken to with great care and positivity, who expects others to stop what they are doing whenever the person wants their attention, who has very detailed expectations about how others will behave or about how the joint living space will be kept by others, or who insists on always being right and will not tolerate disagreements. It is of course entirely possible to live happily ever after with such a partner, but it will not be easy, and one will need considerable self-regulation to keep that person happy.

Conversely, anecdotal impressions and scattered evidence suggest that some relationships and interactions can have the opposite effect of actually strengthening the person and improving his or her capacity to self-regulate in response to other challenges. A full-fledged test of this hypothesis is yet to be found in the literature, partly because it presents a variety of methodological and possibly ethical challenges, but if it is true it would provide an important insight into how people may benefit from a good, supportive attachment.

SELF-VERIFICATION

Self-Verification Theory suggests that once people develop firmly held beliefs about themselves, they come to prefer that others see them as they see themselves. For example, just as those who see themselves as relatively dominant want others to see them as dominant, so too do those who see themselves as relatively submissive want others to recognize them as submissive. This motive seems to influence relationship quality in that people who are more satisfied when their partners confirm their self-views.

Developed by William Swann, the theory holds that among people with positive self-views, the desire for self-verification works hand in hand with another important motive, the desire for self-enhancement. That is, if the self-view is positive, both the desire for self-verification and self-enhancement will compel people to seek positive feedback. If the self-view is negative, however, the two motives conflict. For those who perceive themselves as disorganized, for example, the desire for self-verification will encourage them to seek evidence that others perceive them as disorganized, but the desire for self-enhancement will motivate them to seek evidence that others perceive them as organized. Self-Verification Theory suggests that because stable self-views guide behavior and provide people with a sense of coherence, stable self-views become intrinsically desirable, and so people with negative self-views will sometimes prefer negative, confirming evaluations over positive but disconfirming ones.

Researchers have reported considerable support for Self-Verification Theory. In one study, participants with positive and negative self-views indicated whether they would prefer to interact with evaluators who had favorable or unfavorable impressions of them. Just as people with positive self-views preferred favorable partners, those with negative self-views preferred unfavorable partners. The latter finding showed that self-verification strivings may sometimes override positivity strivings.

The tendency for people with negative self-views to seek and embrace negative evaluations has emerged again and again using many procedural variations. Men and women are equally inclined to display this propensity, and it does not matter

whether the self-views refer to characteristics that are relatively immutable (e.g., intelligence) or changeable (e.g., diligence), whether the self-views happen to be highly specific (e.g., athleticism) or global (e.g., low self-esteem, worthlessness), or whether the self-views refer to the individual's personal qualities (e.g., emotionality) or group memberships (e.g., American). Furthermore, when people choose negative evaluators over positive ones, it is not merely to avoid disappointing the positive evaluators, for people with negative self-views choose negative partners even when the alternative is participating in a different experiment.

If people discover that their relationship partner sees them in a manner that challenges their self-view, Self-Verification Theory predicts that they will strive to change their partner's mind. They may, for example, behave in ways that make it clear to their partner that they have the qualities in question. If these efforts fail, people may decide to leave the relationship. That is, when college students find themselves with positive roommates, those with positive self-views prefer to stay, but those with negative self-views make plans to find another roommate. Similarly, just as married people with positive self-views are especially intimate with spouses who perceive them favorably, people with negative self-views withdraw from spouses who perceive them favorably—and in extreme cases, take steps to divorce them. This pattern does not emerge with dating couples, however, apparently because for dating partners, the first priority is keeping the relationship alive, and positive partners seem more apt to remain interested.

Self-Verification Theory posits that people should intensify their efforts to elicit self-confirmatory reactions when they suspect that others might be misconstruing them. In one study, participants who perceived themselves as either likable or dislikable learned that they would be interacting with people who probably found them to be either likable or dislikable. Overall, there was a tendency for participants to elicit reactions that confirmed their self-views. This tendency was exaggerated, however, when they believed that their evaluators' appraisals might disconfirm their self-conceptions. That is, when participants suspected that the evaluators' appraisals clashed with their self-views, they intensified their efforts to obtain self-verification.

Self-verification strivings theoretically bring stability to people's lives, making their experiences more coherent, orderly, and comprehensible than they would be otherwise. These processes are adaptive for most people because most people have positive self-views, and self-verification processes encourage and enable them to preserve these positive self-views. Self-verification processes are also adaptive for groups of people and society in general in that they make people predictable to one another, and this greases the wheels of social interaction. Not surprisingly, then, research indicates that when members of small groups receive self-verification from other group members, their commitment to the group increases and their performance improves. Self-verification processes seem to be especially useful in small groups composed of people from diverse backgrounds because they foster mutual understanding. Such understanding, in turn, encourages people to open up to their coworkers, which in turn generates creativity and superior performance on tasks that emphasize creative output.

Despite being adaptive for most people most of the time, self-verification strivings may have undesirable consequences for people with negative self-views. For example, self-verification strivings may cause people with negative self-views to gravitate toward partners who mistreat them, undermine their feelings of self-worth, or even abuse them. And if people with negative self-views seek therapy, returning home to a self-verifying partner may undo the progress that was made in therapy.

But if people with negative self-views sometimes sabotage themselves, it is not because they are masochistic or have no desire to be loved. In fact, even people with very low self-esteem want to be loved. What sets people with negative self-views apart is their ambivalence about the evaluations they receive. On the one hand, positive evaluations foster joy and warmth initially, but these feelings are soon chilled by incredulity. On the other hand, although negative evaluations may foster sadness that the truth could not be kinder, it will at least reassure them that they know themselves.

SEX AND LOVE

Sex and love are two fundamental aspects of being human. Love has many meanings but is restricted in this entry to romantic, passionate love. Sex refers to the thoughts, desires, emotions, and behaviors associated with sexual expression.

Love and sex; the words fit together naturally. This apparent truth was not always so, and even today relationship researchers do not necessarily agree on how sex and love fit together in people's lives. Love and marriage is another pairing that seems natural. However, for most of human history, marriages were arranged, and romantic love between partners was of minor concern. Today most people seem to link love and sex rather naturally. But questions such as how love and sex are linked and which of the two may be more important have generated much research and discussion, which is the primary focus of this entry.

One conceptual way to think about the link between love and sex, proposed by Arthur and Elaine Aron, is to imagine a continuum. One end of the continuum is labeled *love is really sex*, meaning that sex is the more important of the two. The other end is labeled *sex is really love*, meaning that love is more important than sex. People can place various combinations of love and sex at different points on the continuum.

The idea that love is really sex is most congenial to approaches that study the evolution of sex and love. Sexual drive in humans ensures procreation,

necessary for survival of the human species. In addition, theorists have argued that beyond sexual mating and reproduction, emotional bonding between mating pairs of early protohumans helped promote survival of offspring. Such bonding would involve each parent's concerns about the welfare of the other parent as well as of the offspring and would give a selective survival advantage for the offspring, as compared to mating pairs without such an emotional bond. In this way, passionate, romantic love slowly evolved as a part of sexual mating.

Considerable research has explored love and sex at other points on the continuum, where sex is less dominant and the two are more balanced in importance. For example, romantic love has been shown to be one motive for sexual activity, and in turn, sexual desire is intertwined with romantic love. Research has shown that college students clearly subscribe to the view that love and sex are both important and that whereas love may be more important initially in a relationship, sex provides a powerful way in which to express that love. In fact, other research found that people interviewed about their intimate relationships reported that sexual activity was one of their predominant ways of communicating their love to their partner. Indeed, considerable scholarly work has shown that passionate, romantic love and sexual activity are consistently linked together.

This balancing of love and sex is important not only for young people in relationships but also for people throughout the life span. Although sexual intercourse may decline with both the age of the partners and the length of a relationship, some type of physical expression of love typically continues to be present in most partnered relationships.

In surveying the Arons' continuum, it is important not only to look at the end, which says that love is really sex or the vast middle range of the continuum where love and sex are more or less balanced, but also to briefly consider the opposite end of the continuum, where sex is really love. Sex expresses love is a view commonly held, but it is not the same as sex is love. Certainly some people believe that love is all there is and that sex is simply intended for procreation. Although research has not shown this to be the dominant view, it should be acknowledged.

Why does research more often show that people believe that love and sex are linked—if not

balanced perfectly—rather than that sex is all there is or love is all there is? In other words, why are humans somewhere toward the middle of the Arons' continuum rather than at one of the two extremes? Perhaps the answer lies in the uneasy tension between people's evolved animal nature and their spiritual (i.e., cognitive, emotional, mystical) strivings, which creates a perpetual social dilemma.

People solve the dilemma by the creation of culture, the vast network of beliefs, attitudes, and material artifacts that enfold people as social beings (persons) and thereby attempt to integrate people's animal and spiritual natures. Cross-cultural research has found that romantic, passionate love may be a universal, something found in all societies. Anthropologists have also commented on the difficulties that any culture has in combining sex and love. Some cultures emphasize sex somewhat more, whereas other cultures emphasize love relatively more. Apparently the struggle to do so is itself a human universal. And as such, it is likely to continue.

Although the why of sex and love is interesting to scholars, the how of sex and love is more compelling to most of humanity. The ways in which people integrate sex and love—or fail to do so—have ever-present implications for people's quality of life.

SEX DIFFERENCES IN RELATIONSHIPS

The popular press would have people believe that women and men are radically different. John Gray uses the metaphor *Men Are From Mars, Women Are From Venus* to represent differences between women and men. Deborah Tannen is more modest in her claims, arguing that because boys and girls grow up in what are essentially different cultures, talk between women and men is cross-cultural communication. If women and men are as different as Gray and Tannen portray them, then one would expect heterosexual romantic relationships to be fraught with misunderstanding and miscommunication. Indeed, Gray's book, *Men Are From Mars, Women Are From Venus*, is filled with stereotypical differences between women and men and their resulting relational problems. If women and men are as different as Gray and Tannen portray them, their same-sex friendships also should reflect these differences. Indeed, in 1982 Paul Wright, a prominent friendship researcher, depicted women's friendships as face-to-face and men's friendships as side-by-side.

This entry briefly reviews research on psychological sex differences and then focuses on research on sex differences in intimacy in heterosexual romantic relationships and sex differences in intimacy in women's and men's same-sex friendships.

Psychological Sex Differences

Thousands of studies on psychological sex differences have been conducted, so many that a number

of meta-analyses of these analyses have been conducted. A meta-analysis is a quantitative summary of the results from multiple quantitative studies on a given topic (e.g., sex differences in self-disclosure). First, an effect size, which measures the magnitude of sex differences, is calculated for each study. A typical measure of effect size is d , which represents the difference between the means for women and men in standard deviation units. Then the average effect size across studies (weighted by sample size) is calculated and represents the difference between women and men across studies. Finally, a homogeneity statistic is used to determine whether the effect size varies across studies more than one would expect as a result of sampling error, in which case a search for moderator variables (e.g., variables that affect the size of effect size) may be conducted.

Jacob Cohen offered the following guidelines for interpreting d : $d = 0.20$ is small, $d = 0.50$ is moderate, and $d = 0.80$ is large. An effect size of $d = 0.2$ indicates that sex accounts for 1 percent of the variance in the dependent variable and represents an 85 percent overlap in the distributions of women and men on the dependent variable. Cohen labeled a value of $d = 0.5$ as a medium effect size. When $d = 0.5$, there is a 67 percent overlap in the distribution of women and men on the dependent variable. Cohen labeled a value of $d = 0.8$ as a large effect size. A large effect accounts for 14 percent of the variance in the dependent variable. When $d = 0.8$, there is a 53 percent overlap in the scores of women and men on the dependent variable. These associations are depicted in Figure 1.

Recently, Janet Hyde advanced the gender similarities hypothesis, which states that women and

Figure 1 Degree of Overlap Between Women and Men for Different Effect Sizes

men are similar on most, but not all, psychological variables. Hyde reviewed 46 meta-analyses on cognitive variables (e.g., cognitive abilities), verbal and nonverbal communication (e.g., self-disclosure), social or personality variables (e.g., aggression, leadership), psychological well-being (e.g., self-esteem), and miscellaneous constructs (e.g., moral reasoning). The results of her review support the gender similarities hypothesis. She provided evidence that most psychological gender differences are in the close-to-zero or small range (78 percent), the major exceptions were aggression and some aspects of sexuality. Hyde also found that gender differences vary substantially in magnitude at different ages and depend on the context in which measurement occurs.

Hyde included several meta-analyses on sex differences in aggression. All of them found a moderate effect size for physical aggression and a small or smaller effect size for psychological or verbal aggression. John Archer recently conducted the most comprehensive meta-analysis on sex differences in aggression. Sex differences in aggression were highest for physical aggression (depending on how measured, they ranged from .39, self-report, to .84, peer report). Sex differences were smaller for verbal aggression (.14 observation to .51 peer report), which is consistent with results from previous meta-analyses. Sex differences in aggression were absent or in the female direction (women more aggressive than men) for indirect measures of aggression (-.74 observation to -.01 peer nomination). Archer also examined sex differences in trait anger to test whether sex differences in aggression may be the result of sex differences in tendency to experience anger and found no sex differences.

Although the studies included in Archer's meta-analysis of sex differences in aggression for non-U.S. samples were limited in number and geographical scope, they showed a pattern of sex differences that were similar to those for U.S. samples, indicating generalizability across cultures. Sex differences in physical aggression began at an early age (as shown in observational studies of children 1–6 years) with differences in verbal aggression developing soon afterward (as shown in self-report studies beginning at age 6). There was no evidence that differences in physical aggression increased with age, and there was no evidence that they increased at puberty (when testosterone levels

increase in men). There was some evidence that they peak between the ages of 20 and 30 (although samples of older participants were limited in number). Indirect aggression was greatest (moderate effect size) in teenage girls as measured by peer report, but this was not the case for self-report data. No differences in indirect aggression were found in young adults (but this only includes self-report measures, no peer report measures).

The largest psychological sex differences found in Hyde's review of meta-analyses involved measures of sexuality. A meta-analysis conducted by Mary Oliver and Janet Hyde found two large gender differences in sexuality, incidence of masturbation (men report masturbating more) and attitudes toward casual premarital sex (men report more liberal attitudes). There were small-to-moderate sex differences in attitudes toward premarital intercourse when the couple was engaged or in a committed relationship, attitudes toward extramarital sex, and sexual permissiveness (males more permissive in all three cases), anxiety or guilt about sex (females more anxious), endorsement of the double standard (more endorsement by women, but Oliver and Hyde point out that all these studies were conducted prior to 1978 and included samples < 20 years old), age of first intercourse (males younger), incidence of sexual intercourse, number of sexual partners, frequency of intercourse, and incidence of homosexual behavior (all higher for males). There were no sex differences in attitudes about homosexuality, attitudes about civil liberties for gay men and lesbians, sexual satisfaction, attitudes towards masturbation, incidence of kissing, and incidence of oral sex. Similarly, in a meta-analysis of sex differences in sexual arousal in response to sexual stimuli, Sarah Murnen and Mary Stockton found a small-to-moderate effect size with men reporting more arousal than women.

Almost all the significant effect sizes in the Oliver and Hyde meta-analysis showed gender differences becoming smaller over time. Examination of age trends was limited in that the sample consisted of adolescents and early adults; however, over this age range, in general, gender differences narrowed with age. The authors note a major limitation of the studies reviewed, that the data were collected by self-report methods rather than direct observations of behavior. It is possible that males have a tendency to exaggerate their sexual

experiences and that females may underreport their sexual experiences.

Sex differences in aggression and sexuality, as well as other sex differences, have been attributed primarily, but not exclusively, to one of two types of explanations, sociobiological explanations or sociocultural explanations. From a sociobiological perspective (labeled evolutionary psychology by David Buss), an individual's goal is reproductive success—that is, maximizing the number of genes passed on to the next generation. Because of the different parental investment of women and men in their offspring—women invest a great deal in individual offspring because they produce few eggs and are pregnant for 9 months, whereas, men have little investment in individual offspring because they do not get pregnant and they produce many sperm—different strategies for reproductive success have evolved for women and for men. Sexual selection is the assumption that members of the sex that have the least parental investment compete for access to the other sex. Thus, men, because they have less parental investment, should be more aggressive than women.

Sex differences in aggression may also be attributed to sociocultural differences. One sociological account of sex differences in aggression is Alice Eagly's Social Role Theory. According to Social Role Theory, sex differences in social behaviors arise from the historical division of labor into women's role as homemaker and men's role as breadwinner. As a result of the different social roles inhabited by women and men, gender roles emerge creating expectations about the characteristics and behaviors of women and men. Men are expected to fulfill the masculine gender role (aggressive, forceful, competitive, etc.), and women are expected to fulfill the feminine gender role (warm, affectionate, gentle, etc.). Boys learn that being aggressive is an appropriate behavior that fits their masculine role. Girls learn that aggressiveness is not appropriate to their gender role.

Sociobiological theory also can explain men's more liberal attitudes towards casual sex. Because sperm are plentiful, whereas eggs are rare, it makes evolutionary sense for men to inseminate many women but for women to be careful about not wasting their eggs. In addition, women are pregnant for 9 months, so at birth their parental investment greatly exceeds men's, leading women to

want to ensure the viability of their offspring by being highly selective in their choice of mate, favoring a mate who is willing and able to provide resources. Sociocultural theories also predict that women should hold more negative attitudes about casual sex than men. Neither evolutionary theory nor Social Role Theory predicts sex differences in masturbation.

Sociobiological accounts of sex differences are supported by results indicating early emergence of sex differences and generalizability of sex differences across cultures (differences are innate not learned). Sociocultural accounts of sex differences, including Social Role Theory, are supported by results indicating later emergence of sex differences and lack of generalizability of sex differences across cultures (sex differences are learned).

Sex Differences in Intimacy in Heterosexual Romantic Relationships

Intimacy plays a critical role in the development of interpersonal relationships, and intimacy is thought to be one of the major differences between women and men. To test whether there are sex differences in intimacy in heterosexual romantic relationships, Arlene Lundquist conducted a meta-analysis. The meta-analysis included 146 studies and yielded 257 independent effect sizes representing 40,600 participants.

Averaged over all effect sizes, d was .11, indicating that females were slightly more intimate than men. Type of intimacy significantly influenced average effect size in 8 of 10 categories of intimacy. Women showed greater intimacy on measures of overall intimacy, self-disclosure, and Erikson-theory-based intimacy instruments (an individual's capacity for intimacy based on Erikson's psychosocial stages), but the differences were small. Men showed greater intimacy on measures of sexual intimacy, marital-relationship satisfaction, and miscellaneous intimacy measures, but again, the differences were small. No differences were found for relationship characteristics or dimensions (e.g., trust, compassion, caring), love-passion, conflict resolution, and self-reported capacity for intimacy. All the effect sizes were heterogeneous (varied more across studies than expected due to chance) except for love-passion and conflict resolution.

The magnitude of gender differences declined over the years.

Lundquist concluded that gender differences in intimacy of romantic relationships are small and that all nine moderator variables studied—research design, data collection method, sample size, sex of researcher, type of intimacy, publication date, participant's age, marital status, and length of relationship—influenced effect size to some degree.

Sex Differences in Intimacy in Same-Sex Friendships

Men's and women's friendships have been portrayed in the popular and scholarly press as different. Men's friendships are portrayed as agentic or instrumental and women's friendships as communal: Female friends talk, while male friends do. There are no meta-analyses of sex differences in intimacy in same-sex friendships, but a number of friendship and relationship scholars have conducted narrative reviews of the research on sex differences in intimacy in same-sex friendships.

Beverly Fehr conducted a narrative review of research on sex differences in same-sex friendships. Fehr reviewed a wide range of variables conceptually defined as or related to intimacy. Fehr concluded that women's friendships are more intimate than men's. She specifically ruled out several rival hypotheses (men are as intimate as women, but only in the closest friendships; men are as intimate as women—they just do not like the word intimacy; men appear less intimate only because intimacy is defined in a female way; men and women have the same definition of intimacy, but different thresholds for what they consider intimate; men are less intimate, but they like it that way) and instead concluded that men's friendships are less intimate than women's friendships because men choose to be, even though they may not particularly like it that way. However, many of the studies reviewed found similarities and differences (indeed, Fehr, says that some support was found for both sides of the issue in virtually every case), and no effect sizes were reported for any of these differences.

Paul Wright conducted a narrative review of the research on sex differences in same-sex friendship, less comprehensive but more focused than Fehr's

review, and retracted his earlier depiction of women's friendships as face-to-face and men's friendships as side-by-side. Wright articulated four problems with the classical view of women's friendships as communal and men's friendships as agentic. First, friendship researchers highlight results showing sex differences and disregard or downplay results showing similarities. Second, agency is assessed in terms of shared activities, and it is assumed that activities are impersonal and instrumental. However, activities as well as talk vary widely in intimacy, and men may express intimacy more through activities than through talk. Third, the findings on friendship communality and agency are reported separately and in a noncontextualized manner. However, most friendship theories portray the development of friendship as marked by an increase in agency and communality, and most research on friendship development supports a positive correlation between agency and communality. Fourth, sex differences in friendship tend to be explained in dispositional terms (e.g., personality traits) to the exclusion of structural terms (e.g., roles); however structural, rather than dispositional, differences may explain differences in men's and women's friendships.

Wright reviewed research that indicates fundamental similarities in women's and men's friendships. First, women and men have similar conceptions of and value the same things in friendship. Second, although there is evidence that women's friendships are more communal than men's, there is no evidence that women's friendships are less agentic than men's. Third, both women and men most often engage in casual conversation (talk for talk's sake) rather than intimate conversation or activities in their same-sex friendships. Fourth, fun and relaxation are common and highly valued features of friendships for both women and men (a point also made by Fehr).

Wright also reviewed research indicating that although there are differences between women's and men's friendships, these differences are embedded in a larger context of similarities. First, using interviews and self-report measures, the typical talk versus activity differences are found (women talk, men do). However, female-male similarity is found in studies using diary techniques, and when more detailed self-report measures are used, women's reports of activities increase as do men's

reports of talk. In addition, female friends self-disclose more than male friends (although the differences are small), but neither sex self-discloses very much. Second, although women's friendships are more intimate than men's friendships, men's friendships are intimate, just not as intimate as those of women. Third, women's friendships are more holistic than men's friendships; however, holistic friendships are relatively rare for both men and women. Fourth, women's friendships are more satisfying than men's friendships; however, again, men's friendships are satisfying.

Although there is no definitive answer to the question of sex differences in personal relationships, when the results of meta-analyses are taken into account and when both similarities and differences are taken into account, it can be concluded that women and men, as well as women's and men's friendships, are more similar than different. The vast majority of problems experienced in heterosexual romantic relationships are most likely not the result of sex differences but are the result of two people who are different from one another (not because of sex) who are trying to live interdependent lives. Although women and men are different with respect to a few variables (such as aggression), women and men are similar or only show small differences with respect to a number of other variables (such as self-disclosure). And although there are some differences between women's and men's friendships, in particular, women's friendships are more intimate (communal) than men's, men's are still fairly intimate, and there are little or no differences in activities in women's and men's friendships. Perhaps it is time to stop perpetuating the myth that women and men are radically different. The truth of the matter may not be that men are from Mars and women are from Venus, but that women and men are from the same planet, Earth.

SEX IN ESTABLISHED RELATIONSHIPS

Most men and women will, at one point in their lives, enter a romantic relationship with someone. Sexuality often plays a part in bringing couples together (e.g., through the experience of sexual attraction), and for most it will continue to play a role after dating and courtship end and they enter a committed, established relationship. The importance of sexuality, however, will vary from individual to individual and from couple to couple. Unlike many other and mostly positive features of a close relationship, such as experiencing intimacy and receiving support, sexuality often brings both joys and challenges. It can contribute to fulfilling and lasting relationships, but it also can be a source of conflict, insecurity, and jealousy and can cause breakups and divorces. People bring different sexual experiences, propensities, and expectations to their romantic relationships. Couples may be more or less compatible in any of those areas, and their degree of compatibility may change over time, as may the couple's ability to recognize and adjust to such changes.

Expectations Regarding Sex in Different Types of Relationship

Although romantic or intimate relationships come in many different forms, most of them come with relatively specific expectations regarding sex. For example, relationships can be categorized as being

either monogamous (sexually exclusive) or non-monogamous (nonexclusive). In Western society, marriage between a man and a woman is the most common form of established relationship and has the strongest governmental, social, and religious recognition. Although heterosexual marriage is equated with monogamy, a marriage can, like other forms of intimate relationships, be nonmonogamous or open by agreement. The arrangement can be limited to sex, but it can also go beyond sex and allow for multiple, concurrent relationships. In addition to marriage, many couples may choose to live together (or cohabit), either as a step towards marriage or as an alternative way to define and express their feelings for and commitment to each other. Many gay and lesbian couples live together, although increasingly, in the United States and other countries, they may get married. Monogamy tends to be more important for lesbian than for gay couples; the latter more often negotiate nonexclusivity. In comparison to heterosexual and gay and lesbian relationships, less is known about bisexual men and women in established relationships.

Frequency and Quality of Sex

A number of studies, involving national samples, have explored how often couples engage in sexual activities. On average, married men and women report having sex about six times a month, although differences between couples are large. The average frequency is higher for cohabitating men and women and for gay couples and lower for lesbian couples. Relationship duration is one of the factors known to influence the frequency of sexual activity; it is highest during the first few years of newly established relationships and then tends to show a steady decline. This applies to both heterosexual and homosexual couples. A number of variables can contribute to changes in frequency, including health problems, pregnancy and childbirth, job stress, and habituation (or reduced novelty). Aging also plays a role, although—and this is true for most other variables—individual differences in its effects on sexual desire and response are substantial. In addition, when considering the frequency of sex, it is important to recognize that sex can be defined in

various ways. Some men and women do not consider oral-genital contact or anal intercourse to be sex even when they report engaging in these behaviors. And for many couples, although the frequency of sexual intercourse may decline, other forms of sexual or physical intimacy (including kissing and genital touch) may not change or may even increase over time. The relationship between frequency of sexual activity and sexual satisfaction is, for these and other reasons, complex. Although higher sexual frequencies tend to be associated with higher sexual satisfaction, frequency of sexual contact does not fully explain overall levels of sexual satisfaction. In addition to frequency, satisfaction depends on the quality of sex, but this variable is not as easy to define and measure and may include a role for other aspects of the relationship, including the experience of emotional intimacy.

Sexual Problems and Problems With Sex

Most couples will at one time or another be confronted with problems, whether transient or more enduring, related to sexuality and sexual health. These problems may arise from various sources, including differences in expectations regarding the nature, timing, and frequency of sexual activity. Also, mood, conflict, daily stressors, and life events, as well as the passing of time itself, may influence a person's sexual needs and desires. Although sexual problems are typically identified in an individual, a couple's relationship is often a key component in the understanding of the onset and course of sexual problems. Determining a diagnosis when dealing with couples can be a challenge because of the presence of disparities between partners. For example, low sexual desire in the female partner is one of the most commonly reported sexual problems by heterosexual couples. Although in some cases this complaint may indicate a true dysfunction, more often than not it reflects a problem with sex rather than a sexual problem. Consistent with this view, relationship conflicts are believed to be the most common cause of hypoactive sexual desire in women. In general, low desire, pain during sex, and difficulties achieving orgasm are examples of sexual problems that all tend to be associated with

poorer relationship satisfaction and with less attraction to, emotional closeness with, and feelings of love for one's partner. Several studies have found that sexual problems are associated with lower relationship satisfaction. Clearly, sexual problems can cause as well as result from relationship problems, and their impact on relationship trajectories can be expected to vary.

In addition to sexual problems that stem from differences between spouses in their expectations and sexual makeup, other factors, including stress, health problems, and the treatment of such problems, can all interfere with an individual's sexual functioning and satisfaction. Depression and other mood disorders have been found to influence sexual functioning in many men and women. In addition, drugs to treat depression, in particular the selective serotonin reuptake inhibitors (SSRIs; e.g., Prozac), have the potential to negatively affect sexual response. Treatments for sexual problems, including medical ones (e.g., Viagra), exist but their effectiveness is variable, and their long-term effects on the couple's relationship and on the dysfunction itself are not well understood.

Infidelity

Sexual exclusivity is one of the strongest norms governing most types of established relationships, including marriage. Yet whereas the vast majority of people in monogamous relationships hold unfavorable attitudes towards extradyadic sex, a substantial number report having sex outside of their relationship at least once in their lives. Studies using nationally representative samples of married men and women have found that approximately 20 to 25 percent of men and 10 to 15 percent of women report engaging in extramarital sex at least once during their marriages. Along with sexual dysfunction, infidelity—while differently defined by different people (e.g., some consider flirtation and sexual fantasies forms of betrayal)—is among the most significant threats to the stability of a relationship. Research comparing over 150 cultures has shown that infidelity is the single most cited cause of divorce. In Western countries, between 25 and 50 percent of divorcees cite a spouse's infidelity as the primary cause of the divorce.

A number of studies have linked personal values, sexual opportunities, and relationship satisfaction to the occurrence of extradyadic sex in monogamous relationships. However, others have failed to find significant associations between extradyadic sex and happiness or satisfaction with the relationship, or even with quality of sex within the relationship. When not caused by relationship conflict or low relationship satisfaction, infidelity may be associated with opportunity and permissive values, but either or both may in themselves be related to an individual's sexual makeup. Some studies, using national samples, have found a higher likelihood of sexual infidelity among men and women with stronger sexual interest levels.

Sexual Aggression

In some individuals, an association exists between sexual impulses and behavior and emotions such as jealousy and anger. In some relationships, these associations can lead to destructive, coercive, and violent forms of behavior. Marital rape, for example, is believed to be more common than any other type of rape, and several studies have found strong associations between jealousy and husband violence. Relationship violence has been found to be associated with higher levels of sexual activity within the relationship. Although a number of studies have explored possible underlying mechanisms, including possible links between sexual aggression and personality traits such as antisociality, research on the question of why these associations are more likely to exist and emerge in some individuals than in others is still minimal, and even less is known about sexual abuse and aggression in gay and lesbian couples.

Pregnancy and Parenthood

Many couples in an established relationship hope to have children at some point or already have them. Although this is particularly true for heterosexual couples, gay and lesbian couples are also choosing parenthood—for example, through adoption or some form of assisted reproduction (e.g., donor insemination, surrogate mothers). For many couples, preparing for parenthood is an exciting but also challenging journey. For example,

approximately 15 percent of married heterosexual couples are estimated to experience problems in conceiving and seek help, which not uncommonly involves recommendations regarding the timing and frequency of sexual intercourse. Little is known about how couples negotiate differences in the desire to have or the timing for children and how they deal with the associated worries or anxieties. In heterosexual couples, pregnancy often affects various aspects of sexual functioning and satisfaction. The frequency of sexual interactions between spouses tends to decline throughout pregnancy, only to increase again weeks and sometimes months after childbirth. Also, pregnancy appears to be a time of increased risk of sex outside of the relationship in monogamous relationships. Although there is less agreement in the literature on the determinants of postpartum sexual activity, most research suggests that parenthood transforms the sexual lives of most couples. A recent statistical analysis involving a large number of studies found that parents tend to report lower marital satisfaction than nonparents, but the role of possible changes in sexual behavior and satisfaction is still largely unknown.

Aging

During midlife and beyond, most men and women will experience a number of changes, physical and otherwise, that may influence their sexual desire and response and thus their relationships. In many men and women, the desire for and frequency of sexual activity (especially intercourse) with one's partner will decrease. In women, menopause brings about hormonal changes (in particular a decrease in the production of estrogen) that impact vaginal lubrication and other physical aspects of sexual response, which together may make intercourse more difficult and uncomfortable. In men, hormonal changes include a gradual decrease in the production of testosterone, which may make it more difficult to obtain or maintain erections or reach orgasm. Also, the increased likelihood of having to cope with diseases and other health problems can negatively impact sexual desire and response. Despite the many biological changes and other, including social, emotional, and health-related challenges (e.g., death of a spouse, moving

to a nursing home) associated with aging, many older people continue to engage in satisfying sexual activity, even at more advanced ages.

SEX RATIO

The sex ratio (SR) is the most popular index of sex composition used in demographic and other scholarly analyses; it is defined as the number of males per 100 females:

$$SR = \frac{P_m}{P_f} * 100$$

An SR above 100 indicates an excess of males, and an SR below 100 indicates an excess of females. In some countries including India, Iran, Pakistan, and Saudi Arabia, the SR is calculated as the number of females per 100 males, but the SR formula shown above is used by most demographers and international bodies such as the United Nations.

Henry Shryock, Jacob Siegel, and Associates have noted that SRs of nations are usually around 95 to 102 unless some major loss of life affects the country. A national SR lower than 90 or higher than 105 is extreme.

Marcia Guttentag and Paul Secord's *Too Many Women? The SR Question* is the best accounting of the SR in historical populations. In high SR societies, young adult women are decidedly valued.

They might be permitted to choose their own marriage partners or to marry into superior socioeconomic classes. High SR societies might promote sexual morality, in particular the virginity of potential brides and the fidelity of women in marriage. Some cultures tend to endorse sexual exclusivity and love on the part of both sexes, while others accept promiscuity and infidelity on the part of men.

Many of the characteristics of low SR societies are the opposite of those in high SR societies. Women are likely regarded as sex objects, feeling immobilized and devalued by the society. Due to their oversupply, they are rarely able to marry into higher socioeconomic classes. Greater numbers of men and women tend to remain single, and those who marry are more prone to get divorced.

Most societies have SRs at birth (SRBs) between 104 and 106. This so-called biologically normal SRB is likely an evolutionary adaptation to the fact that females have higher survival probabilities than males. Since at every year of life males have higher age-specific death rates than females, slightly more males than females are required at birth for there to be around equal numbers of males and females when the groups reach their marriageable ages.

Biology thus dictates that the age-specific SR will be highest at the very young ages and should then decline with age, attaining a value of around 100 for persons in their late 20s and continuing to decline to levels around 50 or 60 in the oldest ages.

Dudley Poston and Karen Glover have shown that the SRB in the United States is invariant, at about 105 for every year. In contrast, China had an SRB only slightly above 107 in 1980, a ratio which began to increase in the late 1980s, reaching 115 in 1990, 120 in 2000, and 118 in 2005. This has occurred in China (and in Taiwan, South Korea, India, and several other Asian countries) for three main reasons: (1) fertility has declined very rapidly in China from six children per woman in the 1960s to around 1.7 at the start of the new millennium; (2) China is characterized by a Confucian patriarchal tradition where son preference is strong and pervasive. When Chinese women were having six children on average, the probability was very low (less than 2 percent) that none of the six children would be male. By comparison, Gilles Pison has written that when women have between one and two children, the probabilities

are between 25 and 50 percent; and (3) ultrasound technology enabling the prenatal determination of sex has been widely available in China since the 1980s; thus, many Chinese use this technology to identify the sex of the fetus, and in many instances, if it is a female fetus, to then abort it.

Researchers have estimated that there have already been born in China around 32 million boys who will not be able to find Chinese women in the marriage market. What will these many millions of young men do when they cannot find brides? These Chinese bachelors will never marry and will have no other choice but to develop their own lives and livelihoods. They will likely resettle with one another in bachelor ghettos in Beijing, Shanghai, Tianjin, and other big cities, where commercial sex outlets would likely be prevalent. John Laub and Robert Sampson have observed that males are more prone to crime if they never marry. Another major issue of concern is the potential for an HIV/AIDS epidemic of a scale previously unimagined. This will especially be the case if China's commercial sex markets in the big cities expand to accommodate the millions of surplus males.

At the end of the 20th century, the population of the world was aging dramatically. In 2000, the average annual growth rate of persons ages 80 and older was 3 times greater than that of the total population and twice as high as that of the population ages 60 and over. Women's life expectancy in every age is greater than that of men. Women hence comprise a majority of the older population. Data from the Population Division of the United Nations for the year 2000 indicate that the global SR of the population ages 60 or over was 81 males per 100 females; there were approximately 63 million more women ages 60 years and over than men.

For the more developed nations, the SR in 2050 of the older population is projected to be around 78 males for every 100 females for those over age 60 and 56 males for every 100 females for people over 80. The U.S. population is projected to include almost 87 million persons over age 65 in 2050, with 56 percent of it female, according to data from the United Nations. The dependency ratio, that is, the economically dependent population (those under 15 and those 65 and over), divided by the economically active (those aged 15 to 64), is projected in 2050 to be 67.5. Knowledge of the SRs of societies provides very important

information and insights about their cultures, economies, and demographics.

SEX-ROLE ORIENTATION

A person's sex-role orientation can be described as the extent to which he or she possesses characteristics of masculinity, femininity, or androgyny (and is separate from sexual orientation). Sex-role and gender-role are two terms that are often used interchangeably, although sex is traditionally reserved for the biological category of male and female and gender is more often used to refer to the societal expectations placed on men and women. Traits and behaviors assigned to the male gender role are described as masculine (e.g., independent, competitive), whereas traits and behaviors assigned to the female gender role are described as feminine (e.g. emotional, kind). Sex-role orientation influences a variety of human relationships ranging from the socialization of children to interactions in

the workplace and most importantly, in close relationships. This entry describes the history of the study of sex-roles, the primary ways in which sex-roles are measured, and key psychological processes related to sex-roles. Sex-role orientation is of particular importance to understanding human relationships, as many relationship behaviors and processes (e.g., communication) are strongly tied to partners' sex-role orientation.

Measurement of Sex-Role Orientation

The study of gender roles began to intensify in the 1930s when intelligence researchers (principally, Lewis Terman) hypothesized that gender may be a better predictor of intelligence than sex. In 1936, the first measure to assess gender, the Attitude Interest Analysis Survey (the name disguised its true intent) was published, followed by the Minnesota Multiphasic Personality Inventory that also had a scale tapping into gender. The Bem Sex Role Inventory (BSRI) and the Personal Attributes Questionnaire (PAQ) are currently the most common measures of masculinity and femininity. The BSRI consists of 20 masculine (e.g., ambitious, self-reliant, independent, assertive), 20 feminine (e.g., affectionate, gentle, understanding, sensitive to the needs of others), and 20 socially desirable but gender-neutral personality traits (e.g., truthful, happy, conceited). The PAQ consists of 12 adjectives assessing femininity-expressivity (e.g., kind, gentle, helpful) and 12 adjectives assessing masculinity-instrumentality (e.g., active, competitive, independent). Given that masculinity and femininity are seen as distinct concepts—that is, a person can have high or low levels of each rather than conceptualizing masculinity and femininity as opposing ends of a single dimension—both measures use separate scales for each. Participants indicate how true each of the adjectives listed are of them.

Many attributes on the BSRI and PAQ are socially desirable, which led to the development of other measures that included more negative items. Individuals are more likely to say they possess positive characteristics regardless of whether the characteristic is masculine or feminine, a tendency which can interfere with true measurements of sex-role orientation. Consequently, an extension of the PAQ

was developed in 1979 that included the darker side of masculinity and femininity—referred to as unmitigated agency and communion. These two concepts are closely related concepts to masculinity and femininity. Individuals high in unmitigated agency (similar to masculinity) focus more on themselves to the exclusion of others. Individuals high in unmitigated communion orientation (similar to femininity) focus on others' needs and forming connections to the exclusion of self. Today gender and sex-role orientation are best viewed as psychological concepts with many different components.

The majority of current research on sex-role orientation is still consistent with early definitions of the concept. Changing times and recent research suggests taking another look at the validity of the BSRI and other such measures. Are the behaviors and values considered masculine in the 1970s the same as those considered masculine today? Do men and women endorse the adjectives in the same way? Evidence suggests this is not the case. For example, women's scores on the BSRI and PAQ masculine scales have increased steadily over time. Today, both men and women are encouraged to develop healthy relationship skills and to treat each other with respect (feminine characteristics). Being androgynous (high on both scales) is associated with better outcomes for both men and women.

One new approach to the study of sex roles, developed by Vicki Helgeson, estimates the probability that a person is male or female given a set of gender-related observable factors such as what the person wears (e.g., a dress) and what the person likes (e.g., football). Examples or responses that discriminate men from women are assigned weights depending on how well they differentiate men from women. This method, known as gender diagnosticity, includes indicators such as work preferences, personality characteristics, attitudes, mental abilities, and leisure activities. Sex category is linked to sex-role based on the assumption that behaviors that show sex differences serve as measures of masculinity and femininity within the sexes. For example, occupational preference ratings that show sex differences (e.g., men more likely to work in construction) in a given population can be used to assess masculinity and femininity within the sexes. Revised measures of sex-role orientation have also been developed in order to differentiate individuals who are neither masculine

nor feminine (called undifferentiated) or high in both (called androgynous).

Determinants of Sex-Role Orientation

An individual's sex-role orientation has been shown to be determined in part by parental behavior and rearing practices. For instance, in one study, males with an androgynous sex-role orientation typically acknowledged having a mother and father who were both equally affectionate. Sex-role orientation is thought to develop based on the rewards or punishment for early childhood behavior as suggested by Social Learning Theory. Parents may have only rewarded behaviors that fit sex-role norms. For example, parents tend to encourage boys to be rugged and encourage girls to be communal. Children also learn sex-roles by observing and modeling the behavior of same-sex parents.

Some theorists believe that sex roles are biologically based. Evolutionary theorists, for example, propose that the behaviors and attitudes exhibited by the different sexes have evolved to be distinct over time, given that each sex had different roles to play (e.g., caregiver vs. hunter) in the human evolutionary past. There are also a number of sex differences in anatomy, hormones, and brain functioning and organization that may account for some differences in sex-role orientation. For example, women have higher levels of the hormone oxytocin that facilitates bonding and nurturing of relationships. Men have higher levels of testosterone, a hormone related to aggression. Cross-cultural and cross-species research also show sex differences. The fact that different cultures with different socialization practices and nonhuman animals with different communication processes (and no media influences) also show sex differences supports biologically based theories of sex-role orientation.

Key Correlates of Sex-Role Orientation

One of the best established correlates of sex roles is aggression. Aggression has been linked to the male sex role by authors such as Myriam Miedzian who argue that violence cannot be studied without considering the fact that men are much more

likely to commit acts of violence than women. Miedzian argues for the existence of a masculine mystique that plays a major role in criminal and domestic violence. This masculine mystique consists of toughness, dominance, emotional detachment, and competition and results in society's not only tolerating violence in boys but also encouraging boys to be violent. This masculine mystique is more dangerous for lower-class than for upper-class boys, who can validate their masculinity through other channels, such as achievement. The female sex role, on the other hand, might also inhibit aggression via the role of empathy, a critical feminine sex-role attribute. The higher one's empathy, the lower one's aggression and as such, empathy training has been used in interventions to lower aggression. For example, children 7 to 11 years old who were trained to be empathic showed a decrease in aggression.

A large literature has studied how sex-role orientation relates to different behaviors, ranging from cognitive abilities to traits such as leadership. Boys who are high in masculinity and low in femininity and girls who are high in femininity and low in masculinity tend to score somewhat lower on scholastic ability tests. Masculinity has been found to be associated with self- and other-perceptions of leadership.

In certain settings, being high in the sex-role orientation of the other sex may have advantages. For example, some studies have found that women in the workplace who are high on masculinity are less anxious and experience less stress on the job compared to women low on masculinity. Other studies have found that individuals with feminine sex-role orientations had higher levels of fear in work settings. Fit between sex and gender role is also important. During an informal 5-minute dyadic discussion, masculine men and feminine women talked, smiled, laughed, and gestured less than other sex-role orientation combinations.

In the health arena, individuals high in masculinity are likely to be at risk for a variety of health-related problems such as coronary heart disease and hypertension. Traits such as aggressiveness and competitiveness, more common to masculine individuals of both sexes, increase cardiovascular reactivity and can endanger health. Men and women with high femininity scores have been found to have decreased risk for heart attacks.

Masculinity has also been associated with some positive health outcomes. A large review of the literature showed that masculinity has a moderately strong relationship to both high adjustment and lack of depression. Femininity in contrast has a major health advantage in that it has been found to lessen some of the harmful effects of stress. Individuals high in femininity both perceive and receive higher levels of social support, which buffers them against stress and is associated with positive health outcomes. In particular, expressiveness and a more developed feminine identity have both been related positively to psychological well-being. In contrast, androgynous individuals tend to have better mental health and higher self-esteem as compared to individuals with feminine or masculine sex-role orientations. Sometimes sex-role expectations can have negative consequences for the person. Sex-role strain is likely to occur when sex-role expectations conflict with natural tendencies. For example, men are supposed to kill bugs and spiders around the house. A husband who does not want to do this but who is expected to may experience sex-role strain.

Sex-Role Orientation in Relationships

Although gender and sex are important factors for studying close relationships, masculinity or femininity (and not just being a man or a woman) may have even greater influence on relationship outcomes. For example, higher femininity in both husbands and wives relates to higher levels of marital adjustment. This is likely because feminine traits such as expressiveness and communality contribute to higher degrees of relationship quality in general. Communal orientation has been correlated with enhanced trust, higher levels of connectedness, and a greater willingness and preference for discussing emotional subjects. Femininity is thought to influence relationship satisfaction via interpersonal skills where those high in femininity are also better at providing social support and at self-disclosing. Masculinity does have some benefits for a relationship. For example, masculinity has been associated with initiating relationships and bringing up issues of conflict.

People apparently recognize the value of feminine traits in a relationship. Men and women both

perceive a potential mate to be more desirable if he or she has feminine as well as masculine qualities (i.e., is androgynous), although feminine characteristics are rated as more desirable than masculine characteristics. Interestingly enough, both men and women rate themselves as behaving in a more feminine way and a less masculine way when they are with their partners than when alone. Especially important is the finding that people who behave in feminine ways with their partners report the highest relationship satisfaction. Relationship satisfaction for women in particular is related to their own and their husbands' degree of femininity.

Of note is the finding that couples in which both members have traditional sex roles have the least relationship satisfaction as a couple compared to relationships in which one partner is androgynous. This finding has also been found for gay and lesbian relationships. Couples who are most distressed are those in which both partners are undifferentiated.

SEXUAL AGGRESSION

Sexual aggression in close relationships involves attempting to achieve one's personal sexual goals without regard for a partner's sexual wishes. There are two broad forms of sexual aggression in a relational context. *Sexual coercion* consists of nonforceful influence techniques such as being physically persistent, using psychological manipulation, lying, and making use of drugs and/or alcohol in an attempt to attain sexual interaction, while *sexual assault* primarily involves threats or use of force against one's partner to attain sexual access. These two forms of sexual aggression sometimes overlap, which is not surprising since they share an underlying theme of power and control. Sexual aggression can also co-occur with psychological and physical aggression. Because of this, some scholars use the term *intimate partner violence* to capture the full range of interpersonal violence that can be experienced in close relationships.

Rates of Sexual Aggression

Patricia Tjaden and Nancy Thoennes's national study of women's and men's experience with intimate partner violence provides the best contemporary estimates of how frequently sexual aggression takes place in close relationships. Of the 8,000 women in their survey, 14.8 percent had experienced rape and 2.8 percent attempted rape. The assailant was a present or past intimate partner for 62 percent of the sexually victimized women. In fact, consistency in rates across this and other studies suggests that 15 percent of U.S. women will experience rape in their lifetime, most frequently at the hands of a relational partner.

Tjaden and Thoennes's findings for the 8,000 men they surveyed stand in sharp contrast to those for women. Rape was exceedingly rare for these men: Only 2.1 percent reported being a victim of a rape, and only 0.9 percent reported being a victim of an attempted rape. Moreover, men's sexual victimization most frequently occurred before age 12 (48 percent of the time), and the assailant was much more likely to be a man than a woman. Comparing the findings for men and women demonstrates that

women are at much greater risk of experiencing sexual aggression.

It is important to highlight that most experiences of sexual aggression occur in the context of a romantic relationship. Scientific investigations focused on adolescents, young single adults, and married partners, as well as gays and lesbians, repeatedly demonstrate that sexual aggression exists across the full range of romantic relationships in these diverse populations.

Describing Sexually Aggressive Men

It is evident that men are much more likely to be sexually aggressive than women, and sexually aggressive men share a number of traits. When compared to men who are not sexually aggressive, they characteristically hold a unique set of beliefs about sex and relationships. For instance, male sexual aggressors are more apt to believe in rape myths (e.g., women say no but mean yes, women dress in a way that invites sexual advances, etc.), to see men and women as sexual adversaries, to accept interpersonal violence, and to see force as a legitimate means for procuring sex. They are also apt to be traditional in their attitudes about women's role in society; a belief that places women in weaker positions relative to men. Sexually aggressive men use these beliefs to justify their aggressive actions towards women.

In addition to holding these beliefs, sexually aggressive men are also likely to possess certain personality characteristics. They can be impulsive and dominant and have problems understanding social rules. Moreover, they are often angry and feel hostile towards women, possibly because they believe women have treated them poorly in the past. There is evidence that they lack empathy and as a result, do not fully comprehend the impact their aggression has on their victims.

Sexually aggressive men, when compared to their nonaggressive peers, additionally possess a unique sexual profile. Again compared to non-aggressive peers, they lose their virginity at an earlier age, often have more sexual partners, and typically engage in sexual intercourse in casual as opposed to committed relationships. They value and may actively seek sexual novelty. Moreover, they find depictions of sex and violence arousing and may view violent pornography.

Collectively, these traits paint a picture of sexually focused, aggressive individuals who use their beliefs, their personality, and their sexuality to dominate women.

Contextual Factors, Relational Dynamics, and Sexual Aggression

Numerous relational dynamics are linked to sexual aggression. First, it is important to consider the contextual factors that are a part of sexual aggression, as they increase the risk of its occurrence. For example, most instances of aggression take place in a private or secluded setting such as a residence or a car. Another contextual factor is whether either partner consumes alcohol and/or uses drugs. Intoxicants can cloud the judgment of the victim, manufacture an excuse for an aggressor's behavior, or do both.

In addition to context, issues of consensual communication are involved. Consent involves knowledge, the consenting individual has all relevant information and is aware of what he or she is consenting to, and agreement, a clear choice to engage in sexual activity free from unwarranted influence. Within the context of sexual activity, individuals might communicate nonconsent (e.g., saying "no," blocking a partner's roving hands), enact affirmative behaviors (e.g., increasing sexual intimacy nonverbally), or use affirmative language (e.g., clearly saying yes). Communicating and attributing consent are complex relational processes, as sexual advances are often responded to with nonverbal messages that represent multiple meanings and are vulnerable to misinterpretation. Moreover, sometimes individuals fail to communicate no with direct assertions but use indirect messages instead. The lack of direct clear communication risks misinterpretations of consent.

Commonly held expectations that an increase in commitment gives one the right to an increase in sexual intimacy also play a role. As a result, romantic partners may become more aggressive in achieving sexual goals that they believe they are entitled to as a part of committing to a partner. This may explain why monogamous young adult romantic relationships experience higher levels of sexual aggression when compared to casual romantic relationships. Beliefs tying commitment to

sexual intimacy also likely contribute to sexual aggression in marriage where some husbands believe they have a right to sexual access whenever they wish as part of their marital contract.

Sometimes one partner wants to have sex, while the other does not wish to, even though they have engaged in sex in the past. The latter partner may still say yes while actually meaning no because of expectations and/or pressure set by society's views about relationships, such as what should take place in marriage or because of the expectations of either partner in the relationship. Sometimes, however, individuals say yes to unwanted sexual interaction or may not clearly communicate "no" because they fear physical aggression will follow if they do not allow sex to transpire. This particular dynamic can be a part of any case of sexual aggression regardless of the commitment level of the relational partners.

Given that control and power are key relational dynamics in sexual aggression, it is not surprising that sexually aggressive men often attempt to control their partners in areas of the relationship outside of the sexual arena. They may attempt to socially isolate their partner, control the economic resources available to the partner, and make partners account for their time. In its most extreme form, this results in some men brutally pairing physical and sexual assault or gaining sexual access by threatening physical violence.

Social Support for Sexual Aggression

Scientists have argued that social support for sexual aggression contributes to its existence. For instance, there is a lack of social consensus as to what constitutes rape. When faced with an account of a man possibly being sexual aggressive towards a woman, individuals consider a number of factors when deciding whether a rape took place. Some of the decision making focuses on the woman and her actions. Individuals are less likely to conclude that she was raped if she wore revealing clothing, had been drinking, did not clearly say no, or had consented to participate in sexual acts other than intercourse. A woman who engages in any of these behaviors is often perceived as being at least somewhat to blame for the circumstances she finds herself in. Some of the decision

making focuses on the man. If he threatens or uses force, individuals will likely conclude that he raped his partner. However, if he was sexually coercive, using techniques such as being physically persistent, plying the woman with alcohol, or psychologically manipulating her, his actions will be judged as wrong but not sufficient to constitute rape. Thus, the societal view of what constitutes rape is not always clear. On one level, sexually aggressive men are aware of the lack of social consensus and use it to their advantage when deciding how to achieve their sexual conquests. On another level, without a social consensus as to what constitutes rape, men can continue to be sexually aggressive without worrying about suffering negative sanctions for their actions.

Sexual aggression among college youth is also higher in communities that ascribe to traditional masculine ideals. Specifically, higher rates of sexual victimization are connected to fraternity functions and/or with fraternity members. When compared to male college students who are independent of the Greek fraternal system, fraternity members are more apt to endorse, support, and use sexual aggression. The fact that fraternity social functions frequently involve heavy use of alcohol likely plays an additional role. Alcohol may be used in these social situations as a means of increasing sexual access to the women who attend these functions.

Social support for sexual aggression additionally occurs at the peer level. Sexually aggressive men tend to choose friends who engage in similar acts. These friends provide social reinforcement for each other's sexual aggression in the form of increased social status. This form of reinforcement is a particularly salient motivator for sexually aggressive men. In other words, such men find the recognition their friends give them for their sexual conquests particularly rewarding.

Finally, support for sexually aggressive acts may be related to certain developmental experiences from the family of origin. Although not uniformly true, some aggressive men grow up in violent family settings. Some were victims of sexual and/or physical abuse; others had parents who were violent toward each other. These early life experiences have the potential to serve as models for how partners should interact in later life romantic relationships.

Survivor Outcomes

It is important to recognize the full reach of sexual aggression in society. Fear of being victimized can cause women, regardless of whether they have personally been victimized, to restrict daily activities such as going to their car by themselves, using public transportation, or even walking by men on the streets. Worries about possible victimization can lead college women to adopt strategies to protect one another at times when there is an elevated risk of victimization. For instance, one female friend in a group may limit her alcohol intake and look out for the other members of her group when going to a singles' gathering. Thus, even women who have not directly experienced sexual aggression often restrict their lives as a precautionary step against possible threats.

Women who survive direct experiences with sexual aggression can be affected in a number of different ways. Some incur physical injuries. These can include bruising, lacerations, and torn muscles, at times focused around their vagina or anus. Psychological function is frequently impaired both in the short and long term. Victimized women can become depressed, angry, anxious, and irritable as an outcome of their traumatic experience. Self-blame, feelings of guilt, and decreased sexual functioning is common. Furthermore, it can affect survivors' romantic relationships. They often find it difficult to trust partners and may experience an overall decrease in relational quality even when paired with a nonaggressive partner at a time following their victimization experience.

SEXUAL COMMUNICATION BETWEEN PARTNERS

Sexual communication is a strong predictor of the degree to which couples are satisfied with their sexual relationships. Just as good general communication is important for relationship satisfaction, good communication about sex is important for sexual satisfaction. Sexual communication can help determine whether a partner is interested in sexual activity and can lead to enhanced arousal when sexual encounters do occur. In addition, open sexual communication plays an essential role in safer sex practices. This entry reports on the nature of research in this area, the correlates and predictors of sexual communication, and the relationship between communication about sex and safer sex practices.

Methodology

The study of sexual communication has involved the examination of various factors, including the frequency of discussion of sex-related topics,

degree of discomfort or apprehension in discussing sexuality, expression of preferences for certain sexual activities and techniques, self-disclosure of sexual history, and negotiation of contraceptive methods. Almost all research has relied on self-report, with that method's inherent shortcomings such as the possibility of deliberate deception, faulty memory, and distorted perception. For certain types of sexual communication such as discussions of safer sex, members of a couple do not agree about the amount of discussion that has occurred between them. Although much sexual communication is indirect or nonverbal, it is largely verbal communication that has been studied. In addition, for many couples, a great deal of communication occurs during the sex act itself, and this exchange of information has rarely been examined.

Function of Sexual Communication

Communication about sex plays a vital role in several aspects of a relationship, including the determination of interest in sexual activity, learning about the types of sexual activities that appeal to one's partner, the effectiveness of various methods of stimulation, and the minimizing of risk of pregnancy and infection. The strong relationship between sexual communication and sexual satisfaction is a consistent finding. Virtually every study that has examined this relationship has found these two relational aspects to be highly positively correlated. Both the frequency and the quality of sexual communication seem to be related to a satisfying sexual relationship. Lack of sexual communication or difficulties in communicating about sex are linked with sexual problems or dysfunction. In one study, the variable most predictive of overall sexual dissatisfaction was inhibited communication. In addition, sexual communication has been related to partners' satisfaction with control over aspects of their sexual relationship. Communication about sexuality is also related to general relationship satisfaction.

The relationship between sexual communication and sexual satisfaction appears to be due to several factors. First, greater communication about non-sexual issues predicts sexual satisfaction independently of sexual communication, so the correlation

could, in part, be related to higher levels of overall communication. Also, both general communication and sexual communication lead to relationship satisfaction, which in turn leads to sexual satisfaction. Finally, and perhaps most obviously, communication about preferred activities directly leads to greater sexual satisfaction.

Predictors of Sexual Communication

Research is mixed with regard to whether men or women are more likely to talk about sex within a relationship, with some studies indicating that males are more likely to raise sexual issues and other studies indicating that females are the ones most likely to do so. It does appear that same-sex couples engage in more sexual communication than do mixed-sex couples. Factors that lead to greater sexual communication include a more positive emotional orientation toward sexuality (erotophilia), less traditional views of sex roles, less belief in the sexual double standard (the notion that casual or permissive sex is more acceptable for males than for females), less apprehension regarding communication in general, and less self-silencing (especially for women). In general, people who are more self-disclosing about other topics also tend to be more self-disclosing about sex. There is a positive relationship between the quality of general communication and the quality of sexual communication. Finally, some research has suggested that sexual communication is more likely within committed relationships.

Sexual Communication and Safer Sex Practices

Past sexual behavior is often underreported to partners, leading to an unrealistic assessment of risk. Young adults tend to avoid conversations regarding negative aspects of sexual behavior such as infidelity and sexually transmitted infection. In addition, discussing HIV/AIDS risk appears unrelated to the likelihood of discussing sexual pleasure. The use of condoms is more closely related to the specific discussion of condoms or sexual history than to more general communication regarding safer sex, but at least among adolescents and young adults, general sexual communication is related to the greater likelihood of contraceptive use.

Many people are hesitant to discuss contraception in the beginning of a relationship, particularly as it pertains to disease prevention, for fear of hurting their partner's feelings or triggering a negative reaction such as anger. This fear is usually unfounded, however, as people report being grateful when a partner raises the issue. Nonetheless, only about half of adolescent couples discuss contraception prior to engaging in sexual intercourse for the first time. Research indicates that adolescents and young adults are frequently untruthful in their discussions of their sexual histories, including the reporting of their past partners and past sexually transmitted infections.

In the United States, women are more inclined to discuss their sexual history and aspects of safer sex than are men and are often the ones to initiate such discussions. Nonetheless, when such discussions occur, they appear to be equally effective for men as for women in terms of leading to less risk-taking behavior. However, in countries with a more traditional or machismo-based culture such as various Latin and African countries and in other countries within certain subcultures where there is a large imbalance of power between the sexes, women are less likely to raise issues of condom use or safer sex, thus putting themselves and their partners at higher risk.

SEXUAL DYSFUNCTIONS

Sexual functioning is affected by a complex interplay of physiological, psychological, and contextual factors (e.g., physical health, life stress, past interpersonal experiences, current relationship quality) and may therefore change over time with age, life stages, and duration of relationships. Indeed, everyone may experience ups and downs in his or her sexual functioning. However, when sexual difficulties are persistent or recur frequently and cause marked distress and interpersonal difficulties, then one may have a sexual dysfunction. The general heading of sexual dysfunctions encompasses a variety of disorders that are characterized by disturbances in the various phases of the sexual response cycle of desire, arousal, orgasm, and resolution, as well as sex-related pain disorders. These disorders may be lifelong problems or develop after a period of normal functioning. They may be situational difficulties, which develop only under certain circumstances or with specific partners, or generalized ones. To be sure, sexual dysfunctions are fully understood only when taking into account their interpersonal context. Thus, whether an inhibited sexual response is a dysfunction per se rather than an adaptive reaction to adverse circumstances (e.g., relationship difficulties) remains controversial. This entry describes the sexual response cycle and impairment of its functioning, and examines the causes of impairment as well as related treatment.

Sexual Response Cycle

The fundamental diagnostic categories of sexual dysfunctions reflect the traditional view of the four-phase model of human sexual response. This model, which is based on sexual response more characteristic of men than women, assumes a linear progression of relatively discrete phases. The cycle begins with an initial awareness of

sexual desire (i.e., yearning for sex and thinking or fantasizing about it) that leads to the arousal (excitement) phase. The *arousal phase* is characterized by increased blood flow to genital tissues that produces vaginal lubrication in women and erection in men. This phase may lead to the reflex rhythmic muscular contractions of the *orgasm phase* that release muscular tension and blood from the engorged blood vessels. In the *resolution phase* that follows, the physiologic changes that took place during the preceding phases are reversed and the body returns to an unaroused state.

Contemporary research suggests that women's sexual response is more complex than is indicated by this model, and involves overlapping phases of sexual response in a variable sequence, particularly when engaged in a long-term relationship. In the initial phase of a relationship, women typically experience relatively high and spontaneous sexual urges. At later stages of a relationship, when couples are more likely to experience habituation to sex and tend to show lower levels of sexual intimacy (e.g., engagement in foreplay, expressing signs of affection), women's sexual desire, which is more affected by relational context than men's, may become a responsive rather than a spontaneous event. As such, at the beginning of a given sexual interaction, a woman may not necessarily sense sexual desire per se, but rather be motivated to engage in sex for other reasons (e.g., promoting her sense of closeness, pleasing her partner, obtaining relief from stress). Then, when a woman is willing to become sexually receptive, she may consciously focus on sexual stimuli and feel sexually aroused. This subjective sense of arousal may, in turn, trigger the desire for sex itself (i.e., responsive sexual desire). If the sexual stimulus is perceived as effective and the woman can stay focused long enough, she may experience sexual satisfaction (with or without orgasms).

These differences between men's and women's sexual responses have proven useful for defining, diagnosing, and treating sexual dysfunctions. Current understanding of dysfunctions and related definitions acknowledge that decreased spontaneous desire ahead of sexual activity does not necessarily constitute a desire disorder. It is also recognized that whereas genital congestion in men (i.e., erection produced by an increased blood flow

to genital tissues) is equated with the subjective sense of arousal (i.e., feelings of excitement), there may be discrepancies between the two in women. Women's subjective sense of arousal is more likely to be affected by the thoughts and emotions elicited in the presence of erotic stimuli than by the physical response in and of itself. Women may therefore exhibit genital lubrication without feeling sexually aroused or feel sexually aroused without genital lubrication.

Definitions and Prevalence of the Major Sexual Dysfunctions

Desire Disorders

An individual is considered to have a *desire dysfunction* when he or she is not motivated to have sex for any reason and is not receptive to adequate sexual stimulation. This lack of interest should be beyond the normative lessening that may occur with life cycle and relationship duration and should cause marked distress or interpersonal difficulties, such as in the case of discrepancies of sexual desire.

Arousal Disorders

Female Subjective Sexual Arousal Dysfunction. A woman is considered to have this dysfunction when she experiences markedly diminished (or absent) feelings of sexual arousal (i.e., sexual excitement and pleasure) from any type of sexual stimulation but shows vaginal lubrication or other signs of physical response.

Female Genital Sexual Arousal Dysfunction. A woman is considered to have this dysfunction when she experiences impaired (or absent) genital sexual arousal (i.e., genital congestion) from any type of sexual stimulation and reduced sexual sensations from caressing genitalia but feels a subjective sense of sexual arousal from nongenital sexual stimuli.

Female Combined Genital and Subjective Arousal Dysfunction. A woman is considered to have this dysfunction when she experiences markedly reduced (or absent) subjective and genital sexual arousal from any type of stimulation.

Erectile Dysfunction. A man is considered to have an erectile dysfunction when he cannot attain or sustain penile erection sufficient for sexual activity for at least 3 months.

Orgasmic Disorders

Female Orgasmic Disorder. A woman is considered to have an orgasmic disorder when she experiences markedly diminished intensity of orgasmic sensations or marked delay (or an absence) of orgasm from any kind of stimulation, although she does experience high sexual arousal.

Male Orgasmic Disorders. This category includes a spectrum of disorders ranging from delayed ejaculation (i.e., undue delay in reaching a climax during sexual activity) to orgasmic dysfunction and anejaculation (i.e., the absence of ejaculation during orgasm).

Premature Ejaculation. A man is considered to have premature ejaculation when he ejaculates with minimal stimulation before, on, or shortly after penetration (i.e., brief ejaculatory latency of 2 minutes or less) and before he wishes it, and over which he has minimal or no voluntary control.

Pain Disorders

Dyspareunia. A woman is considered to have dyspareunia when she experiences pain with attempted or complete vaginal entry or penile vaginal intercourse.

Vaginismus. A woman is considered to have vaginismus when she experiences difficulties in vaginal entry of a penis or any object, despite her expressed wish to do so. There is often (phobic) avoidance, involuntary pelvic muscle contraction, and anticipation or fear or experience of pain. Structural or other physical abnormalities must be ruled out.

These sexual dysfunctions are relatively prevalent in both sexes, with estimates ranging from 10 percent to 52 percent of men and 25 percent to 63 percent of women. Figures for the prevalence of sexual dysfunctions vary from study to study due to differences in study populations, definitions, and measures. The most widely cited

survey showed that the most common sexual problem is premature ejaculation in men (28 to 32 percent, depending on age group) and a lack of interest in sex in women (27 to 32 percent, depending on age group). Although this survey is believed to provide some of the best estimates of sexual problems in the United States, it neither used the formal clinical diagnostic categories of sexual dysfunctions nor indicated the severity of the problem and related distress. Indeed, less than 20 percent of respondents in this survey had sought professional help for their sexual problems, implying that most people may have less severe problems, apparently unlikely to qualify for a clinical diagnosis. Of course, there may well be other reasons for not seeking professional help (e.g., embarrassment, ignorance, perceived ineffectiveness).

Causes and Treatment of Sexual Dysfunctions

The causes of sexual dysfunctions may be psychogenic (e.g., developmental, intrapersonal, interpersonal, environmental factors) or organic (e.g., illness, injury, drug effects). Some sexual dysfunctions (e.g., orgasmic disorders, premature ejaculation) are most commonly caused by psychogenic factors, whereas other dysfunctions (e.g., erectile dysfunction, painful intercourse) are more frequently caused by organic antecedents. In many cases, these factors tend to be intertwined because emotional and cognitive reactions (e.g., anxieties) to sexual dysfunctions of organic origin may further interfere with sexual functioning.

Physiologically, smooth functioning of the sexual response involves interaction between the nervous, endocrine, vascular, and musculoskeletal systems. Impairments in any of these systems may potentially cause sexual dysfunctions. Physical conditions that may cause or contribute to sexual difficulties include neurological disorders, disorders affecting blood vessels, and hormonal deficiencies, as well as fatigue, chronic pain, and mental health problems (e.g., anxiety, depression). Spinal cord injuries and complications of surgery of or near reproductive-urinary systems or abdomen (e.g., prostate surgery, hysterectomy) are other common causes of sexual dysfunctions. Side effects of certain medications, such as some birth

control pills, blood pressure medications, antidepressants, and antipsychotic and chemotherapy drugs, as well as adverse health habits (e.g., cigarette smoking, high alcohol consumption, substance abuse) may also interfere with sexual functioning.

Psychogenic factors that predispose the individual to developing sexual dysfunctions include prior learning (e.g., past negative sexual experiences, negative family attitudes toward sex), intrapersonal factors (e.g., poor body image, fears of intimacy), and contextual factors (e.g., stress related to job demands, children and parents care). Relationship discord and partner-related factors may also play a key role in developing or perpetuating sexual dysfunctions. These interpersonal causes commonly include unresolved relational conflicts, power struggles, partner's health problems, sexual difficulties, and unresponsiveness and feelings for the partner (e.g., lack of sexual attraction, anger, distrust).

Nevertheless, clinical evidence suggests that such predisposing factors do not necessarily lead to sexual difficulties (e.g., people who have a history of traumatic sexual encounters do not always develop sexual dysfunctions; some couples have turbulent relationships but good sex lives). To develop a sexual dysfunction one also has to translate these predisposing factors into immediate defense mechanisms that directly inhibit sexual responses. These mechanisms consist of anxieties (e.g., performance anxiety), cognitive interference (e.g., self-monitoring, judgmental thoughts), failure to engage in effective sexual stimulation, and lack of open communication. Although the translation of predisposing factors into immediate mechanisms explains how individuals with a particular combination of distal etiological factors may develop sexual dysfunctions, it remains unclear why these people employ such mechanisms, whereas other people, with a similar constellation of possible harmful factors, do not.

Because sexual functioning and related impairments are complexly determined by multiple psychogenic and organic antecedents, assessment of the dysfunction should involve gathering information on the history and context of the problem from both partners, as well as on personal and interpersonal issues, including sexual, relational, and medical histories. Psychological treatments

target psychophysiological responses and include sex education, cognitive-behavioral techniques (e.g., identifying and altering maladaptive cognitions and unrealistic expectations of performance, anxiety reduction), communication and sexual-skills training, and couple therapy. Medical treatments (e.g., estrogen therapy, topical anesthetics, and surgical treatment) aim to directly change physiological responses. Erectile dysfunction is unique among the sexual dysfunctions for the effectiveness of medications, no matter what its etiology. Typically, however, regardless of the cause of sexual dysfunction, emotional and relationship issues need to be addressed for treatment to be effective and enduring.

SEXUAL HARASSMENT

Modern social life is experienced in two overlapping spheres of relationships: a personal and a

professional sphere. The focus here is upon problem relationships that occur in the professional sphere. Specifically, this entry discusses the problem professional relationships that can constitute sexual harassment. Sexual harassment will be examined from both a legal and a social psychological perspective. Sexual harassment can occur in many relationship settings including the workplace, educational settings, and even relationships between landlords and tenants. The common stereotype of sexual harassment is one where a male supervisor makes sexual advances toward a female employee with the understanding that going along with his advances will result in a raise or promotion or that refusal will result in the employee's being fired or perhaps demoted. Although such a scenario certainly represents one form of sexual harassment, research consistently shows that such behavior is not the most common form of sexually harassing behavior that takes place in the workplace or other settings. The term *sexual harassment* was first coined in employment discrimination cases that were argued in U.S. Federal Courts. In U.S. law, sexual harassment is considered a form of illegal, gender-based discrimination. From a legal standpoint, the stereotypic sexually harassing behavior where a person in power uses his or her social position to sexually exploit an underling is called *quid pro quo* sexual harassment. Psychologists also refer to such behavior as sexual coercion. Though surveys show that experiences of sexual coercion are relatively rare, sexual coercion represents a socially significant form of sexual harassment because such experiences can be very psychologically stressful to those who are targeted.

Another form of legally recognized sexual harassment involves sexual or gender-related behavior that causes a hostile or offensive environment. In this form of sexual harassment, there is no necessary formal power imbalance between the perpetrator and the target of the behavior. Psychologists distinguish between two subtypes of hostile environment sexual harassment: unwanted sexual attention and gender harassment. Unwanted sexual attention is similar to sexual coercion except that the perpetrator does not attempt to tie going along with the behavior to any sort of reward or punishment. Nevertheless, the behavior in question is definitely sexual in nature and is unwelcome by the target of the behavior. Examples

include staring at a target's body, unsolicited sexual touching, and persistent requests for dates after rejection.

Gender harassment is another type of behavior that can contribute to a hostile environment. Unlike sexual coercion or unwanted sexual attention, gender harassment does not involve an aim to gain sexual access to a target. Instead the aim of gender harassment often seems to be to express hostility. Women who work in traditionally masculine jobs such as firefighting, police work, or the military often report experiencing this form of sexual harassment. Examples range from the posting of offensive pornography on computers where others can see it to comments or jokes that demean a person with gender-specific insults (e.g., calling a woman a bitch). A graphic example of gender harassment was once reported by a woman who was one of the first female firefighters in New York City. One day on the job, she opened her lunch box to find a used condom in her sandwich, presumably placed there by her male coworkers. Research has consistently shown that gender harassment is the most prevalent form of sexually harassing behavior across all relationship settings.

Sometimes people experience one of these different types of sexually harassing behavior and not the others, but often people experience them in combination. Gender harassment is most likely to occur without experiencing the other two types. Sexual coercion on the other hand is more likely to occur in relationship settings when people have also experienced gender harassment and/or unwanted sexual attention. It is important to understand that sexual harassment involves only unwanted sexual or gender-related behavior. For instance, an exchange of sexual jokes between two willing participants is not sexual harassment, unless of course it was witnessed by a third party who found the behavior offensive. People have legal protection from sexual harassment in work settings, in academic settings, and in housing. Although similar behaviors might occur in other settings, they would not be considered illegal under U.S. law. Although U.S. law recognizes that both men and women can be the targets of sexually harassing behavior, research consistently shows that it is more often experienced by women and that women find such experiences more stressful than do men. Similarly, U.S. law does not make

assumptions about the gender of perpetrators. However, the vast majority of perpetrators for both male and female targets are men.

Social psychologists have studied a variety of potential antecedents of sexually harassing behavior. Certain situational factors present more risk for sexually harassing behaviors than others. In work settings where men are numerically dominant and hold positions of organizational power, sexually harassing behavior is more likely to occur. Also, social norms play a role in the risk for sexually harassing behavior. In some work settings, there is sometimes an atmosphere of tolerance or indifference toward sexually harassing behavior—those in charge allow such behavior to happen or in worst cases participate in the behavior. Not surprisingly, such work places have a higher incidence of sexual harassment. Person factors also play a role in sexual harassment. Men who view sexuality and social power as going hand-in-hand are more likely to perform sexually harassing behavior. Men who hold sexist attitudes are more likely to sexually harass. Situational and person factors can be jointly important in producing sexually harassing behavior. People who have tendencies to sexually harass are more likely to act on these tendencies when social norms support such behavior.

What are the consequences of sexual harassment? Research conducted in many work settings has found that the occurrence of sexual harassment is related to diminished individual and work group productivity. People who are the targets of sexually harassing behavior are more likely to take sick leave or vacation time to escape the behavior. They are also more likely to seek a job transfer or simply quit their jobs. Psychologists suggest that sexual harassment on the job represents a form of work-related stress. Experiences of sexual harassment have been related to anxiety and depression and a variety of stress-related psychological and physical symptoms.

SEXUAL INTENT, PERCEPTIONS OF

People's perceptions of sexual intent are their judgments that others are interested in them as sexual partners. The degree of interest people judge to exist may range from simple recognition (in which others merely notice their potential as partners) to avid pursuit (in which others' desires for them are blatant and conspicuous). Explicit invitations sometimes occur, but the cues that signal others' interest in them are more often both subtle and complex. People's own expectations and appetites also shape their judgments, and actions that seem sexually provocative in some settings may seem merely playful on other occasions.

Perceptions of sexual intent thus emerge from diverse influences in complex interactions, and mistakes can be made. Partners in an interaction may disagree with regard to the amount of sexual interest that is being communicated from one to the other, and misunderstanding, frustration, and conflict may result. In particular, men are more likely than women to perceive sexual intent in others when it does not exist. This entry delineates this difference between the sexes and describes some of the influences that lead people to make such mistakes. First, however, what behavioral cues are involved?

Signs of Seduction

When people wish to communicate sexual interest and desire to others, they smile more, look longer, lean closer, and touch more than they do when they are merely being friendly. They laugh frequently, use an intimate tone of voice, and lick, bite, and touch their lips. If they are alone in a bar, women who display all of these signals are quite likely to be approached by men.

Male Misperceptions

Once conversation begins, there are two types of mistakes people can make in judging another person's interest in them. They may fail to notice that the other is interested and available, or alternatively, they may judge the other to be interested and accessible when he or she is not. As it turns out, one of these errors is much more likely than the other. On average, when men engage in small talk with women, they typically perceive the women to be more promiscuous and more sexually attracted to them than the women say they are. On occasion, these judgments may occur because the women are unintentionally behaving more provocatively than they intend. However, male and female observers of these interactions come to the same conclusions: Men who merely watch a woman conduct an affable conversation with another man judge her to be more interested in him as a sexual partner than female observers do. Whether they are participating in the interactions or simply listening in, men perceive women to be more sexually available and responsive than the women wish to seem (and other women think them to be).

Men and women also tend to differ in their interpretations of videotapes and written vignettes portraying sociable interactions with the other sex. On average, men perceive heterosexual interactions to have more sexual overtones than women do.

Why does this occur? Theorists have considered several possibilities that may all be influential. An evolutionary perspective suggests that modern men are attuned to the sexual implications of their interactions with women because it was more costly, in terms of reproductive success, for prehistoric men to be sexually inattentive than for them to be constantly on the prowl. Social role and social learning perspectives point out that people expect men to initiate sexual interactions and that many men have benefitted, at least now and then, from being pushy and assuming that women often feign disinterest when they are actually available. Men also tend to experience more frequent sexual arousal than women do, so sex is simply more often on their minds.

Individual Differences and Situational Influences

Nevertheless, like other distinctions between the sexes, the differences in men's and women's perceptions of sexual intent should not be overstated. A majority of both women and men have encountered a situation in which someone of the other sex misjudged their intentions and overestimated their sexual interest. Women make these mistakes, too. Moreover, some men are more likely than others to misjudge a woman's interest in them. Nontraditional men who view women as equals are relatively unlikely to misperceive their intentions, whereas highly traditional, masculine men with more stereotyped views of the sexes often perceive sexual interest where it does not exist. Such misperceptions are also more frequent in men who hold rather hostile attitudes toward women, believing, for instance, that women often say no when they really mean yes. Men who avidly pursue casual, uncommitted sex with women also tend to be prone to these errors.

The circumstances matter, too. Alcohol is an important influence. When a woman drinks heavily, observers tend to assume that she is sexually available. Intoxication also robs people of their discernment, so misperceptions are more common when people have been drinking. The more attractive a woman is, the more often her friendliness is misunderstood, and any woman in revealing clothing runs the risk of seeming sexually interested to the men she meets.

Conclusions

These mistakes can be consequential; in particular, misperceptions of a woman's interest are often involved in cases of sexual assault. Seductive behavior does differ from friendly behavior, but the difference can be lost on callous or drunken observers. Thus, people should not naïvely assume that one's interests and intentions are always unambiguous to others. Instead, people should strive to assertively, consistently, and clearly communicate their wishes when the time is right.

SEXUAL INTERCOURSE, FIRST EXPERIENCE OF

Losing one's virginity, or first intercourse, traditionally has meant engaging in vaginal–penile penetration. However, younger individuals are much more likely to view virginity loss as including a range of sexual activities. Most scholarly research, including this entry, defines first intercourse as the first-ever vaginal–penile penetration. Engaging in first intercourse is often not the same as first sexual activity. Many young people who have not engaged in intercourse have engaged in other genital sexual activities with a partner such as genital touching or oral sex.

Age of First Sexual Intercourse

Most of the research focuses on the age when individuals first engage in vaginal–penile penetration. The average age of first intercourse is between 15 to 18 years old. Robert Michael and his colleagues report that more than 80 percent of 20 year olds in the United States have engaged in intercourse, and they argue that teenage sexual experiences tend to be episodic and less frequent compared to adult sexuality.

From the 1970s to the 1990s, the average age of first sexual intercourse declined, and although the decline in age is well documented, there is less consensus regarding why this is so. Explanations often include historical changes (such as the 1960s sexual revolution), an increase in the age of first marriage, and less parental supervision (due to an increase in parental divorce and to both parents working outside of the home) particularly in the afterschool hours. Scholars such as Barbara Risman and Pepper Schwartz have found that at the beginning of the 21st century, teens are slightly more sexually conservative and particularly for boys, may be delaying their first sexual intercourse.

Race, ethnicity, social class, and gender are some of the more powerful factors that consistently differentiate early from later debuts of sexual intercourse. Studies consistently find that African Americans compared to Whites or Latinos and that persons from lower social classes compared to those from higher income brackets are more likely to engage in sexual intercourse at a younger age. Regarding gender, males tend to report a younger age of first sexual intercourse than females; however, in the last decade, the gender gap is closing with boys' decreasing sexual activity.

Context of First Sexual Intercourse

The context of the first sexual intercourse typically occurs within a dating relationship and is described as a spontaneous event. Sexual debut, for men and for especially women, tends not to be a very satisfying emotional or physical experience. Both men and women report experiencing anxiety at the first sexual event. Compared to men, women tend to be much less likely to report having an orgasm, more likely to report feeling guilty (especially if a dating relationship is not established), and more likely to say retrospectively that they wish they had waited. Females experience less pleasant reactions to first coitus than do males; for example, they are more likely to be nervous, in pain, worried about pregnancy, and worried about possible negative outcomes of having intercourse. Women who were in late adolescence or young adulthood when they lost their virginity reported less negative reactions compared to those who were younger. The age of the

first sexual partner also impacts women's reactions, as sex with someone younger or the same age is often reported as more pleasurable than first-ever sex with an older partner. As for why people engage in first intercourse when they do, women are more likely to report they engaged in first sex to strengthen a relationship, while men are more likely to cite physical pleasure as the reason for engaging in first sex.

An increasing number of adolescents use contraception, with the condom reported as the most common method at first intercourse. The Allan Guttmacher Institute reports that contraception use has doubled since the 1970s, with nearly 80 percent of adolescents today using contraception at the first intercourse.

A later age of first sexual intercourse is correlated with women indicating that they wanted the sex to occur. About one quarter of women report that their first intercourse was voluntary, but not wanted. Wanting to engage in first intercourse is significant for quality of life factors; the meaning of sexuality in society is that it is a pleasurable event and not a chore that people choose to engage in. Additionally, women who are more likely to want the first sexual intercourse to take place are more likely to report using contraception.

Implications

Adolescent sexual behavior, especially for women, often carries a negative connotation. Researchers and policymakers often make the connection between a younger age of first sexual intercourse and increased risks of social problems such as unwanted teen pregnancy rates, increased risk of sexually transmitted infections, including HIV/AIDS, and juvenile delinquency. Early sexual debut is also associated with ineffective sex education programs, a harsher reputation to especially young women, and poor decision making of ignoring potential risks.

Research has found that persons who have sex at a younger age tend to have more nonvoluntary sex partners, to have more sex partners, to have more frequent intercourse, to be less likely to use effective contraception, and to be more likely to cite that they were too young to have sex. Many of these consequences are as a result of having more

opportunities for risk-producing behaviors (such as more chances of unwanted pregnancy). Several studies note that young teenagers are less likely to use contraception, not out of lack of knowledge, but out of greater perceived costs (economic, social stigma) as opposed to rewards (less likely to get a disease or pregnant). This may be because the costs are immediate, and the rewards may be delayed. Because adolescent sexuality is often viewed as a negative health risk, policymakers have tried to utilize various strategies, often argued to be ineffective, to delay teenagers' first sexual event. Tactics include relying on abstinence-based sex education programs or encouraging adolescents to sign virginity pledges.

Engaging in first sexual intercourse marks an important life experience for most youths. For good or bad, it is an event that most will remember throughout their lives. Examining the experience of first intercourse provides insights into how it impacts other behaviors and risks and how it influences future relationships.

SEXUALITY

Human sexuality is the set of emotional, intellectual, behavioral, and physical experiences of humans related to their sexual nature. Sexual

nature involves the tendencies and responses that are characteristic of a person related to erotic bodily stimulation and contact; these tendencies are both physical and psychological and include degree of interest in sensual bodily contact and in relationships based on sensual bodily contact.

Sexuality is fundamentally based upon the system of the body responsible for reproduction of offspring. Yet sexual feelings, thoughts, and behaviors extend substantially beyond the behaviors and bodily organs directly related to procreation. Individuals are quite capable of interpreting and conceiving of a wide range of events and situations in erotic, sensual ways, even if the events are not viewed as related at all to sexuality by most people.

Sexuality for humans is strongly based on the individual's degree of subjective desire to experience sexual arousal and the degree of interest in expressing that desire. This means that it is an individual's understanding and interpretation that determines whether a particular situation is erotically arousing and whether sexual behavior, either by oneself or with another person, is desirable. It also means that individuals will be different from one another in how interested they are in sexual expression in general. For this reason, sexuality may be considered an aspect of human personality, in fact an important aspect. Human sexual nature involves not simply the functioning of the reproductive organs and related biological systems. It also involves characteristics based on learning, experience, thought processes, acquiring information, forming beliefs, intellectual maturation, the nature of relationships with peers and family members, romantic relationships, societal and cultural values, and religious background.

Importance of Involvement in an Intimate Relationship

For many people, sexuality is strongly linked to involvement in a romantic relationship. Most individuals are interested in becoming involved with a partner in a sexual relationship only when they believe they are in love and in a lasting intimate relationship with that partner. The need to be romantically and intimately involved is not true for everyone in all situations; some individuals engage in casual sex or in extramarital affairs. Yet

quite a bit of evidence suggests that in general most people believe not only that love and sexuality are strongly linked but also that they should be linked. Many believe that intense feelings of love, respect, and devotion must develop within a relationship before a couple engages in sexual behavior.

In fact, research on the way that people think about being in love and being in a romantic relationship indicates that sexual passion and physical intimacy are important aspects of romantic love. Yet sexuality does not rank at the top of the list of qualities involved in romantic relationships. In most people's minds, feelings of emotional closeness, being understood, and valued are the most important attributes of romantic love. Sexual passion and desire for physical closeness, however, distinguish romantic love from love for family and friends.

Given the close association between sexuality and love in common thinking, the strong connection between emotional intimacy and sexual behavior in actual relationships is not at all unexpected. Feelings of shared love and commitment are identified by college students as the most important factors weighing in their decision to engage in sexual intercourse. Research in fact confirms that many couples do not engage in sexual behavior until their relationship reaches substantial levels of emotional intimacy and commitment.

Yet women and men differ substantially in the threshold that justifies beginning sexual behavior in a romantic relationship. Among college students, men on average expect sex to occur after around 10 dates or 6 weeks of dating, while women consider 17 dates or 13 weeks of dating to be the point at which sexual involvement becomes more appropriate. Some couples engage in sex earlier in their relationship than do others, of course. However, those who do begin earlier report greater feelings of love at earlier stages in their relationship than couples who engage in sex later. Again, emotional closeness and commitment tend to run parallel to the tendency to begin a sexual relationship.

Likewise, an important factor influencing whether people believe they would engage in sexual behavior with their relationship partner is the partner behaving toward them in ways that convey feelings of affection and commitment. In particular, behavior that communicates a sense of value

for one's partner, a need for compassion for oneself, or a concern for the well-being of the partner all are associated with an estimation that individuals would engage in sexual behavior with their partner. This is true for both women and men. Being involved in a more serious, permanent relationship additionally strengthens people's belief that they would engage in sex.

Intimacy and love are important aspects of lesbian and gay relationships as well, although very little research has focused on the association of love and sexuality for these couples. Research has also found that lesbian couples engage in sexual behavior primarily following the development of intense closeness and commitment.

Frequency of Sexual Behavior

The frequency of sexual intercourse (i.e., penile-vaginal intercourse, penis in the vagina) varies by the type of relationship in which individuals are engaged. Married heterosexual couples on average engage in sexual intercourse two to three times a week, although heterosexual couples who cohabit (live together, but are not married) do so more frequently, even taking into account other factors such as age and having children. Gay male couples have the highest levels of genital sex; yet lesbian couples have the lowest frequency of all couples. On the other hand, lesbians may tend to engage in more nongenital sexual behavior, such as caressing, touching, kissing, and cuddling.

Frequency of sexual behavior decreases over time for all couples. This is most likely due to declines in physical and sexual functioning related to aging and to the effects of great familiarity and predictability on sexual desire for a relationship partner. One reason that familiarity reduces desire is related to a basic psychological principle called habituation; this is a type of learning in which a stimulus that is experienced repeatedly loses its stimulating properties because individuals become accustomed to it. Increasing familiarity decreases the novelty of a relationship partner, reducing the stimulating nature of sexual interaction with the partner. Another factor that contributes to declining frequency of sexual behavior for couples is the increasing level of demands and responsibilities typical of later adulthood. Lack of time and energy

resulting from tending to work, maintaining a household, and caring for children frequently interferes with time and energy available to many aspects of romantic relationships, including sexual interaction. By middle age, responsibilities may include care for aging parents, as well.

One of the highest quality large studies on sexuality, the National Health and Social Life Survey conducted by Edward Laumann and his colleagues, provides evidence on what sexual behavior women and men find to be most appealing; this study was based on a national probability sample of 3,432 U.S. adults between the ages of 18 and 59. The vast majority of heterosexual women and men of all age groups view penile-vaginal intercourse as the most appealing sexual behavior, with the second most appealing behavior being watching one's partner undress. Receiving and giving oral-genital sex are considered appealing by lower proportions of heterosexuals compared to their views of penile-vaginal intercourse, with men finding oral-genital sex more appealing than women. Nonetheless, on average, over 70 percent of men and women report having engaged in oral-genital sex, although the proportions vary by ethnicity, with White individuals more likely to have done so than Latino and Black individuals. Furthermore, research indicates that approximately 10 percent of heterosexual individuals have engaged in penile-anal intercourse (penis in the anus) in the last year; even greater proportions have engaged in penile-anal intercourse at least once in their lives, approximately 20 percent of both women and men, according to a number of studies, one of them the national survey described above.

A study of 161 married women who recorded all sexual behavior with their husbands over a 21-day period provides evidence about the types of sexual behavior in which married couples engage. When heterosexual couples engage in sexual behavior, it almost always involves penile-vaginal sex, approximately 46 percent of the time it involves fellatio (the man receiving oral-genital sex) and approximately 32 percent of the time it involves cunnilingus (the woman receiving oral-genital sex). Lesbian couples engage in a wide range of sexual behaviors, according to a large survey of the readers of a national magazine focused on lesbian and gay culture. Mutually stimulating genitals with fingers and inserting fingers into the vagina are, however, the

most prevalent. Oral-genital sex is the most common type of sexual behavior among gay male couples, followed by stroking and caressing the body and genitals, again based on another large survey of readers of the lesbian-gay culture magazine.

According to the study of 161 heterosexual women described above, their husbands experience orgasm virtually every time they engage in sexual behavior, whereas the women report that they experience orgasm only about a quarter of the time. A number of studies have found that penile-vaginal intercourse is associated with relatively low levels of orgasm for women, at least in part because it does not always provide the optimal type of stimulation necessary for orgasm. In contrast, women reported that they experience orgasm over 80 percent of the time when their husbands engaged in cunnilingus with them. Direct stimulation of the vulva (the external sexual organs of women), including the clitoris, with either the mouth and tongue or with fingers provides an optimal type of physical stimulation more often leading to orgasm. Sexual satisfaction for these women was related to the consistency with which they experienced orgasms when they engaged in sexual behavior with their husbands (the proportion of orgasms when they had sex) rather than the absolute number of times they experienced orgasm. In other words, it is more important to have good sex almost every time a person has sex rather than to have a lot of good sex. It is not the quantity; it is the quality.

Sexual Satisfaction

In general, frequency of sexual behavior does not seem to be extremely important in how satisfied individuals are with their sexual relationships. Even those who engage in sexual behavior with their spouse or partner infrequently report that they are sexually satisfied, according to the National Health and Social Life Survey by Edward Laumann and his colleagues described previously. The vast majority of people indicated that they are very satisfied with both the physical and the emotional aspects of their sexual relationship. Other research has suggested that the frequency of sexual behavior is at least somewhat related to how satisfied individuals are with their sexual relationship,

which in turn may affect how satisfied they are with their relationship overall. However, it is likely that the frequency of sexual behavior, sexual satisfaction, and overall relationship mutually affect one another.

One study found that husbands who are satisfied with either their sexual relationship or their relationship in general are more interested in engaging in sex with their partner. For wives, satisfaction with their relationship in general was related to greater interest in sex with their partner, although sexual satisfaction was not related. For women, then it is not the quality of the sexual relationship that determines sexual interest, it is how happy a woman is with all aspects of the marriage.

Sexuality is certainly important to the well-being of romantic and marital relationships. Sexual satisfaction is strongly associated with both general relationship satisfaction and with psychological well-being as well. In fact, sexual dissatisfaction has been found to relate to later relationship breakup, for both marriages and for dating relationships, according to a number of different studies.

Role of Personality in Sexuality

As noted at the beginning of this entry, sexuality is a function of the perceptions and interpretations individuals make of the situations they encounter or choose to enter, as well as their understanding of their own sexual nature. This is supported by research that suggests that people differ from one another in their motivation to experience erotic pleasure and in their reactions to sexual issues and situations.

One line of research in this regard has focused on a dimension called erotophobia-erotophilia, the tendency to respond more negatively or more positively to sex-related issues. Erotophobia is the tendency to experience negative emotional reactions (e.g., discomfort, nervousness, revulsion) toward sexual issues and situations. Erotophilia is the tendency to experience positive emotional reactions (e.g., pleasure, delight, interest) toward sexual issues and situations. Erotophobia and erotophilia are the two extremes of a range of possible reaction tendencies, and most people have more moderate or middle-of-the-road reactions to sexual stimulation and issues.

Individuals who have a positive view of sexuality—those who are more erotophilic—are much more likely to experience pleasure and gratification in the sexual behavior in which they engage. Individuals with negative reactions to sexuality—those who are more erotophobic—tend to have less sexual experience than those with more positive reactions to sexuality. During pregnancy, women with more negative reactions to sexuality express less sexual interest and are less interested in engaging in sexual behavior with their partner than women with more positive reactions. They also experience less sexual satisfaction. After the birth of their baby, women with negative reactions to sexuality delay resuming sexual intercourse with their partners longer. They are even less likely to breastfeed their newborn child. Erotophobic individuals also place themselves at greater risk for unwanted pregnancy and sexually transmitted diseases because they tend to avoid learning about contraception methods, tend to rely on more ineffective methods, and underestimate the likelihood of becoming pregnant, further contributing to their tendency to avoid the use of sexual protection techniques.

Another notable personality characteristic that has been examined with respect to sexuality is sociosexuality or sociosexual orientation. This refers to the degree of interest in engaging in sexual behavior outside the context of an intimate, committed relationship. Individuals with a restricted sociosexual orientation express negative feelings toward sexual behavior occurring outside of committed relationship and tend not to engage in such behavior. Those with an unrestricted sociosexual orientation experience positive feelings toward sexual behavior outside of a committed relationship and are likely to have engaged in casual sex. Individuals with an unrestricted sociosexual orientation, relative to those with a restricted orientation, exhibit more non-verbal behaviors indicating interest in a potential partner early in the relationship process, base their selection of romantic partners more on the partners' physical and sexual attractiveness, and engage in sexual behavior earlier in their relationships. Unrestricted individuals characteristically feel less invested, express less love, and experience lower levels of commitment to their relationships.

Sexual Affairs

Sexual behavior with someone other than one's romantic partner while involved in a committed, monogamous relationship is known as extradyadic sex (or extramarital sex in the case of marriage). More commonly, this type of sexual involvement is called an affair. The vast majority of people in the United States consider adultery to be always wrong, and often, involvement in extradyadic relationships substantially destabilizes the primary committed relationship. According to the nationally representative survey by Laumann and his colleague discussed previously, 15 percent of women and 25 percent of men have engaged in extramarital sex at least once in their marriage. Factors related to likelihood of engaging in sexual affairs include unhappiness with the primary, committed relationship; lower sexual satisfaction in the committed relationship, especially for men; longer duration of involvement in a committed relationship; younger age of becoming involved in a committed relationship; and personal characteristics, such as greater interest in sex, more sexual partners before involvement in the committed relationship, liberal sexual attitudes, parental divorce, and preoccupied (anxious) attachment style.

Sexual Coercion

Being forced to engage in sexual behavior against one's will through intimidation, threat, or physical force is known as sexual coercion. According to one national survey, 7 percent of 17- to 23-year-old women have been sexually coerced or raped, and coercion is more likely for girls who first engaged in sexual intercourse before age 13. Between 15 and 25 percent of men have been coerced into unwanted sex, usually through psychological intimidation rather than physical force. One set of factors that may contribute to the likelihood of sexual coercion is the fact that expectations about heterosexual dating and relationships place women and men in different roles. Men are generally expected to take the lead in initiating and controlling relationships, placing them in a position of power that may undermine concerns about the wishes of the woman. Women are

expected to be the caretakers in the relationship, possibly leading them to try to keep the relationship going even in the face of forcefulness and lack of consideration on the part of the man. Other factors contributing to the possibility of sexual coercion are belief in rape myths (sexist attitudes that women want and deserve rape, particularly if they behave provocatively), belief that one's partner is inferior in some way (e.g., coming from an impoverished background), belief that being in a committed relationship privileges one to demand sex, and personal characteristics, such as poor control over one's impulses, inability to empathize with others, being socially dominant, and belief in traditional gender roles in which men have higher status than women.

Importance of Sexuality

Sexuality is an important factor in the psychological and physical well-being of individuals throughout their lives. Sexual satisfaction is very strongly associated with overall happiness with romantic relationships and with psychological well-being. Sexual dissatisfaction actually predicts the ending of relationships as much as 8 years later. Moreover, remaining sexually active into later years of life protects against declines typical of increasing age, as well as being associated with longer life. Sexuality is most certainly an integral component of human experience and quality of life.

SEXUALITY AND ATTACHMENT

Although sexual behavior can serve a variety of physical, emotional, instrumental, or relationship-centered needs, prominent among them are such attachment-related needs as love, acceptance, closeness, intimacy, physical or emotional comfort, and control of access to one's attachment figure. This entry discusses how such attachment-related goals and concerns can affect (a) whether one chooses to engage in sex at all, (b) the reasons one seeks or avoids sexual intimacy, (c) the strategies one chooses to enact these choices, and (d) the objective and subjective results of these choices, such as sexual or relationship satisfaction.

John Bowlby's Attachment Theory proposes that a person's attachment style begins to form during the first 1 1/2 years of life based on the nature of caregiver behaviors toward the infant. These experiences form the basis of expectations concerning the responsiveness and benevolence of others, and of oneself as lovable and deserving of support from others, that pervasively affect social thinking and behavior from the cradle to grave. These individual differences in "attachment style" are associated with differences in preferences for, and active pursuit of, closeness, intimacy, and interdependence with others versus suppression of attachment needs, distancing behaviors, independence, and self-reliance. Attachment style is also associated with self-esteem, confidence, worry, and

other expectations and emotions that affect the person's projections of how others are likely to react to him or her.

Because sexual behavior involves physical intimacy and can involve emotional intimacy, it can provide an important mechanism for regulating intimacy. As with any interpersonal behavior, sexual behaviors can affect one's reputation or relationships with others. Sexual attractiveness and performance are often central to the ability to attract and keep romantic partners, and therefore affect one's ability to satisfy needs for love, closeness, and intimacy. Partners may become more attracted and committed as a result of satisfying sexual interactions or disinterested as a result of less satisfying interactions. Sexual attractiveness can also be central to social status and to approval from others. For these reasons, sexual behavior can provide a mechanism for increasing love, closeness, and commitment from sexual partners; promoting positive reactions to oneself; self-esteem enhancement; and promotion of social status. Sexual behavior for these purposes is more likely among those who value such outcomes and who believe others are likely to react positively to them as sexual beings.

Attachment style fundamentally reflects differences in these feelings and motives. Secure persons are comfortable with intimacy, enjoy high self-esteem and self-confidence, and do not tend to worry about their ability to elicit positive regard from others. Anxious persons have great desire for intimacy, but experience low self-esteem and heightened worry over others' love, availability, and positive regard. These worries are central to anxious persons' thinking and provide a prominent motive for behavior (hyperactivation of attachment needs). Avoidant persons prefer to minimize intimacy and emphasize self-reliance, personal competence, and mastery (deactivation of attachment needs). These orientations are pervasively reflected in the way that persons with varying attachment styles think about sex and in their choices of whether, when, how, and with whom to have sex.

Sexual Desire and Engagement

To the extent that sex is associated with intimacy, anxious persons' hyperactivated attachment needs

can promote increased sexual motivation, whereas avoidant persons' deactivated attachment needs can undermine it. Although sexual behavior is more likely when sexual motivation is high, attachment-related concerns can simultaneously promote interest and undermine overt sexual behavior. Sexual anxiety and worry about performance are high among both anxious and avoidant persons. Anxious persons tend to view sexual behavior in terms of attachment-related implications (such as gaining a partner's love, acceptance, and commitment), whereas avoidant persons are more likely to view sex in terms of self-enhancing motives such as self-esteem or social status. Excessive worry over love, rejection, appearances, or social prestige can create anxiety about others' reactions, undermine self-confidence, discourage initiation of sexual activity, and interfere with physiological sexual arousal.

Secure persons, who are low in both anxiety and avoidance, can engage in sexuality relatively free from interference by attachment concerns, anxiety, or lack of sexual self-confidence. However, avoidant persons appear to experience a double whammy of dampening influences on sexuality. That is, their preference to minimize closeness and intimacy dampens the desire for physical and emotional closeness, and higher sexual anxiety and worry over performance interfere with arousal, performance, and enjoyment.

These influences are reflected in a variety of overt sexual behaviors. Avoidant attachment is associated with greater discomfort with touch, having first sex at a later age, less frequent sex (generally and also within the context of ongoing relationships), dissatisfaction with the frequency of sex (more sex than wanted, particularly for females), and reported efforts to avoid sex with existing partners. Despite this general avoidance of sex with partners, avoidant persons report more frequent masturbation.

In contrast, anxious persons experience contradictory influences on sexual motivation. Chronic worry about partners' continuing love and commitment fuels higher sexual desire as a way to achieve reassurance and enhance partner love and commitment; but attachment anxiety is also associated with worry over partners' potential reactions, lower sexual self-confidence, sexual anxiety, and other concerns that may inhibit overt efforts

to have sex—with somewhat different results for the two genders. Generally, attachment anxiety is associated with greater overall motivation to have sex and with less loss of sexual passion for relationship partners over time. Among females, anxiety is associated with having first intercourse at a younger age, greater likelihood of having sex during adolescence, and greater reported sexual motivation. Although anxious males also report greater sexual motivation, they tend to have less sex, and tend to report greater dissatisfaction with the frequency of sex (less than wanted).

Anxious persons' enhanced worry about others' reactions tends to lead them to defer to others' wishes, and they report greater tendencies to defer to their partners' sexual preferences. Overall, females prefer to defer sex until later in relationship development and prefer less frequent sex than males. Therefore, when anxious males defer to partners, they have sex later and less frequently than desired; and when they do have sex, it tends to be in more committed relationships. The reverse pattern occurs when anxious females defer to male partners.

Attachment Motives Are Reflected in Overt Sexual Behaviors

The core regulatory motives associated with attachment style, most prominently the regulation of closeness and intimacy, affect the motives underlying sexual behavior, as well as the context and manner in which sexuality occurs.

Motives for Having Sex

Reported reasons for having sex prominently include expressing and receiving love, reassurance of a partner's love and commitment, emotional closeness, and maintaining access to a partner. Such motives tend to be exaggerated among anxious persons and suppressed among avoidant persons. Instead, avoidant persons tend to report self-enhancing motives of fitting in, impressing others or gaining peer acceptance, or motives to control a partner or to manage distress. Even motives for cheating on one's partner reflect attachment concerns. Anxious persons tend to report cheating to achieve closeness and to feel

loved, whereas avoidant persons tend to report cheating to gain freedom or distance from a primary partner.

Relationship Contexts for Sex

Attachment motives are reflected in the contexts for sex. Secure persons tend to prefer having sex within committed romantic relationships and report less casual sex with strangers or acquaintances. Anxious persons also express desire for long-term relationships, but nevertheless engage in more uncommitted forms of sex than secure persons do. This occurs in part because their enhanced desire for closeness and intimacy leads to more rapid infatuation with potential partners and in part due to their deference to partners' preferences. For anxious women, deference to partners can promote earlier sexual engagement in less committed relationships, but can result in the opposite pattern for anxious men.

Avoidant persons' distancing motives tend to lead them to view casual or emotionless sex positively, and to engage in sex in a variety of less intimate uncommitted contexts, such as with strangers or casual acquaintances. They express less interest in long-term commitments and are more likely to cheat on their own relationship partners and to poach those of others.

Choice of Sexual Activities

Because specific sexual activities vary in physical and/or emotional intimacy, it is not surprising that intimacy regulation motives affect the choice of specific sexual activities. Both anxious and avoidant persons have a more restricted approach to sexuality and are less prone to (nondeviant) sexual experimentation. Further, whereas anxious persons appear to enjoy affectionate intimate behaviors such as kissing and cuddling more than genital sex, avoidant persons eschew such behaviors in favor of strictly genital sex and tend to lose their virginity with less experience of noncoital foreplay than persons of other attachment styles.

Attachment motives also affect "safe-sex" practices. For example, insistence on condom use may interrupt the flow of sexual activities, risking disengagement or partner disapproval. Anxious persons' greater concern with pleasing partners and

avoiding rejection can inhibit condom use for these reasons. Condoms may be viewed as a barrier to intimacy, interfering with complete physical closeness and intimacy; in some persons, a conscious or subconscious desire to conceive may interfere with use of protection. The desire for a baby may derive from attachment needs to love and be loved and is more characteristic of anxious persons, particularly women. Reflecting these concerns, anxious attachment is associated with more negative attitudes toward and less use of condoms, less discussion of safe sex with partners, and greater rates of unplanned pregnancy; whereas avoidant attachment is associated with more discussions of safe sex and positive attitudes toward and greater use of condoms.

Strategies of Goal Pursuit Affect Sexual Behavior

Ideally, sex is pursued through open, effective communication with potential partners and mutual expression, negotiation, and satisfaction of both persons' needs. However, both forms of insecurity are associated with deficits that affect the way sexual goals are pursued, including lower sexual self-confidence, more negative appraisals of partners and their behaviors, greater difficulties controlling emotions, use of drugs or alcohol in sexual contexts (to manage sex-related worries), inhibited and ineffective sexual communication with partners, lesser mutuality, and less effective and more coercive strategies for negotiating sexual encounters. Extreme deficits in these areas may underlie the relationship of attachment insecurity to sexual offender status. Although the exact nature and magnitude of these deficits differ sometimes for anxious versus avoidant persons, attachment insecurity is related to sexually coercive behaviors among nonoffender populations.

Subjective Sexual Experiences and Outcomes

Secure attachment is presumed to underlie positive attitudes toward self and others and is crucial to the formation of mutually satisfactory close relationships. Therefore, it is not surprising that attachment is related to feelings about sex,

sexual partners, and oneself as a sexual being. Secure persons report more positive and less negative emotions in sexual relationships, more enjoyment of sex, and more positive appraisals of sexual aspects of themselves than insecure persons.

As with relationships in general, both anxious and avoidant persons report more dissatisfaction with sex, in part, as a result of enhanced sexual anxiety and performance concerns that can interfere with relaxation and enjoyment. However, reflecting attachment needs, anxious persons report dissatisfaction with the romantic, affectionate aspects of sex, whereas avoidant persons report dissatisfaction with the physical aspects of sex, and both report dissatisfaction with the control of sexual activities.

Attachment can affect the link between these reactions to sexual activities and feelings about romantic partners. Because anxious persons tend to use sexual activities to satisfy needs for intimacy and confidence in being loved, and tend to interpret sexual interest as a sign of love and approval, sexual experiences more strongly affect overall relationship satisfaction for anxious persons than for avoidant or secure persons. Also, because worries over love and acceptance can translate into worries and anxieties during sex, positive and negative relationship experiences exert greater influence on sexual experiences among anxious persons.

Conclusion

This entry has discussed how attachment concerns influence sexual motivation, sexual behavior, and feelings about sexual activities and partners. However, it should also be noted that the relationship between attachment and sexuality is bidirectional. Infatuation, sexual attraction, and sexual behavior can initiate and facilitate consolidation of the attachment bond, and problems with sex can undermine existing attachment bonds.

SEXUALITY IN ADOLESCENT RELATIONSHIPS

A normative aspect of the adolescent period is sexual exploration and associated decision making regarding how “far to go” sexually. Transitioning from being a virgin to a sexually active teen is meaningful in terms of both personal and social identity. Teenagers may view sex with a boyfriend or girlfriend as a step toward greater commitment and intimacy in their relationship. It also represents a developmental marker toward adulthood and sets the groundwork for later adult sexual relationships. At the same time, teenage sexual intercourse is a public issue in part because of health concerns stemming from sexually transmitted infections, involuntary sex, and teenage pregnancy.

Sexuality is a broad concept and can refer to many types of sexual behaviors, attitudes, and desires, not just sexual intercourse. Recently, researchers have paid more attention to sexual activities besides sexual intercourse, such as oral sex. Oral sex among adolescents is of interest because of sexual health risks associated with oral sex and the notion that oral sex is a way to satisfy sexual desires and maintain virginity and avoid pregnancy. There is a sense that oral sex is the precursor to sexual intercourse. Although it is important to consider a full range of sexual behaviors (e.g., masturbation, genital stimulation, anal sex, oral sex), this entry focuses on sexual intercourse. This approach could result in excluding sexual minority youth, so they are showcased later in the entry.

Trends

The context of teenage sexuality has changed. In 1950, the median age at marriage for women was 20, so a considerable proportion of teenage sex occurred within the confines of marriage. Today, the average age at marriage is 25.5 for women; as a result, most teenage sex occurs outside of marriage.

Despite the media and public concerns, there has been a slight decline in the proportion of teens who report that they have had sexual intercourse. In 1995, 53 percent of high school students reported having had sex, and in 2005, 47 percent did so. Thus, a considerable proportion of teenagers have not had sexual intercourse prior to graduation. Further, most teens did not recently have sex; only about one third of high school students report having had sexual intercourse in the last 3 months. When studying the sexual behavior of adolescents, it is important to consider their specific ages because the proportion of sexually active youth increases by age, suggesting an important developmental trend. For example, according to the 2002 National Survey of Family Growth, 13 percent of 15-year-olds have had sexual intercourse, but about half of 18-year-olds and 70 percent of 19-year-olds report ever having had sexual intercourse.

Sexual Initiation

Decisions about initiating sexual intercourse include a range of motivations, such as social factors including parental or peer approval/disapproval, opportunities for sexual activity, romantic relationship dynamics, religious beliefs, and perceptions of health beliefs and pregnancy risks. Recent longitudinal analyses, which have included all of these factors, suggest that peer social network behavior and relationship dynamics—being in love, religious beliefs, and opportunity—are significantly related to whether teens initiate sex. Furthermore, situational context factors such as alcohol and drug use have been found to influence sexual initiation. Some research focuses on the voluntary nature of sexual activity and finds that alcohol and drugs are tied to regrettable or involuntary sexual experiences. Thus, the decision

to initiate sexual activity is complex and involves multiple perceptual, social, and interactional domains.

Considerable research attention has been focused on the age in which teens first engage in sexual intercourse. Concerns exist about teens engaging in sexual activity too young based, in part, on empirical evidence that earlier sex is associated with involuntary sex, greater numbers of lifetime sexual partners, and lower and inconsistent contraceptive use. Although the average age at first sex is 17 in the United States, a small subgroup of teens report having had sex at a relatively early age. In 2002, about 14 percent of girls reported having sex prior to age 15; this represents a decline from 20 percent in 1995. Race/ethnicity differences in age at first intercourse exist, with a greater percentage of African-American youth having had sexual intercourse at earlier ages than White or Hispanic youth. Adolescent males are more likely to initiate sexual intercourse at younger ages than adolescent females. Alcohol use is cited by some young teens as a factor associated with initiating consensual sexual intercourse. The vast majority of teenagers' first sexual experiences are with a boyfriend or girlfriend or within the confines of a dating relationship.

Research on very young ages at sexual initiation has focused on statutory rape and involuntary sex. The age at consent differs according to state (most often age 16) and often includes a provision for a legal age gap between partners. Controversy centers around the inconsistent enforcement of these laws. Estimates vary, but nearly one fifth of girls who had sex before age 14 or younger reported it was involuntary.

Sexual Experience

Although nearly half of teens report having had sex prior to age 18, the regularity/frequency of sex and the number of sex partners, on average, are not high. In 2002, the median number of lifetime sexual partners among sexually active 15- to 19-year-old girls and boys was two to three. An indicator of the irregularity of sexual activity is that only about one quarter of sexually active teens had sex during the month prior to being interviewed. Yet among those who did have sex in

the last month, about 60 percent of girls and 50 percent of boys had sex four or more times.

Although most teenagers initiate sex with a boyfriend or girlfriend, they may go on later to have sex with someone outside of a dating relationship context. About 60 percent of sexually active teens have had sex at some point with someone they were not dating. However, these nondating sexual relationships are often with friends or ex-boyfriends and girlfriends, and about one third would like to be romantically involved with the sexual partner. Moreover, most teens agree it is best to have sex with someone they love.

Not all teenage sexual relationships share the same norms of fidelity associated with formal adult relationships, such as marriage. Most sexually active teens are monogamous, but to assess cheating behavior, the focus needs to be on teens who have had sex with more than one sexual partner. Two fifths (40 percent) of teens with two or more sexual partners in the 18 months prior to the Longitudinal Survey of Adolescent Health (national survey of 18,924 teens in 1994–1995) had concurrent (overlapping partners), and 60 percent had sequential partnerships. Indeed, some teens in dating relationships report it is okay to see others, and approximately one fifth of dating teens reported their partner was not sexually exclusive.

Correlates

Parents are a key socializing agent and have been found to influence adolescent sexual activity. Nontraditional family structure, lack of supervision, perceived parental approval of teenage sexual behavior, and lower parental attachment are associated with an earlier age of sexual onset. Attachment styles developed with parents are associated with sexual activity initiation, with more securely attached teens having later and more positive experiences.

During adolescence, teens shift away from their family as the primary source of influence, and peers become an important socializing influence, especially in the area of sexual exploration. Studies find that having sexually active friends (or the perception that one's friends are sexually active) and peers with liberal attitudes are related to earlier onset of sexual intercourse. Ethnographic and

qualitative research by Elijah Anderson as well as Donna Eder has shown how peer interactions influence views about romance and sexuality, specifically how peer socialization results in distinctively gendered meanings about romance and sexuality, with boys viewing romance as a competitive game where sex is the prize and girls valuing romance and the development of intimacy.

Not surprisingly, having a boyfriend/girlfriend is associated with sexual initiation and activity. H. Harrington Cleveland has accounted for both partners' characteristics and finds that sexual experience of both partners' delinquency and drinking is related to the odds that sex occurred. More attention to characteristics of teenage relationships by Peggy Giordano and colleagues indicates that intimate self-disclosure, caring, and other forms of emotional engagement are positively related to the likelihood of sexual behavior in dating relationships. Healthy or prosocial relationship dynamics are significant predictors of sexual intercourse, and the evidence suggests that boys as well as girls are influenced in their sexual decisions by relationship-centered processes and dynamics.

Research highlighting some of the prosocial characteristics of relationships associated with sexual initiation is important because much prior research has viewed adolescent sexuality through a problem behavior lens, linking sexual behaviors to delinquency, drug and alcohol use, violence, depressive symptoms, smoking and school dropout, or poor academic performance. Researchers have begun to uncover how these problem behaviors are tied together and have recognized that not all teenage sexual behavior is part of a package of high-risk behaviors.

Douglas Kirby's recent review of sex education programs shows that programs which educate teens about contraception as well as encourage abstinence are positively related to delaying sexual and using contraception. To date, programs with an abstinence-only message are not associated with changes in adolescent sexual behavior. One effort to encourage sexual initiation delay that has had some reported success are virginity pledges, which are an effort to provide a community of adolescents who vow to wait to marry before having sex. Peter Bearman and colleagues find that virginity pledges matter for certain teens between ages 14 and 16, but notably are also related to

lower contraceptive use when youths who have taken such pledges do have sex.

Social scientists are beginning to connect how social factors are interlinked with biology in influencing sexual behavior. Adolescents are undergoing biological changes in terms of puberty and hormonal shifts, which have consequences for their physical appearance and sexual desires. Currently, puberty for girls occurs around age 12, suggesting a decline in the age of puberty. New data collections, which include biomarker data, will provide opportunities for innovative studies of the intersection of biology and social indicators on adolescent sexual behavior.

Sexual Minority Youth

Most of the research on adolescent sexual behavior focuses on opposite sex sexual behavior and has ignored sexual minority (gay and lesbian) youth. Attention to sexual minority youth and sexuality often centers on concerns about sexual health, specifically HIV. Measurement challenges persist in identifying gay and lesbian teens, in part, because sexual identity in adolescence may be more fluid than in adulthood as teens struggle to understand their sexual orientation. New work has shown that gay and lesbian teens often engage in heterosexual relationships and have had sex with the opposite sex. At the same time, some teens who identify as heterosexual also have had same-sex sexual relationships in adolescence. Lisa Diamond, Rich Savin-Williams, and Stephen Russell's research has been important groundwork on the sexuality of gay and lesbian teens. It is sometimes difficult for teens who are developing same-sex attractions to deal with potential stigma and lack of norms about how to proceed in relationships, especially during a time when conformity is stressed. Much has been written about depression and alcohol use of sexual minority teens, but additional work should focus on those who successfully explore their sexuality.

Consequences

There has been much attention focused on the negative consequences of teenage sexual activity. Most often the health consequences of adolescent

sexual intercourse are highlighted. For instance, recent statistics indicate that 1 in 10 teens has a sexually transmitted infection, about one fifth of young adults reported their first sex was unintended, 750,000 teens get pregnant each year, 82 percent of teen pregnancies were unplanned, and 23 percent of children born out of wedlock were born to teen mothers. More recent research has evaluated the psychological consequences of sexual intercourse, stressing the potential effects on depression. Initiating of sexual activity is associated with increases in depressive symptoms even when accounting for depressive symptoms prior to sexual initiation. To best understand the implications of teenage sex requires sophisticated modeling and longitudinal designs that attempt to address causality and selection issues. Furthermore, it is important to move away from just deficit or problem-centered approaches and incorporate perspectives that acknowledge the potentially healthy and appropriate ways that sexual activity may be integrated into adolescent lives.

SEXUALLY TRANSMITTED DISEASES AND RELATIONSHIPS

Sexually transmitted diseases (STDs), which are also referred to as sexually transmitted infections (STIs), are illnesses that have a significant probability of transmission in humans through sexual contact, including penile–vaginal intercourse, oral–genital contact, oral–anal contact, and penile–anal sex. Some STDs can also be spread via skin-to-skin contact such as rubbing or petting, childbirth, breastfeeding, and sharing needles. STDs have been in existence for hundreds of years.

There are several types of STDs, including bacterial, viral, fungal, protozoal, parasitic, and enteric infections. The incidence rates of STDs remain high in most of the world; however, proper therapeutic treatment can cure most of these. The widespread dissemination of antibiotics for a number of bacterial infections has resulted in mutations in some bacterial forms of STDs, producing strains

that are resistant to traditional drug therapies. These strains often require more aggressive treatments with potent antibiotics and are typically more costly than traditional treatments. Many STDs, particularly in women, do not cause symptoms. Therefore, asymptomatic individuals may unknowingly transmit an STD to their sexual partner(s).

In the United States, chlamydia is the most frequently reported bacterial sexually transmitted disease. In 2006, for example, 1,030,911 chlamydial infections were reported to the Centers for Disease Control and Prevention (CDC) from 50 states and the District of Columbia. Gonorrhea is the second most commonly reported STD. The CDC estimates that more than 700,000 persons in the United States get new gonorrheal infections each year. Only about half of these infections are reported to CDC. In 2006, for instance, 358,366 cases of gonorrhea were reported to CDC. Other STDs, including the Human Immunodeficiency Virus (HIV), are less common but still prevalent within the United States. According to the CDC, adolescents and young adults under the age of 25 years are most likely to be infected with STDs, although there has been a rise in prevalence among older adults in recent years. Many scientists believe that the increased rates of STD, including HIV, among older adults are related to the prevalence of divorce and the increase in life expectancy. Older adults may be more likely than ever before to be dating and having sex with new partners. However, these same individuals may be less likely to use condoms or be tested for STDs because they came of age in generations prior to the HIV pandemic and STD education and prevention campaigns.

Although the proper and consistent use of male latex condoms has proved to greatly reduce the likelihood of STD transmission, condom usage rates remain low. Among individuals who do use condoms, condom use errors may result in failures that place individuals at risk for disease exposure and transmission. Common condom errors identified in research include condom breakage, slippage, and using the same condom for multiple sexual behaviors within a sexual event (e.g., vaginal and anal intercourse). One explanation for the lack of condom use is attributed to condom negotiation skills. In new relationships, individuals may be embarrassed to explicitly discuss sexual behaviors,

which may make it unlikely that condom use will be negotiated. Individuals also report that discussing condom use decreases the spontaneity of a sexual event—they ruin the mood. Further, many men and women do not like to use condoms because of the way that they feel. For example, some men find it more difficult to maintain an erection when using condoms, while women often report that condoms dry out natural vaginal lubrication, making sex uncomfortable.

Research has demonstrated that, even among couples who use condoms consistently at the beginning of a relationship, people are less likely to do so as the relationships progresses. As a relationship develops, couples often stop using condoms because they feel they are no longer necessary. In heterosexual relationships, this is often attributed to the use of hormonal contraception by the woman. Individuals assume that they are in committed relationships, thus when pregnancy and disease are no longer thought to be issues, condom use declines drastically. In addition, many people believe that condoms act as barriers to intimacy and trust—if you trust your partner is monogamous, there is no need to use condoms.

Even in relationships that are thought to be exclusive or monogamous, extrarelational sex may occur. Although the rates of infidelity are difficult to estimate due to the sensitive nature of the topic, conservative estimates place rates of extramarital relationships at one in three. Among unmarried couples, rates are even more difficult to gauge; however, it is likely that they may be similar to those of married couples. Among individuals who are exclusive and monogamous in their relationships, serial monogamy or multiple exclusive relationships may make it likely that a person could accrue a high number of sexual partners over time. Whether through extrarelational sex or serial monogamy, an individual may be exposed to an STD while he or she is engaged in what is believed to be a committed relationship. Commonly, individuals who contract an STD within the context of a relationship will experience a range of emotions, ranging from betrayal to anger. Some may feel that their partner knowingly “gave” them an STD; however, in some cases, their partner may not be aware that he or she is infected.

In most cases, it is likely that a person does not knowingly infect his or her partner with an STD.

Aside from not knowing that he or she is infected, a person may not disclose his or her STD status because he or she fears rejection, retribution, or accusations of infidelity. If the relationship is of a casual nature or a “one-night stand,” contacting a partner to notify them may be difficult. In established relationships, it is common for partners to reinfect one another with STDs. Reinfection can occur for a number of reasons, although typically it results from one or both partners not completing their treatment or resuming sexual contact before the disease/infection has cleared the body.

STDs not only affect an individual’s physical health, but they can have a major impact on psychological functioning. STDs can also have a number of implications for the quality and endurance of sexual relationships. For these reasons, it is important that those entering new sexual relationships be screened for STDs prior to having sexual contact with their new partner. It is also important to use condoms consistently and correctly. Perhaps the most important methods of prevention of STDs within both new and established relationships is open and honest communication between partners, which includes disclosing STD status.

SEXUAL MOTIVES

The term *sexual motives* refers to the underlying reasons for, or purposes served by, sexual behavior. Typically assessed through self-report, motives or reasons represent a person’s own understanding of *why* he or she has sex and thus provide an important window onto the meaning that individuals ascribe to their sexual experiences. According to this perspective, sexual behavior motivated by different needs or goals should be triggered by unique antecedents, characterized by qualitatively different styles of behavior and emotions, and ultimately result in distinct consequences. This entry (a) distinguishes sexual motives from related feelings, desires, and thoughts and then identifies the most important goals thought to underlie and drive sexual behavior; (b) describes patterns of endorsement; and (c) reviews research linking these motives to unique patterns of sexual behavior and outcomes.

How Are Sexual Motives Different From Other Sexual Feelings and Thoughts?

Sexual desire or lust is experienced as an interest in sexual activities, a drive to seek out sexual objects, or a wish, need, or craving for sexual contact. Sexual thoughts refer to cognitive representations of sexual activity, such as fantasies, whereas sexual emotions include specific emotions experienced in connection with sex, such as jealousy, joy, and passion, as well as more general emotional responses to sexual stimuli, known as *erotophilia* (a positive emotional response) and *erotophobia* (a negative emotional response). Although sexual desire, thoughts, and emotions typically co-occur with sexual motives, they are readily distinguishable. For example, an individual may desire and fantasize about having sex with her partner because she wants to strengthen an emotional bond or because she wants to experience specific physical sensations. In both cases, the intensity or frequency of sexual desire and fantasy may be similar, but the needs or goals the person hopes to satisfy differ. Similarly, an individual may experience positive emotions in connection with a sexual experience regardless of whether the sexual

experience was primarily motivated by a need to connect with one's partner, bolster one's self-esteem, or have a physically exciting sexual encounter.

Motives are typically measured by asking individuals to rate the relative importance of different reasons for having sex (e.g., In general, how important is expressing love for your partner?) or to report the frequency with which they have sex for different reasons (e.g., How often do you have sex to avoid a fight or hassle with your partner?). Dispositional or trait-like measures that focus on usual or typical reasons for having sex have been used, as well as more specific measures that assess reasons for having sex on a particular occasion (e.g., at last sex) or with a particular partner.

Why Do People Have Sex?

Having sex to promote intimacy and to enhance one's physical or emotional pleasure are the most common reasons for having sex. Other less commonly reported motives for sex that nonetheless have important consequences for sexual experience include: to cope with negative emotions (coping motives) or affirm one's self-worth (affirmation motives); to please or appease one's partner (partner approval motives) or alternatively, to dominate or control him or her (power motives); and, finally, to fit in with, or avoid censure by, peers (peer approval motives). Although procreation is clearly an important motive in an evolutionary sense, research shows that only a small percentage of all intercourse occasions is motivated by a desire to conceive and, moreover, that people actively try not to conceive in the vast majority of instances. Thus, an explicit desire to procreate cannot account for most day-to-day sexual experiences.

As discussed, intimacy and enhancement motives are the two most common reasons for having sex, and this is true for men and women, Blacks and Whites, adolescents and college students, as well as single individuals and their coupled counterparts. Interestingly, however, which of these two motives is more important is less consistent. In young, predominantly White samples, men more strongly endorse enhancement (than intimacy) motives, whereas women more strongly endorse intimacy (than enhancement) motives. In contrast, in the

only study ever conducted among middle-age adults, the reverse pattern was found (women more strongly endorsed enhancement, men intimacy), and in the only study to examine this issue among Blacks, no gender difference in the strength of endorsement of the two motives was found. Finally, patterns of endorsement have also been shown to differ as a function of relationship status. Compared with unattached individuals, people in committed relationships reported higher levels of intimacy motives and lower levels of all other motives, except for enhancement, which did not differ.

The Underlying Structure of Motives

Past research characterizes sexual motives along two dimensions: (1) approach versus avoidance and (2) self-focus versus other focus. The approach-avoidance dimension distinguishes behaviors that involve the pursuit of positive or pleasurable experiences (approach or appetitive behaviors) from those that involve the avoidance of, or escape from, negative or painful ones (avoidance or aversive behaviors). Behaviors motivated by approach goals are thought to be rooted in the behavioral activation system, a complex, biologically based system that controls reward-seeking behaviors (e.g., adventure seeking) and the experience of positive emotions, whereas behaviors motivated by avoidance goals are thought to be rooted in the behavioral inhibition system, a similarly complex biological system that controls responses to threat and punishment (e.g., fearful behavior) and the experience of negative emotions. The second dimension distinguishes behaviors that are primarily internally, self-focused, self-directed, and self-controlled from those that are primarily externally or socially focused and controlled. Behaviors motivated by self-focused goals are thought to serve agentic, identity, or autonomy/competence needs, whereas behaviors motivated by other-focused goals are thought to serve attachment or communal needs.

Both theoretical and empirical considerations indicate that intimacy is high on approach and other focus, whereas enhancement is high on approach and self-focus. In contrast, all of the less commonly endorsed reasons for having sex are high on avoidance, although some are primarily

self-focused (e.g., having sex to prove your attractiveness) and others are primarily other focused (e.g., having sex to avoid angering your partner). Conceptualizing motives in terms of these dimensions provides a useful framework for thinking about the meaning and consequences of sexual experience motivated by different needs or goals.

Approach Motives for Sex: Consequences and Correlates

People who have sex for approach reasons, by definition, seek a positive or rewarding outcome, be it a closer connection with their partner or a physically enjoyable experience. Accordingly, sexual behavior among such individuals should be seen as a way to obtain benefits and achieve important life goals. Consistent with this expectation, both intimacy and enhancement motives have been strongly associated with more frequent intercourse, positive feelings about sex, and higher levels of sexual satisfaction. At the same time, the contexts in which sexual experiences occur should differ for people who have sex to build intimacy versus to enhance. Consistent with this idea, high-intimacy-motive individuals endorse a stronger general need for intimacy and have fewer, less risky, and better-known sexual partners than their low-motive counterparts, whereas high-enhancement individuals report stronger thrill and adventure-seeking needs, more permissive attitudes toward casual, uncommitted, more sex partners (especially casual ones), and more risky sex practices. Overall, then, the data suggest that individuals high in intimacy motives gravitate toward environments conducive to the satisfaction of these needs (*viz.*, committed relationship contexts), whereas those primarily high in enhancement gravitate toward environments better suited to the satisfaction of their particular needs (*viz.*, casual or novel sexual contexts).

Avoidance Motives for Sex: Consequences and Correlates

People who have sex for avoidance reasons, by definition, have sex to escape from, minimize, or avoid aversive states or anticipated negative outcomes, such as negative moods, fear of inadequacy,

or rejection by others. In turn, this negative orientation or focus is thought to evoke processes that undermine the quality of sexual interactions and the development of intimate bonds, including negatively biased perceptions (e.g., assuming the worst about one's partner's intentions), attention (e.g., focusing on negative partner qualities), memories (e.g., remembering hurtful experiences), emotions (e.g., fearing one's partner), and behaviors (e.g., turning a cold shoulder). Not surprisingly, then, avoidance motives for sex have been consistently associated with erotophobic responses to sex and low levels of sexual satisfaction. Interestingly, however, two avoidance motives—coping and affirmation—have also been associated with higher sexual desire and erotophilic responses to sex, thus suggesting an ambivalent, or approach–avoidant, orientation toward sex among individuals high in these motives.

Finally, the focus on negative experiences or possibilities thought to characterize avoidance goal pursuit not only generates anxiety, distress, and dissatisfaction, but also interferes with clear thinking and constructive action. Accordingly, sexual behaviors motivated by avoidance concerns should also be riskier. This expectation has been most strongly supported for partner approval motives, with individuals high in partner approval reporting greater involvement in risky sexual practices, less birth-control use, and higher rates of unplanned pregnancies presumably because they are reluctant to assert themselves and risk partner disapproval. Also consistent with this interpretation, both women and their sexual partners report higher levels of sexual coercion by the male partner when the female partner is high in partner approval motives.

Individuals high in avoidant coping motives show an interesting “promiscuous-but-safe” pattern: They report more casual sex partners, but better birth-control use and fewer unplanned pregnancies. High avoidance-coping individuals also report more frequent masturbation, and both they and their partners report fewer displays of romantic affection. Together, these findings suggest a calculated, impersonal quality to the sexual experiences of high avoidance-coping individuals, an interpretation that fits with the greater self- (vs. other) focus thought to underlie this motive.

Are Motive Effects Similar For Men and Women and Across Relationship Contexts?

Although only a few studies have addressed these issues, their results nevertheless indicate that both gender and relationship context matter in important ways. First, motives predict sexual behavior more strongly among single individuals than among their coupled counterparts, thus suggesting that sexual behavior is more strongly shaped by the partner's needs and desires in close, committed relationships than in casual ones, where each individual is freer to pursue his or her own needs. Second, whereas the effects of avoidance motives appear to be largely harmful regardless of relationship context, the effects of approach motives are more conditional. For example, enhancement motives have been associated with increased protective behaviors (e.g., condom use) among single individuals, but with decreased protective behaviors in close relationships, whereas the reverse pattern was found for intimacy motives and protective behaviors. Third, in the only study of motives to use couples (as opposed to individuals), both one's own and one's partner's motives were found to shape the male partner's sexual experience, but not the female partner's experience. Finally, this same study also found strong evidence that both partners' motives combine in a synergistic fashion or interact to shape the couple's sexual experience. For example, male enhancement motives were found to interact with female partner approval motives to predict intercourse frequency (as reported by both the male and female partner) such that male enhancement more strongly predicted the frequency of sexual relations when the woman was high versus low in partner approval motive. This pattern was observed across multiple sexual outcomes, thus providing strong evidence that women who have sex primarily to appease their partner do in fact conform more to their partner's preferences. The same pattern was not, however, found among men high in partner approval motives.

Concluding Remarks

In short, the reasons that people have sex matters. People who have sex for approach reasons

consistently report more positive and rewarding sexual experiences, whereas those who have sex for avoidance reasons report more unpleasant and dissatisfying ones. Behavior patterns associated with specific motives do not, however, reduce to a simple approach-adaptive versus avoidant-maladaptive distinction, but also appear to be selectively channeled to more impersonal versus intimate relational contexts, respectively, by the extent to which one is focused internally on one's own needs or externally on more communal or social needs. Thus, it is the unique combination of both underlying dimensions—approach versus avoidance and self versus other—that shapes how sexuality is expressed. Finally, despite a limited empirical base, current evidence strongly suggests that both gender and relationship context profoundly affect how sexual motives are expressed and, consequently, how they shape sexual behavior.

SEXUAL PREJUDICE

Sexual prejudice refers to negative or hostile attitudes against an individual or group based on the latter's sexual orientation. Such prejudice can potentially be directed at anyone regardless of whether they are heterosexual, homosexual, or bisexual. Viewed within its broader cultural context, however, sexual prejudice is best understood as the individual expression of *sexual stigma*, the inferior status that society collectively accords to same-sex sexual desire, homosexual behavior, nonheterosexual intimate relationships, and sexual minority identities and communities. Insofar as it is the internalization of sexual stigma, sexual prejudice represents an individual's endorsement of an ideological system that disempowers sexual minorities, creates institutional barriers to their full participation in society, and fosters enactments of stigma against them, including extreme violence. Thus, as used here, sexual prejudice refers specifically to heterosexuals' negative attitudes toward sexual minorities and toward nonheterosexual desires, behaviors, identities, relationships, and communities. This entry describes sexual prejudice and other phenomena associated with sexual stigma; discusses some of their demographic, social, and psychological correlates; and explains some of the ways that sexual prejudice and stigma affect interpersonal relationships.

Sexual Prejudice and "Homophobia"

Sexual prejudice has come to be recognized as a socially significant phenomenon worthy of scientific research only recently as a consequence of shifts in cultural constructions of human sexuality, gender, and minority rights. Sexual stigma has long been manifested in religion, the law, and other social institutions whose ideologies and practices work to the disadvantage of sexual minority groups. This structural stigma—also referred to as *heterosexism*—operates even in the absence of individual prejudice or discrimination. It functions to make nonheterosexuals largely invisible, and, when they become visible, it promotes the assumption that they are inferior to heterosexuals and deserve ostracism, discrimination, and even violence.

The legitimacy of sexual stigma went largely unquestioned for much of the 20th century. In the 1960s, however, the tenets of heterosexism began to be challenged by an emerging political movement of sexual minorities and their heterosexual allies. One such ally was psychologist George Weinberg. In his psychoanalytic training, he had been taught that homosexuality was a form of mental illness. Based on personal experiences with gay friends, however, Weinberg questioned the validity of this assumption. Moreover, he observed strongly negative reactions among professional colleagues when they encountered homosexual persons outside their therapy practices. He ultimately labeled those reactions *homophobia*, which he defined as the dread of being in close quarters with homosexuals. His 1972 book, *Society and the Healthy Homosexual*, provided the first extensive discussion of homophobia as it is manifested among both heterosexual and nonheterosexual individuals. Thus, Weinberg challenged the conventional wisdom of his time, arguing that what was then typically framed as the "problem" of homosexuality was actually rooted in heterosexuals' unwarranted negative reactions to homosexuality and to gay people.

Although the significance of Weinberg's contribution was substantial, it is important to note that *homophobia* is a problematic term mainly because it suggests that heterosexuals' negative reactions to homosexuals are based on irrational fears (i.e., that they are phobias). There is little empirical evidence to support this assumption. Indeed, data indicate that antigay attitudes have multiple sources and are often based on religious and political values or conformity to social norms, rather than irrational fears. In recognition of homophobia's limitations, social scientists have begun to refer to the phenomenon described by Weinberg as *sexual prejudice*, a term that does not convey any particular theoretical assumptions about the nature or origins of heterosexuals' negative reactions to sexual minorities.

Sexual prejudice also has the advantage of linking this phenomenon with other intergroup prejudices, such as those based on race, ethnicity, and religion. Nevertheless, although the psychological dynamics of the various forms of prejudice have much in common, it is also important to recognize at least two distinct features of sexual prejudice.

First, in contrast to social norms that condemn racial, ethnic, and religious prejudice, there is currently no broad societal consensus that sexual prejudice is inappropriate or undesirable. Indeed, U.S. public opinion surveys show that negative attitudes toward homosexuality remain widespread. A second difference is that, because sexual orientation is usually a concealable characteristic, anyone can potentially be labeled as *nonheterosexual*. Consequently, heterosexuals may feel impelled to publicly assert their sexual orientation to avoid being mistakenly perceived as gay, lesbian, or bisexual. They may even do so by overtly expressing sexual prejudice.

Correlates of Sexual Prejudice

Like many other forms of prejudice, sexual prejudice is reliably correlated with a variety of demographic variables. It is more likely to be observed among men than among women, especially in attitudes toward gay men. In the aggregate, heterosexual men's attitudes toward gay men are generally more negative than their attitudes toward lesbians or than heterosexual women's attitudes toward sexual minorities of either gender. Sexual prejudice is positively correlated with age and negatively correlated with educational level and income: Heterosexuals tend to be more prejudiced to the extent that they are older, have less formal schooling, and earn a lower income. Sexual prejudice is also more common among residents of regions where socially conservative attitudes prevail. In the United States, for example, it is stronger in rural areas than in cities and suburbs and in the Midwest and South than in the Northeast or on the Pacific Coast.

Sexual prejudice also has several consistent social and psychological correlates. Reflecting ideological divides within society, it is more common among political conservatives than among self-described moderates and liberals. It is also more often observed among religious fundamentalists, persons holding orthodox religious beliefs, and members of conservative religious denominations than among the nonreligious and members of historically liberal denominations. Sexual prejudice is also more likely to be manifested by heterosexuals to the extent that they have a high level of

psychological authoritarianism, subscribe to traditional gender roles, and hold traditional beliefs about sexuality (e.g., that sexual behavior is permissible only between heterosexual spouses).

In addition, heterosexuals with high levels of sexual prejudice are more likely than their non-prejudiced counterparts to hold stereotypical beliefs about sexual minorities (e.g., that the latter are sexual predators or are mentally ill). In the United States, sexual prejudice has also been found to be reliably correlated with beliefs about the origins of sexual orientation: Heterosexuals with high levels of sexual prejudice tend to believe that being gay or lesbian is a matter of individual choice, whereas those with low levels of prejudice tend to believe it is something over which an individual can exert little or no control. Finally, one of the most consistent correlates of sexual prejudice is the extent to which heterosexuals have had personal contact with sexual minorities. Those who personally know a lesbian or gay man tend to display less sexual prejudice than others, especially if that individual is a close friend or immediate family member.

Related Phenomena

In addition to being manifested in sexual prejudice, sexual stigma is also overtly expressed through individual actions such as the use of anti-gay epithets, shunning and ostracism of sexual minority individuals, and explicit discrimination and violence. For example, substantial numbers of sexual minority adults report having experienced verbal abuse because of their sexual orientation, and many have been the target of discrimination or violence. In addition to inflicting physical harm, violence against sexual minorities appears to create greater psychological trauma for victims than other kinds of violent crime. Behavioral enactments of sexual stigma also target heterosexuals, including the friends, family, and associates of sexual minorities. Moreover, because of sexual orientation's concealable nature, any heterosexual can be mistakenly labeled homosexual or bisexual and is thus potentially vulnerable to enactments of sexual stigma.

Although behavioral expressions of sexual stigma are often motivated by an individual's sexual prejudice, they can occur even in the absence of

a high level of prejudice on the perpetrator's part. This is the case, for example, when a heterosexual person engages in antigay actions to avoid being mistakenly perceived as homosexual (and, consequently, becoming a target of ostracism or attack). The desire to avoid such victimization also motivates many heterosexuals to modify their own behavior in other ways. For example, they may display extreme conformity to traditional gender roles or avoid physical contact with friends of their same sex—all in an effort to avoid being labeled homosexual. This awareness of the existence of sexual stigma and the desire to avoid being its target has been referred to as *felt stigma*. Felt stigma is also experienced by sexual minorities, and it can lead them to avoid situations in which stigma enactments are possible. For example, they may try to pass as heterosexual, a strategy that can reduce their risk for discrimination and attack but can also disrupt their lives, restrict their options, and limit their opportunities for receiving social support. Indeed, concealing one's sexual minority identity has been linked to psychological distress and health problems.

Effects on Interpersonal Relationships

Sexual prejudice and the related phenomena discussed previously have important consequences for interpersonal relationships. Not only does prejudice create impediments to relationships between heterosexuals and nonheterosexuals, but it also has important consequences for relationships between individuals within each sexual orientation category. Sexual prejudice and, more broadly, sexual stigma impose negative sanctions—both interpersonal and institutional—on individuals who are in a same-sex relationship (e.g., they restrict the extent to which such relationships are accorded legal recognition and often limit the amount of social support that such individuals receive for their relationship). Felt stigma motivates many sexual minority individuals to conceal their sexual orientation, which can create stress in their intimate relationships.

Sexual prejudice and stigma also create difficulties for many heterosexuals. As with sexual minority individuals, felt stigma often leads heterosexuals to constrict their own range of behaviors to avoid being

mistakenly perceived as gay. This can include self-imposed limitations on emotional or physical intimacy with same-sex friends. In addition, lesbians, gay men, and bisexuals are less likely to voluntarily disclose their sexual orientation to a heterosexual whom they perceive to be highly prejudiced, even if the latter is a family member or close friend.

Although sexual prejudice can create interpersonal barriers between heterosexuals and sexual minority individuals, it is also the case that close personal relationships have considerable potential for reducing a heterosexual person's prejudice. As noted, heterosexuals who personally know a lesbian or gay man tend to display less sexual prejudice than others. Sexual prejudice tends to be even lower to the extent that a heterosexual has multiple relationships with lesbians and gay men and has directly discussed the friend or relative's sexual orientation with her or him. Thus, encouraging the formation and nurturing of close, open relationships between heterosexuals and nonheterosexuals may be one of the most potent strategies available for eventually eradicating sexual prejudice.

SEXUAL STANDARDS

Sexual standards are attitudes about appropriate sexual behaviors. They are typically measured by asking people to agree or disagree with statements about the acceptability of particular kinds of behaviors, for each gender, at different stages of a relationship. In 1964, Ira Reiss published a widely used scale that asked about kissing, petting, and full sexual relations for an unmarried male and for an unmarried female when engaged to be married, when in love, when feels strong affection, and even if does not feel strong affection for the partner. Acceptability was found to be lower for more intimate behaviors, but greater at later stages of a relationship.

In 1988, Susan Sprecher and her colleagues updated the scale by changing the behaviors to be more specific: heavy petting (defined as touching of genitals), sexual intercourse, and oral-genital sex. The stages of relationship were changed to the mutually exclusive categories of first date, casually dating, seriously dating, pre-engaged and engagement. They also asked about different ages: 16, 21, and 26 years. They found that the biggest differences were between casually dating and seriously dating, and between ages 16 and 21, with less approval for casually dating and for teenagers. Other researchers have simplified the measurement by asking only about sexual intercourse when in a casual relationship and when in love.

Research on predictors of sexual attitudes has examined gender, religiosity, social class, culture, parents, and peers.

A major concern has been to examine whether a sexual double standard exists. Traditionally, women have been expected to remain virgins until marriage, whereas men are supposed to be ready to have sex whenever possible. When a child is born, it is obvious who the mother is, but there may be uncertainty about the father; hence, men have traditionally tried to control women's premarital and extramarital sexual behavior to ensure their own paternity. Sometimes respondents have rated premarital sex as more acceptable for men than for women and at other times as equally acceptable for men and women. More consistent has been higher acceptability ratings by men than by women. Since birth-control pills and legal abortion have become available, the risk of pregnancy has been reduced, and the gender gap in ratings of permissibility has narrowed. But a double standard still persists to some degree. In particular, women who have many sexual partners are still viewed more negatively than men.

Religiosity is often related to sexual attitudes. The ancient Hebrews had a marginal subsistence and emphasized procreation for group survival, condemning any sexual activity that did not lead to reproduction in the family. This prohibition was passed down to modern Jews and Muslims, who both trace their ancestry to sons of Abraham, as well as to the Catholic Church, which extended the ban to modern birth control and abortion. As a result, many people feel guilty about sexual arousal and any sexual activities, and this can lead to negative sexual attitudes even in marriage.

In the past, lower socioeconomic groups were more favorable to premarital sexual intercourse, but less favorable toward masturbation and oral sex. These differences have decreased as sexual behaviors have generally become more acceptable since the 1970s. Immigrant groups often express more negative attitudes about sexual behaviors, whereas later generations are more permissive. Cross-cultural studies have found more permissive attitudes in cultures that are more economically advanced. This may be related to education; women who are better educated generally want fewer children and are more likely to use birth control.

Parental values are sometimes predictive of sexual attitudes, as are attitudes of peers. In research on dating couples, Anne Peplau and her colleagues found some matching on sexual attitudes, although men were generally more permissive. The couple members exhibited three patterns of attitudes about sex and love. Sexual traditionalists viewed premarital sex as wrong, and men expressed their love by refraining from pressuring their partner to have sex. Sexual moderates felt that premarital sex was acceptable at a certain stage of relationship and viewed sex as a way of expressing their love. Sexual liberals felt that casual sex was acceptable and may be used as a means of increasing emotional intimacy.

Similar predictors apply to attitudes about extramarital sex. Although national surveys indicate that at least three fourths of U.S. adults feel that extramarital sex is always wrong, those with more permissive attitudes are more likely to be male, less religious, and better educated. They also tend to be younger and live in urban areas.

Although most research on sexual attitudes has focused on heterosexual relationships, additional research has examined attitudes about homosexuality. Several homophobia scales have been developed, although the attitudes may involve feelings of anger and disgust as well as fear. More homophobia is associated with more conservative heterosexual attitudes, sexual guilt, religiosity, racism, and geography (higher in the South, Midwest, rural areas, and small towns). It is strongly correlated with rigid sex roles and gender stereotyping. Men often have more negative attitudes about homosexuality than women and more negative attitudes about gay men than about lesbians. Adams and his colleagues found that men who were more homophobic were much more likely to be sexually aroused by a male–male sexual video. But younger adults are generally more accepting than older adults.

In addition to research on predictors of sexual attitudes, much more research has studied sexual attitudes as predictors of sexual behaviors and their consequences. For example, research by Peplau and her colleagues on dating couples has found that women's attitudes and experience are more predictive of couple sexual behavior than men's attitudes and experience. With the discovery of AIDS, there has also been much research on

attitudes about condom use and risky sexual behaviors.

SHARED ACTIVITIES

Spending time and sharing activities with loved ones are among the most basic ingredients of romantic relationships. The goal is for shared activities to be rewarding and enjoyable for both partners. This entry describes how and why companionship develops in romantic relationships and some of the difficulties associated with it.

Companionship in Dating

Companionship is particularly important in the early stages of dating because it is a means by which partners discover each other's personality and their mutual interests. Research indicates that it is important for partners to have similar preferences for the same activities so that sharing activities will be mutually rewarding. If, for example, Jack thoroughly enjoys snow camping, whereas Jill prefers opera and the theater, it may be difficult for them to find mutually rewarding ways of spending time together, at least during the winter months.

The degree of involvement in dating also helps to determine the amount of companionship. Research shows that, as partners get more seriously involved, they increase the amount of shared activities. Early in relationships, partners continue to spend independent time with friends and family, but as partners become more seriously involved, they withdraw somewhat from interaction with friends and kin. This withdrawal is more intense from friends than from family because one of the important features of many committed dating relationships is the integration of the partner into one's family. Thus, as daters become more serious, they spend more time doing activities as a couple in the presence of family and friends.

Companionship as a Source of Tension in Dating

Although these changes occur naturally as daters become more committed, shared activities and time are a common source of tension. Individuals' own explanations for turning points in their dating relationships indicate that the partners' demands for each other's time frequently conflict with demands for time from family and friends. Such demands then interfere with and create conflicts within the relationship. Similarly, research on married couples shows that the more partners spend separate time with friends, the less satisfied they are with their marriages. Working out the tensions between time with romantic partners and time with social others is likely to be a prerequisite for moving toward more deeply committed and satisfying relationships.

Companionship in Marriage

Research clearly shows that once partners marry, pursuit of shared activities is generally beneficial to the marriage. It is well documented that the more time spouses spend together, the greater their marital satisfaction. It may be that happy spouses seek out each other's company, that sharing activities fuels satisfaction, or some combination of the two. In marriage, as in dating, the impact of shared activities also seems to be affected by each spouse's enjoyment of the activity. Wives become more dissatisfied with their marriages if they continue to engage in activities that their husbands like but they do not enjoy.

When Companionship Is Difficult

Although the evidence is unequivocal that sharing rewarding activities is beneficial for close relationships, there are qualifications. Research shows, for example, that participation in joint activities is more central to the health of relationships for men than for women in both dating and marriage. Whereas men seem to evaluate the quality of their relationships on the basis of doing activities and having a companion, women seem to evaluate quality more in terms of talking about relationships. The nature of the activity also is important. Particularly satisfying to spouses is involvement in intensely interactive activities, such as eating out, as compared to passive or parallel activities (e.g., watching television). Participation in leisure activities that spouses find exciting also has a positive effect on satisfaction perhaps because it diminishes boredom in relationships. For both dating and marriage, the more partners participate in and prefer competitive sports and games, the less satisfied they are, possibly because competitive activities fuel power imbalances in relationships or violate traditional norms for what men and women prefer to do. In addition, the amount of communication during joint leisure time is related to marital satisfaction. When communication is high during joint leisure, marital satisfaction is greater. Thus, the benefit of joint activities seems to stem, in part, from the opportunities they provide for interaction.

The effects of participation in shared activities also vary with the environment surrounding

marriage. Wives who have high stress, for example, seem to benefit more from joint participation in leisure than those who have low stress. Once partners bear children, shared activities change. New parents participate in as many activities as couples without children, but new parents often spend more time together doing household tasks and child care instead of leisure and recreation. Over time, as wives return to work, participation in shared leisure increases, but it does not return to its prenatal levels. Research suggests that shared leisure time also may act as a buffer against the strains of parenting. Spouses who spent more time together in shared leisure are more satisfied with their relationships, more in love, and report less conflict after the child's first birthday. Findings such as these bolster the popular advice that spouses need to make time to do things as a couple throughout their marriage.

Synchronizing Activities and Interests

It is unrealistic to think that coupled partners will do all of their activities together. Part of the dance of close relationships is the way in which partners synchronize their separate and together activities. According to theories of interdependent relationships, relationship success is measured, in part, in terms of how well partners coordinate their activities separately and together in a mutually enjoyable way.

Likewise, it is unrealistic to think that coupled partners have so much in common that each of them derives pleasure from all of the same activities. One of the most interesting questions that remains to be studied is: What do partners do when their preferences for an activity do not match? One theory proposes that partners' differing preferences for activities gives them opportunities to show how much they care for each other. If Jill decides to go snow camping with Jack even though she does not like it much, Jack will see her action as an indication of her caring for him. Jill also benefits from being altruistic toward a loved one. What may be most central to successful relationships is the balance between similar and dissimilar preferences and how partners negotiate their differences.

SHYNESS

Shyness is the term most often used to label feelings of anxiety and inhibition in social situations. Common synonyms include *bashfulness*, *timidity*, *self-consciousness*, and *reticence*. Ratings of shyness-eliciting situations reveal that interactions with strangers, especially those of the opposite sex or in positions of authority, encounters requiring assertive behavior, and explicitly evaluative settings such as job interviews or first dates provoke the strongest feelings of social anxiety. The tendency to be shy can create barriers to achieving life satisfaction in love, work, play, and friendship. This entry defines *shyness* as a personality trait and discusses how shy people tend to be more lonely and less satisfied with their relationships than those who are not shy.

Emotional State and Personality Trait

The experience of shyness typically involves three components. Global feelings of emotional arousal and specific physiological complaints, such as upset stomach, pounding heart, sweating, or blushing, define the somatic anxiety component of shyness. Acute public self-consciousness, self-critical

thoughts, and worries about being evaluated negatively by others constitute the second, cognitive component of shyness. The third component includes observable behavior such as quietness, cautiousness, awkward body language, avoidance of eye contact, and social withdrawal. From an evolutionary perspective on emotional development, a moderate amount of wariness, concern, and caution regarding strangers and unfamiliar or unpredictable situations has considerable adaptive value. In addition, anticipatory social anxiety is functional when it motivates preparation and rehearsal for important interpersonal events, and shyness also helps to facilitate cooperative group living by inhibiting individual behavior that is socially unacceptable.

Situational shyness as a transitory emotional state appears to be a normal aspect of human development and everyday adult life. For some people, however, shyness is more than a temporary situational response; it occurs with sufficient frequency and intensity to be considered a personality trait. About 30 to 40 percent of adults in the United States label themselves as dispositionally shy persons. Three quarters of the shy respondents said that they did not like being so shy, and two thirds of them considered their shyness to be a personal problem. Almost half of shy adults report that they have been shy since early childhood. For those with early developing shyness, genetic and physiological factors play a significant role in personality development. Research studies of identical and fraternal twins indicate that the temperamental predisposition for shyness has the highest heritability in the normal range of individual differences in personality traits. Infants with this highly reactive temperament in the first year of life are more likely to be wary or fearful of strangers at the end of the second year, and they are also more likely to be described as shy by their kindergarten teachers than are children with an opposite, behaviorally uninhibited temperament. Retrospective reports indicate that 75 percent of young adults who say they were shy in early childhood continue to identify themselves as shy persons.

Slightly more than half of shy adults report that they first became troubled by shyness between the ages of 8 and 14, and they do not appear to have the temperamental predisposition for becoming shy and inhibited. Instead, late-developing shyness

is caused by the adjustment problems of social development normally encountered in the transition from childhood to adolescence. The bodily changes of puberty, the newly acquired cognitive ability to think abstractly about the self and other people, and the new demands and opportunities resulting from changing social roles combine to make adolescents feel intensely self-conscious and socially awkward. The developmental peak for shyness occurs around age 14 when two thirds of the girls and more than half of the boys identify themselves as shy. Late-developing shyness, however, seems to be less likely to endure than the early developing temperamental predisposition. Adolescent self-consciousness gradually declines after age 14, and less than 50 percent of survey respondents who first became shy during later childhood and early adolescence still consider themselves to be shy by age 21.

In the United States, the prevalence of labeling oneself as a shy person is higher for females than males in most age groups, although samples of college students do not show this gender difference. College men rate shyness as more undesirable than women do, and both genders agree that shyness is less socially desirable for a man than for a woman. Indeed, raters of both actual and hypothetical individuals regard a shy male as less likable than a shy female. Some research findings suggest the interpretation, consistent with traditional sex-role stereotypes, that the burden of shyness as a problem of self-concept disturbance may be greater for females in American culture, whereas behavioral problems related to taking the initiative in social encounters may be more salient for shy males.

Some people prefer to spend time alone rather than with others, but also feel comfortable when they are in social settings. Such people are nonanxious introverts, who may be unsociable, but are not shy. The opposite of shyness is social self-confidence, not extraversion. The problem for truly shy people is that their anxiety prevents them from participating in social life when they want or need to.

Shyness, Self-Concept, and Self-Presentation

One way to approach the distinction between shy people and those who are not shy is simply quantitative: Dispositionally shy people experience

physical tension, worry, and behavioral inhibition more frequently, more intensely, and in a wider range of situations than do people who do not label themselves as being shy. There are also significant qualitative differences in psychological processes. For example, shy people perceive various social situations as inherently less intimate and more evaluative, they expect that their social behavior will be inadequate and will be evaluated negatively by others, and they perceive the same interpersonal feedback as more evaluatively negative, compared with those who are not shy. When they encounter social difficulties, shy people also tend to make more self-blaming causal attributions and to remember more negative details than do people who are not shy. Moreover, shy individuals more readily accept negative feedback than positive feedback, and they tend to resist, and to doubt the accuracy of, positive evaluations.

These habitual self-concept processes appear to make it difficult for shy people to conduct successful social interactions and to develop relationships with others. Part of the problem is that shy individuals tend to focus too much of their attention on themselves and not enough on other people. For example, in one laboratory study of the getting acquainted process, shy college women reported spending 33 percent of a 5-minute social interaction engaged in self-focus, compared with about 20 percent of the time for those who were not shy. Moreover, the content of their self-focusing was dominated by negative thoughts about being tense and making a poor impression, as would be expected by the conceptualization of shyness as a propensity for engaging in anxious self-preoccupation. Not surprisingly, shyness is related to poor performance on a measure of sensitivity to the verbal and non-verbal communications of other people.

The tendency to be anxiously self-preoccupied has a pervasive influence on social behavior. Shy people typically adopt a cautiously conservative or protective style of self-presentation, seeking to get along with others rather than to get ahead. For example, they tend to conform to majority opinion, to change their personal attitude toward the position advocated by an authority figure, and to avoid disclosing much personal information about themselves. When faced with a situation in which others hold high expectations of them, shy individuals

may even fail strategically as a means of creating lower and safer standards of evaluation. Those who are not shy are more likely to pursue an acquisitive self-presentation style by actively seeking to obtain social rewards.

Relationships and Interpersonal Styles

The typical pattern of social life for shy children is poor relationships with peers, but positive interactions at home, especially with their mothers. So the home environment appears to be a decisive factor for developmental outcomes of shyness. A growing body of literature demonstrates a relationship between increased shyness and measures of both inhibition of emotional expressiveness in the family environment and a perceived lack of parental support, which has been found in studies from infancy through college age. Of course, positive experiences with peers at an early age help to develop social skills, but such experiences are not easily available for the shy child. Shy children and their friends report lower friendship quality in elementary school compared with those who are not shy, and the shy children tend to be passive or avoidant when facing social challenges. Elementary school teachers may not be likely to help the shy child much because they tend to appreciate the passive compliance of such a child while their energy is focused on problem children who act out aggressively.

Cultural differences in the prevalence of shyness may reflect the impact of socialization practices. In Israel, children tend to be praised for being self-confident and often are included in adult conversations, two factors that may account for the low level of shyness reported by Israelis. In Japan, in contrast, the incidence of shyness is much higher than in the United States. Japanese culture values harmony and tends to encourage dependency and quiet loyalty to one's superiors. Talkative or assertive individuals risk being considered immature or insincere, and there is a high level of concern about avoiding the shame of failure. All of these values may promote shyness, yet also make it a somewhat less socially undesirable personality trait. In contrast, American cultural values that emphasize competition, individual achievement, and material success appear to create an environment in which

it is particularly difficult for the shy person to feel secure and worthwhile. Recent research in China further illustrates how broader cultural values influence the extent to which shyness is perceived to be a problem. Chinese teachers tend to see shyness as a favorable trait in children, and among Chinese children, shyness is not associated with loneliness, unlike in the United States or Canada.

Research conducted in North America and Europe consistently finds that loneliness is the most obvious undesirable consequence of shyness. Shy children have fewer playmates, shy teenagers date less often, and shy adults are less satisfied with the quality of their social relationships, compared with those who are not shy. Several longitudinal studies show that when shy children grow up, they are likely to experience delayed social transitions, with shy males marrying or forming their first stable partnership, becoming fathers, and getting established in a stable occupational career several years later than those who were not shy. Once in a relationship, shy people may become too dependent on their partner, silencing the self in favor of pleasing the other, and missing out on authentic mutuality. These qualities of relationship dynamics are important because for shy people excessive dependency (also called unmitigated communion) is a risk factor for depression, as is loneliness.

Love-Shyness and the Internet

The term *love-shyness* was introduced to isolate specifically sexual issues from other intrapsychic and interpersonal issues that are involved in the psychology of shyness. Shy college men identify problems with dating and lack of sexual experience as troubling personal issues, and among extremely shy middle-age men, there are some who say that they live unhappy lives of enforced virginity due to their love-shyness. Surveys of college women find that shyness is not correlated with attitudes about or quantity of sexual experience, but it is associated with lower quality of sexual relationships and lower levels of sexual self-esteem. Shy college women report that their dating relationships are characterized by a protective self-presentation style and a validation-seeking interpersonal orientation, whereas those

who are not shy report a growth-seeking interpersonal orientation in their dating relationships. The newest research topic in shyness and relationships involves use of the Internet for developing online relationships that might lead to face-to-face interactions. Initial studies indicate that, in contrast to offline social interactions, the online communications of shy people showed more self-disclosure, less protective self-presentation, and lower levels of inhibition and rejection sensitivity. These encouraging findings suggest that use of the Internet may become a worthwhile addition to traditional treatment programs of social skills training, practice dating, and cognitive therapy for helping shy people who are experiencing relationship problems.

SIBLING RELATIONSHIPS

A sibling relationship is a relationship one has with a sister or brother who have one or both parents in common. The relationship between siblings is enduring, lasting from birth to old age, and is longer than the relationship with parents, spouses, or children. In the United States, approximately 80 percent of children have at least one sibling, and children spend most of their time with siblings (33 percent) as opposed to time spent alone (12 percent), with peers (13 percent), or parents (23 percent mothers, 19 percent fathers). Sisters and brothers spend a great deal of time together and serve as each other's first companions and playmates. The sibling relationship may be considered a relationship that affords children the opportunity to learn and develop socially, emotionally, and cognitively. This entry focuses on several aspects of multifaceted and complex relationship between siblings. The entry begins with a discussion of positive and negative sibling relationships, sibling rivalry, and how families might be able to manage sibling conflict. It then reviews research and theory on parental favoritism, as well as different family forms, and concludes by considering the benefits of sibling relationships.

Positive Sibling Relationships

There is considerable variability in sibling relationships; some are filled with warmth, affection, and involvement, whereas others are riddled with conflict, hostility, and rivalry. How well siblings get along can have an important impact on a child's development. As siblings interact with one another, some develop a relationship characterized by prosocial interactions and nurturance, whereas others may be more antisocial. Prosocial behavior occurs when someone acts to help another person, particularly when they have no goal other than to help that person. Children with warm and caring sibling relationships are generally friendlier and share more with their sisters and brothers in childhood, and as they age and mature, they can become competent teachers for younger siblings. Older siblings can provide support to younger siblings when they are sad or

hurt. They can utilize social control over younger siblings and encourage prosocial behaviors. Social control refers to societal mechanisms regulating behavior that leads to conformity and/or compliance.

Many children today live in households where both parents work outside the home, sometimes leaving siblings home alone to fend for themselves. Older siblings often assume a nurturing role and take on the responsibility of teacher, manager, and helper for their younger siblings. Teaching a younger sibling to express feelings and communicate emotions can help siblings develop a positive relationship with one another. Each sibling influences the development of the other and vice versa through social interchanges. In these ways, older siblings can help shape the social and emotional development of a younger sibling.

Negative Sibling Relationships and Rivalry

Sibling conflict and rivalry are two different concepts, and the motivations behind each differ considerably. Conflict is a normal aspect of social relationships and is defined by the exchanges or mutual opposition between two individuals, whereas rivalry reflects more of the competitiveness for limited resources such as attention, time, love, and approval. Sibling conflict is not unusual, and high levels of conflict can set a negative tone to family life. Sibling violence is the most frequently occurring type of family violence, affecting about 70 percent of homes in the United States. Sibling relationships that are typically filled with intense hatred toward one another or those that are aggressive and destructive can have devastating consequences for the children involved. Children and adolescents in such hostile and aggressive relationships risk not only physical harm, but there are also serious psychological consequences such as low self-esteem, poor academic achievement, poorer peer relationships, conduct problems, feelings of loneliness, and sometimes even depression. There are two basic types of conflict. First, there is destructive conflict, which is characterized by high levels of negative affect and aggression. Destructive conflict can weaken and damage the sibling relationship. Second, there is constructive conflict, where siblings display low

levels of negative affect and utilize conflict management skills to solve the problem at hand. Constructive conflict offers siblings opportunities to develop good problem-solving and conflict management skills that they can use in any relationship, including their sibling relationship. Sibling conflict also offers children and adolescents opportunities to learn to tolerate and regulate negative emotions. In this sense, we can look at sibling conflict as helpful because it has the potential to teach sisters and brothers how to manage conflict and how to regulate emotions in aversive situations.

Rivalry in the sibling relationship manifests as competitiveness and jealousy between sisters and brothers. Problems with rivalry usually begin at the birth of the second child, when the attention of caregivers is no longer focused on the only child, and can persist throughout childhood and adolescence. There are several factors that contribute to sibling rivalry, such as age and position of the child in the family. For example, older siblings may have to care for younger ones, and younger siblings may feel inferior to their older counterparts. Gender also can be a factor in sibling rivalry. For instance, a father may treat a daughter more tenderly than a son or a daughter may want to throw a ball with her dad like her brother gets to do. Developmental stages of children can also play a role in sibling rivalry. Young children are more egocentric and may not be able to share. School-age children are more aware of what is fair and may not understand parental favoritism toward a younger sibling or why they may receive more parental discipline and less warmth than their younger counterparts. Finally, adolescents may resent not being able to exercise their independence because they have to care for a younger sibling or engage in household chores. As children's evolving needs change, so do the ways in which they fight with one another. Rivalry and friendly competition between siblings can also help promote academic achievement and encourage children to set higher personal goals and to persist in meeting those goals when dealt with in constructive ways. Therefore, it is important for parents to try and minimize sibling rivalry by not making comparisons between children, not playing favorites, and promoting cooperation and perspective taking between siblings.

Dealing With Sibling Conflict

Coping with sibling conflict is something that many family members must do when emotions are highly charged. *Coping* is defined as a deliberate behavioral and cognitive effort to modify and manage stressful life demands. Children need to learn to cope with frustrating feelings, compromise, negotiate, and value other perspectives in order for them to control aggressiveness with a sibling.

Parents must manage sibling conflict to help sisters and brothers negotiate their relationship. There are several different ways that parents may help (or hinder) children in managing relationships. First, they can choose to do nothing and let the siblings try to work it out themselves. This is helpful if children possess good conflict management skills and are able to resolve disagreements, otherwise conflict and rivalry may be perpetuated. Second, they may choose to punish aggressive acts. Physical punishment is not recommended, but giving timeouts or other forms of punishment that are constructive and promote learning and problem solving can help parents manage conflict. Punishment alone may cause resentment toward the parent as well as toward the sibling. Third, they can reinforce behaviors (i.e., positive or negative) by responding consistently (or inconsistently to promote negative sibling behaviors). Positive reinforcement encourages prosocial behaviors, whereas reinforcing negative behaviors perpetuates the conflict. Fourth, they can separate the children and not allow them to work things out. Oftentimes separation leads to avoidance, and if siblings are not brought back together once they are calm to resolve issues, agonistic behaviors will rule, and involvement and warmth in the sibling relationship will be minimal if at all. Fifth, they can help children learn to resolve conflict by teaching them to talk to one another and express their thoughts and feelings about these situations. Conflictual moments are opportunities for teaching children conflict management skills. Often parents want sibling conflict to stop, so they ask the older child to defer to the younger child in order to end the dispute, which can create resentment on the part of the older child. In a conflict situation, it is important for parents to allow children to express their feelings about one another

without violence, name-calling, or yelling. Parents can teach children how to do things fairly, compromise, and respect each other.

Parental Differential Treatment

Parental socialization practices and how parents treat their children can vary greatly within a family. Parental differential treatment or parental favoritism can occur in families and has been linked to poor emotional and behavioral functioning in children and adolescents. Differential treatment refers to whether parents direct more or less discipline and less warmth toward one sibling than the other sibling. Children who see parental favoritism as being unjustified are more likely to develop psychological and behavioral problems than children and adolescents who view differential treatment as justified. As a result, siblings who view parental favoritism as unfair may feel worthless and demonstrate behavioral problems such as intense rivalry, aggression, and avoidance of one another.

Different Family Forms

Increased divorce rates in the United States have led to greater numbers of children with stepsiblings and half-siblings. Stepsiblings are not biologically related, but become siblings when one of each of their parents marries. Half-siblings are where two children share one biological parent and the second parent is from a previous marriage. Also, one child may come from a previous marriage, but the other child is the product of the current marriage. When stepfamilies are formed, parents often worry about how stepchildren will embrace the new marriage and how stepsiblings will get along with one another. They may also worry whether a newborn half-sibling will be accepted by an older sibling. More conflict and rivalry has been reported between stepsiblings in remarried families than between siblings in intact (or nondivorced) families or half-siblings. How parents manage life with their children and adolescents during the remarriage can play a role in how well step- and half-siblings will get along.

Benefits of Sibling Relationships

Early positive childhood experiences in the family have been shown to contribute to higher self-esteem and competent intimate relationships with others outside the family environment. Self-esteem is constructed throughout childhood, continuing into adulthood, and is derived from the love, support, and protection a child feels from parents and siblings. When children feel they are being treated equally by both parents and have prosocial sibling interactions, they have a better sense of self and more competent romantic relationships. Sibling relationships change as people become adults. Rivalry usually decreases and closeness increases in adult sibling relationships. Adult siblings can provide social support, companionship, and emotional support for each other as they age. Health and well-being in old age has been attributed in part to having a close, supportive sibling relationship, whereby elderly sisters and brothers who share a life history and childhood memories are able to provide emotional, psychological, and instrumental support during times of stress. Sibling relationships, in general, from birth through old age can play a beneficial role in the development and maintenance of social interactions that last a lifetime.

SIMILARITY IN ONGOING RELATIONSHIPS

The tendency for people in a relationship to be similar can affect the quality of the relationship, the nature of partners' interactions, and the likelihood that a relationship will continue. Although most research on similarity in relationships has studied dating or married couples, the same principles and processes apply to many different types of relationships, including family, friends, and coworkers. This entry reviews how similarity is measured, how relationship partners are alike, how partners may become more alike or converge over time, and how similarity and convergence affect relationship quality.

Definition and Measurement

Similarity in an ongoing relationship is how alike two relationship partners are at one point in time. Romantic partners and friends are generally the most similar on demographic characteristics such as age, education level, and socioeconomic status, as well as intelligence and cognitive abilities. To a lesser extent, partners are similar across behavioral and psychological characteristics, including personality, attitudes, emotional tendencies, interests, psychopathology, and sexual experience. This tendency of partners being alike is also known as *homogamy*. There is extensive evidence for *homogamy* and less evidence for *heterogamy*, or the tendency for long-term partners to be dissimilar to each other.

Researchers measure similarity in a variety of ways. The first is a *discrepancy score*. The absolute difference of two partners' scores is used to measure how similar two partners are on a given characteristic with lower scores indicating similarity. Often, absolute differences across a number of different questions measuring the same characteristic are averaged together. Discrepancy scores have some important limitations. First, greater scores indicate greater dissimilarity; however, there is no set point for when an individual stops being similar and starts being dissimilar. Second, discrepancy scores can be confounded with each partner's individual score. If an individual scores a 5 out of 10 on an agreeableness scale, he or she can have a maximum discrepancy of 5 from a partner, whereas if an individual scores a 10, he or she can have a maximum discrepancy of 9.

A second way of measuring similarity is a *variable-centered* correlation, where partners' scores are correlated on the same characteristic (height, extraversion, intelligence). This is a correlation between one partner's score with the other partner's score on the same characteristic across a sample of dyads. Higher correlations indicate greater similarity. This approach also has limitations. First, this approach can only estimate similarity one characteristic at a time and cannot show how similar couples are across multiple characteristics. Second, a variable-centered correlation shows levels of similarity across an entire sample and cannot estimate the similarity for one specific couple.

A third way of measuring similarity is by computing a *couple-centered* correlation. Here, a profile correlation of two partners' responses is computed. This is a correlation between one partner's responses on a number of items with the other partner's scores on those same items within the same dyad. This approach addresses some of the limitations of the other methods of computing similarity. It can be an index of when couples are similar (positive correlations) or dissimilar (negative correlations). It can also be used to measure similarity across a single characteristic, such as extraversion, or multiple characteristics, such as an overall measure of personality. However, computing this correlation requires that there be multiple items assessing the characteristic, so it cannot be used when the characteristic is measured by a single item, such as

height and age. Thus, although this method of computing similarity has the fewest limitations, it cannot be used for all characteristics.

Finally, some research has investigated perceived similarity by asking partners how much they believe they are similar to their partner. However, perceived similarity can be discrepant from more direct and objective measures of similarity.

Each of these methods of determining similarity has another important limitation. A pair of individuals may appear to be similar, but they might be no more similar than a typical pair of strangers. For example, if asked what they prefer—to win \$1,000,000 or \$10—it is likely that a married couple will appear as similar as a pair of strangers in preferring more money to less money. This is known as *stereotype similarity*. For any given characteristic, belief, or attitude, there may be a baseline level of similarity in a population that is significantly greater than zero. To show that partners are more similar to each other than expected by chance, the partners must be more similar to each other than they are to strangers on that same characteristic. This latter limitation of stereotype similarity has been overlooked in much of the work on partner similarity.

One can also relate these indices of similarity to other relationship attributes. For example, each couple can be assigned an absolute difference score or a standardized profile (i.e., couple-centered) correlation. These can be related to relationship satisfaction, amount of conflict, or other relationship-relevant constructs. One can also measure how much couples converge by measuring the change in similarity between two time points on absolute difference or standardized profile correlation scores.

Reasons That Relationship Partners Are Similar

Relationship partners are similar to each other for a number of reasons. The first reason is *assortative mating*. This is the tendency for individuals to depart from selecting a partner at random or *panmixia*. Although there are several types of assortative mating, the primary type is positive assortment, where people select partners who are similar to themselves. In contrast, in negative assortment, people select partners who are opposite to

themselves. Partners are much more likely to display positive assortment than negative assortment. There is also passive and active assortment, where individuals have different levels of personal control over the assortative mating process; these are explained in more detail next.

Passive Assortment

Passive assortment occurs when individuals are forced to choose one type of partner because their environment constrains the choices they have for a relationship partner. One constraint is propinquity. Individuals are more likely to meet those who live in close physical proximity and can only start relationships with those whom they meet. It has been shown that the likelihood of marrying someone drops significantly for each city block farther away he or she lives. People who live close to each other are also more likely to be from similar ethnicities, socioeconomic classes, religions, and education levels. Thus, individuals tend to grow up in environments of similar others and are therefore more likely to start relationships with people who share the same demographic characteristics. Moreover, similar individuals will often choose the same environment. Individuals with similar cognitive abilities, family backgrounds, or political ideologies are more likely to go to the same university, work in the same industry, and/or move to the same geographic area. This makes it more likely that an individual will meet and form a relationship with a similar other.

There are sometimes social constraints for the type of partner an individual can choose. Some religions prohibit or look unfavorably on a marriage to an individual of another faith. Similarly, couples from different ethnic, socioeconomic, and educational backgrounds are more likely to elicit disapproval and less support from others relative to couples that share the same ethnic, socioeconomic, and educational backgrounds. Violating these social rules can be met with frowns of disapproval, being ostracized by one's family or community, or even being killed for marrying an individual from another religious faith or ethnic background.

Finally, the tendency for partners to be similar may be a byproduct of individuals having strong

preferences for highly attractive prospective partners. These preferences alter how much choice people have in selecting their partners by making it more likely that more attractive individuals will pair off and restrict the choice of less attractive individuals. The most attractive individuals have the most power and greatest freedom to select their partners and will likely choose a partner who is also highly attractive. This removes the most attractive individuals from the pool of potential partners for everyone else. The next most attractive individuals in the pool of potential partners will then have the most power to pair with those who are of similar attractiveness. This process will continue until all individuals have mated, resulting in couples that are ordered in attractiveness.

Active Assortment

Individuals can also actively search for and select partners who are similar to themselves. This is a process known as *active assortment*. Unlike passive assortment, active assortment involves the individuals choosing their partners based on some criteria. Active assortment is likely to result in couples where the partners are similar to each other because individuals are attracted to, and prefer, others who are similar to themselves across a variety of characteristics. This can happen for a number of reasons.

First, people find those who hold similar attitudes validating. Individuals like to believe that their own attitudes are correct, and one way that individuals confirm the truth of their attitudes is by assessing the attitudes of others. If they share the same attitudes, it validates those attitudes as correct. Because this process of validation is rewarding, individuals tend to like those who share the same attitudes.

Second, individuals who are similar tend to construe the world and react to the same situation in the same way. Therefore, similar couples are more likely to have coordinated and smooth social interactions because each partner is better able to anticipate and respond appropriately to his or her partner's behavior. By making social situations easier to negotiate, similarity reduces the likelihood of conflict or stress that may undermine the quality and duration of the relationship.

Third, it is easier to interpret and understand the thoughts and feelings of someone who is similar relative to someone who is different. Because similar partners share experiences, attitudes, and personality traits, they have a natural reference point to understand each other, their own experiences, attitudes, and personality traits. Thus, both partners are more likely to be accurate in perceiving and interpreting the internal thoughts and feelings when they are similar to each other. For example, individuals are more accurate at interpreting sympathy from an individual who has similar levels of dysphoria relative to one who differs on his or her level of dysphoria.

Finally, people enjoy interacting with similar others more than dissimilar others. Similar others are more likely to share interests and attitudes, which is likely to lead to smoother and more pleasant interactions. Moreover, dissimilar others are more likely to spark disagreement and conflict because they have different attitudes and interests. Because validation, understanding, and enjoyable interactions are the building blocks of intimacy, the more similar partners are to each other, the more likely they are to keep the relationship intact.

Tendency for Individuals to Converge Across Time

Another reason that individuals in relationships tend to be similar to each other is that they converge or become more similar over time. New college roommates will become more alike in the emotions they experience, romantic couples will adopt each other's attitudes and interests, and married couples tend to look more alike over time.

There are several reasons that partners converge across some characteristics. First, individuals find adopting a new partner's interests, attitudes, and beliefs exciting and rewarding and are therefore highly motivated to integrate aspects of the partner into their own self-identity. For example, new partners will often cultivate similar interests by trying out the interests of each other. Second, partners share some of the same environment. To the extent that the environment shapes an individual's beliefs, personality, interests, and behaviors, partners will become more similar the longer they share the same environment. It has been shown that married

individuals become or remain similar depending, in part, on how much overlap they have in their environment. Third, being dissimilar to a partner in attitudes or beliefs can cause an individual discomfort because this is a signal that the attitude or belief is wrong. Because of this, individuals are highly motivated to balance their attitudes and will often align their attitudes with their partner to reduce this discomfort.

Genetic Consequences of Similarity

There can be substantial genetic consequences when individuals select partners who are similar to themselves. When individuals select a similar mate on a heritable characteristic, it ensures that there will be greater variance in that characteristic in the next generation. For example, if partners sort on height, then very tall people will tend to mate with other very tall people, and their children will be more likely to be very tall. However, if people do not sort on height, then a very tall person will be more likely to mate with someone who is shorter (because most of their potential mates will be shorter), and their children's height will be more likely closer to the average. Thus, in a given population, assortative mating maintains greater genetic variance in the next generation.

When people mate with genetically similar others, it also means that more of an individual's own genes will be passed to his or her children and that the children of that couple will be more similar to each other. Because people tend to be more altruistic toward those with whom they share genes, this may cause families that are genetically more similar to help each other more often. However, when inbreeding (i.e., mating between two related individuals) occurs, it increases the occurrence of rare disorders caused by recessive genes in the offspring of that couple, making those offspring less healthy and more likely to die.

Relationship Consequences of Similarity

Partners who are similar to each other tend to be more satisfied with their relationship and less likely to end their relationship, although the relationship between similarity and relationship quality varies from characteristic to characteristic. For

example, similarity in overall personality has been related to higher levels of marital satisfaction, but some individual personality domains do not relate to relationship satisfaction as consistently, such as neuroticism and extraversion. Although a few studies have shown no relationship between similarity and relationship quality, only rarely do studies show that complementarity predicts higher relationship quality. There is also evidence that partners who become more alike over time will be more satisfied with their relationship than partners who become less alike. Finally, even the perception that a partner is similar relates to greater relationship satisfaction.

There are several reasons that similarity and convergence relate to higher relationship quality. First, similarity can facilitate partners feeling validated and understood, and thus will build intimacy in a relationship. Being dissimilar can lead to increased disagreement, misunderstanding, and conflict. Second, similarity can smooth daily social interactions between partners by facilitating and understanding of each other's emotions, attitudes, and beliefs. Third, similarity in personality and interests can lead to more shared activity and interests in a relationship. Finally, others outside the relationship are likely to assume similar partners are in a relationship, while dissimilar others are not, and treat each type of couple differently. For example, they may ask similar partners about the history of their relationship, reinforcing partners' positive perception of their relationship. But if they believe that dissimilar couples are not an actual couple, they may ask whether they are dating other people, undermining the partners' perception of themselves as a couple.

SIMILARITY PRINCIPLE OF ATTRACTION

Many individuals hold beliefs about the importance of similarity for attraction. These beliefs can be expressed in sayings such as “Birds of a feather flock together” and “Opposites attract.” This entry focuses on beliefs expressed by the first of these sayings—that individuals prefer others who are similar to themselves. One of the most basic

principles of interpersonal attraction is that individuals form relationships with people who are similar to themselves and dissolve relationships because of a loss of similarity. This has been referred to as the *similarity-attraction hypothesis*. These effects are found across relationship types from interactions among strangers to friendships and romantic relationships. Therefore, attraction in this context refers to a variety of variables from liking or willingness to interact with a stranger to loving or relationship quality in a marriage. Research on this topic has been conducted in a number of areas, such as whether similarity leads to attraction or whether attraction leads to similarity, whether it is actual or perceived similarity that is related to attraction, and why similarity is important. This entry examines each of these topics.

Similarity Leads to Attraction

Beginning with Aristotle’s essay on friendship in 330 BCE, the idea that similarity increases interpersonal attraction has permeated our beliefs. Near the end of the 19th century, Sir Francis Galton provided empirical verification of this belief when he found that spouses were similar in many attributes. However, his findings could not address the cause-and-effect relation between similarity and attraction. In the 1950s and 1960s, Theodore Newcomb conducted one of the earliest studies examining the influence of similarity on attraction at the University of Michigan. He examined friendship formation among male housemates who were initially strangers. At first, men’s friendships were influenced mostly by *perceived similarity*, but as the semester continued and the men learned more about their housemates, these friendships were influenced mostly by *actual similarity*. In both cases, however, higher similarity was associated with higher attraction. This research suggested that similarity leads to attraction, but the naturalistic setting and lack of experimental manipulation and control still raised questions about cause and effect.

To examine the cause-and-effect relation in the similarity-attraction hypothesis, Donn Byrne and his colleagues conducted a series of studies using the “bogus stranger paradigm.” In the bogus stranger paradigm, a participant is led to believe that there is

another individual in the study. However, the other individual does not actually exist—hence, the “bogus stranger.” In these types of studies, attitudinal similarity of the bogus stranger to the participant is experimentally manipulated to determine its effects on attraction. Attraction in these studies is typically measured by a question about how much the participant liked the stranger or how willing the participant would be to work with the stranger on a future task. These studies, then, asked whether an individual would be more likely to express a desire to work with an unknown stranger (attraction) the more similar the stranger’s attitudes were to one’s own attitudes (similarity). Supporting the cause-and-effect relation, individuals who were randomly assigned to the experimental condition in which the bogus other was presented as being similar to the individual were more attracted to the person than individuals who were randomly assigned to condition where the bogus other was presented as being dissimilar. These findings are robust, with the importance of similarity on attraction extending from interactions with strangers to marital relationships.

Arthur Bochner and Michael Sunnafrank have criticized the similarity-attraction research, mostly that of Donn Byrne’s early work, indicating that this research deals with stranger or bogus-stranger relationships, those with unilateral awareness and no interdependence, and confuses the timing of learning about someone’s attitude and meeting the person. Therefore, they criticized whether the attraction-similarity findings can be generalized to the initiation and development of interpersonal relationships. However, research examining whether actual or perceived similarity is the important predictor of attraction supports the similarity-attraction relation in real, interdependent relationships. This issue is discussed in more detail later. Although in real life we may not know another person’s attitudes before we meet them, we tend to meet people in situations that allow us to infer these attitudes, such as through our involvement in school, work, social clubs, or church. Sharing similar interests in these activities (e.g., a social club) implies that the two individuals will also share other beliefs or interests. That is, we can infer similarities in a number of domains based on similarities in one domain. As is discussed next, these inferences may or may not be accurate.

Despite that Donn Byrne’s research indicated a linear relation between similarity and attraction, this relation depends on a variety of other factors, including the kinds of similarity being shared and the perceiver’s personality. In terms of the types of similarity being shared, attitude similarity is more important than personality similarity, and value similarity is more important than demographic similarity for attraction. The effects of similarity on attraction are also stronger for central than peripheral attitudes. Central attitudes refer to issues that are important to an individual’s self-view or self-concept, whereas peripheral attitudes would have little or no importance to the self. The similarity-attraction relation is also greater for attitudes with high, as opposed to low, heritability and for personality traits that are more important (e.g., caring, jealous) compared with less important (e.g., quiet, cold) for the relationship. Finally, the similarity effect is stronger for positive traits than for negative traits.

Personality characteristics also influence preferences for the type of similarity important to attraction. For example, low self-monitors prefer attitudinal similarity over activity similarity, whereas high self-monitors prefer activity similarity over attitudinal similarity. Individuals high in social anxiety indicate greater attraction to agreeing strangers and lower attraction to disagreeing strangers than do individuals low in social anxiety. Similarly, individuals with a positive self-concept, as measured by the self-assurance scale, prefer similar to dissimilar others, whereas individuals with a negative self-concept do not show this preference for similarity.

Attraction Leads to Similarity

Although the similarity-attraction research indicates that these variables are related and among strangers similarity leads to attraction, in ongoing relationships, the direction of influence may differ. Arthur Bochner notes that relational partners assume that they should have a variety of things in common and communicate to foster this impression. In fact, he argues that one purpose of communication is to foster perceptions of similarity and create an impression of being an interesting person. Supporting this role of communication,

attitude alignment or changing one's own attitude to match the attitude of a partner is found when individuals are aware of an attitudinal discrepancy (the individuals have discussed it), when the issue is central to the partner (they know what each other believes and what is important to them), and when the interactions are among dating partners rather than strangers.

Perceptions of similarity in ongoing relationships may also occur because individuals assume similarity and, therefore, project themselves onto their partners. Although we believe we hold accurate impressions of our friends and romantic partners, partner impressions are affected by a variety of factors; for instance, observer's own behaviors and attitudes influence their ratings of others' behaviors and attitudes. Thus, we are attracted to people who are similar to us, the similarity-attraction hypothesis, but may also perceive similarities that may not be there. Marian Morry and her colleagues have referred to this latter aspect as the *attraction-similarity hypothesis* and suggest that an ongoing relationship attraction to another person may lead individuals to perceive self-other similarities. Supporting the attraction-similarity hypothesis, Marian Morry and her colleagues have found that asking individuals to write about the most positive or negative event in their relationship caused these individuals to rate their relationship satisfaction (a measure of attraction) as higher or lower, respectively. These changes in attraction then caused changes in perceived similarity in both friendships and dating relationships. That is, increasing ratings of attraction increased ratings of perceived similarity and decreasing ratings of attraction decreased ratings of perceived similarity. In summary, it appears that in ongoing relationships, attraction influences perceived similarity.

Actual or Perceived Similarity

Having found that similarity is important to attraction, and vice versa, researchers are also interested in whether actual similarity is necessary or whether perceived similarity is sufficient. Supporting the effects of actual similarity, a number of studies found evidence of assortative mating or the tendency of like to marry like (e.g., sharing the same religion). In fact, most individuals become

friends with or marry people who are similar to the self. Evidence for assortative mating has been found for intelligence, social class, religion, race, sensation seeking, and attachment styles, among others. Close relationship partners exhibit greater than chance similarity on these variables, and this actual similarity is positively associated with attraction and the continuation of the relationship. Because most of these variables predate the onset of a relationship, these findings indicate that in interdependent relationships, actual similarity leads to attraction.

Considerable discrepancies, however, exist between self and peer ratings of attitudes, values, beliefs, and personality, suggesting that perceptions and reality are not the same. For example, individuals perceive their partners to be more similar to themselves than the partner self-rates in terms of personality traits such as extraversion, neuroticism, openness, agreeableness, and conscientiousness, and interpersonal traits such as being kind, affectionate, controlling, or dominant. These perceptions of similarity then may impact the similarity-attraction relation. For example, perceived, not actual, value similarity predicts liking among college roommates. In romantic relationships, perceived not actual similarity of coping styles is the best predictor of satisfaction.

In the context of ongoing relationships, the question of actual or perceived similarity refers to whether one is accurate in one's perception of the partner. That is, does Peter's perception of Sue match Sue's self-ratings? To test for actual or perceived similarity, researchers ask both individuals to rate themselves and their partner on a variety of traits, opinions, behaviors, and so on. It is then possible to test whether there is actual similarity. Peter and Sue rate themselves the same; a perception of similarity, Peter rates Sue as being similar to his own self-ratings, but Sue does not rate herself similar to how Peter rates himself; or a combination of the two, some similarity in self-ratings and Peter rates Sue as being more similar to himself than is warranted. A variety of research studies indicates that, although somewhat accurate in their perceptions of friends, dating partners, and spouses, individuals tend to perceive greater similarity than warranted. That is, although there is some actual similarity, individuals project themselves onto their intimate others and perceive

similarities that are not there to the same degree. This tendency to perceive greater similarity than warranted has been found for attitudes, personality characteristics, attachment styles, behaviors, and so on. In addition, these perceptions of similarity are found across a variety of relationships from friendships to dating relationships to marriages. As noted earlier, in ongoing relationships, experimental changes in relationship satisfaction, by writing about a positive or negative event in the relationship, caused changes in perceived similarity. These results also support the importance of perceived rather than actual similarity.

Explanations for Why Similarity and Attraction Are Related

Another area of research in the similarity principle of attraction domain is why these variables are related. Explanations have included rewards of interacting, balance theory, and general expectations. The first explanation, rewards of interacting, indicates that individuals are motivated to be logical and accurate in interpreting their environment. Similarity with others validates their view of the world and confirms that they are correct in their thinking. In addition, an interaction with someone who shares your attitudes, beliefs, or values results in fewer disagreements and conflicts, which should foster a sense of safety. Similarity can also facilitate interaction as each individual can predict the other's responses.

Fritz Heider's balance theory has also been proposed as an explanation for the relation between similarity and attraction. According to this theory, individuals prefer relationships that are balanced. For example, the participant (P) likes his or her friend (O), and the participant has a particular attitude, behavior, or trait (X). With two positive relations (PO and PX), the third relation should also be positive (e.g., the friend should have or be perceived to have X) to achieve a balanced relationship. Supporting the current application of balance theory, people perceive similarities between themselves and intimate others based on projections of the self. Theodore Newcomb hypothesized that increases in attraction (PO) or of the relevance of the characteristic (PX) to the relationship would motivate individuals to change the relationship

into a balanced one. Consistent with his reasoning, manipulations of attraction influence perceptions of similarity, individuals overestimate attitude similarity more in close relationships such as marriage than in the stranger paradigm, and similarity effects on attraction are stronger for central than peripheral attitudes and for moderate compared with low relationship-relevant traits.

Another explanation for the relation between similarity and attraction is that individuals expect similar others to like them. That is, similarity implies liking, and we are attracted to individuals who like us (i.e., reciprocity of liking). In line with this reasoning, John Condon and William Crano manipulated both how positive a stranger evaluated the participant and similarity of the stranger to the participant. To manipulate the stranger's evaluation, they indicated that the stranger thought that the participant was above average in a number of ways and expected to like him or her and wanted to work with him or her or provided no such information. Both positivity and similarity affected the participant's attraction to the stranger. In addition, similarity led to inferred positive evaluations by the stranger, and these inferred evaluations then led to attraction. This expectation of liking explanation is also consistent with the role of communication in developing relationships. More specifically, individuals tend to reciprocate the level of disclosure. Disclosure provides the opportunity to learn about similarities, which implies the other likes the self, and increases liking for the other.

Current and Future Directions

Current research continues to look at the types of similarity important for attraction, the direction of influence between similarity and attraction, and the reasons that similarity and attraction are related. For example, Eva Klohnen and her colleagues examined attitudes and personality traits and found substantial actual similarity on attitudes, but not on personality characteristics. However, greater perceived similarity on personality characteristics, and especially attachment styles, was the best predictor of relationship satisfaction (attraction). In addition, this perceived similarity-satisfaction relation continued even

when actual similarity was controlled for. Together these results suggest that the type of similarity being examined is important and that perceived similarity may be more important to attraction than actual similarity.

Research on the similarity principle of attraction can also be enhanced by using more diverse research methods. For example, research on the direction of influence can be enhanced with techniques from speed-dating research. For instance, in speed-dating research, it would be possible to test whether initial actual similarities in the interaction leads to later liking or whether liking at the end of the speed-dating session leads to later perceived similarity. Longitudinal research could also be used to determine when the effects of similarity on attraction among strangers become the effects of attraction on perceived similarity in ongoing relationships.

Finally, research is still needed to explore the reasons for the similarity and attraction relation. As noted earlier, these explanations involve rewards of interacting, balance theory, and expectations. The motivational and cognitive underpinnings of these explanations, however, need to be explored. Such questions could include: How do individuals develop expectations of similarity? Do these expectations vary across relationship types (friendships, marriages)? Do they change over time or with experience?

Summary

Although there are a variety of variables that are important for interpersonal attraction, one such variable that has captured the attention of both lay people and researchers is similarity. A number of studies have indicated a positive, linear relation between similarity and attraction. The strength of this relation varies based on the importance of the characteristics, one's personality traits, and so on. In addition, both perceived similarity and actual similarity are important correlates of attraction. The direction of influence also seems to vary based on the closeness of the relationship, with actual or perceived similarity leading to attraction among strangers, but attraction leading to perceived similarity in ongoing relationship.

SINGLEHOOD

Although research on human relationships covers relationships with friends, siblings, parents, children, neighbors, colleagues, mentors, and others,

most scholarship has been devoted to relationships with romantic partners or spouses. Little research has explicitly focused on the implications of being single. *Singlehood* can be defined in legal or social terms. Adults who are not currently married are legally single. They are socially single if they are not in a mutually acknowledged romantic relationship. Therefore, the only defining characteristic of people who are single is that they do not have a spouse or romantic partner. Because marriage and romantic relationships are valued so highly in our culture and many assume that marriage is a sign of maturity and a harbinger of happiness, the lives of singles are often assumed to be lacking in important ways—a presumption that is explored in this entry. Also to be discussed are the trends that have made legal singlehood more common in the Western world over the past several decades. The relationships that are important to singles are discussed, and research on the happiness and health of singles is reviewed. Finally, many commonly held misperceptions and stereotypes about singles are addressed, and ways in which singles are targets of discrimination are noted.

Singlehood: An Increasingly Common Status

Over the past 35 years, the number of people who are legally single has increased markedly. In 1970, people who were single—whether divorced, widowed, or always single—accounted for only 28.3 percent of the U.S. adult population (18 and older). As of 2006, singles comprised 44.1 percent of the adult population (including 4 percent of the legally single population who cohabit with opposite-sex partners). One of the reasons that there are so many more singles is that the age at which people first marry (for those who do marry) has been increasing. The median age of first marriages in 1970 was 23 for men and 21 for women; by 2005, the ages were 27 and 25, respectively. The divorce rate increased for a number of years and has remained at a high level. Singlehood is also common for older women, who tend to outlive their partners and remarry less frequently than do men. All of these changes add up to a new demographic reality: On average, Americans now spend more of their adult years single than married. The median age of first marriage has also increased in other parts of the

world, including most countries in Western and Eastern Europe and parts of Africa and Asia.

The Lives of Singles: Relationships, Happiness, and Health

Although singles are typically defined as lacking a spouse or serious romantic partner, singles do not lack meaningful and fulfilling social relationships. Having positive relationships with others is an important part of any person's life, and singles often have such relationships with their friends, siblings, relatives, and coworkers. Recognizing the importance of these relationships may help to explain a finding that some might find counterintuitive. Although many people assume that marriage increases happiness, reviews of past research reveal that there is actually little difference in the happiness levels of people who are married and those who have always been single. This finding suggests that always singles meet their interpersonal needs through other important relationships in their lives. In fact, people who have always been single tend to have closer relationships and greater contact with their parents, siblings, friends, and neighbors than do their married peers.

When comparing the happiness of married people to singles, researchers often group the always singles together with the divorced and widowed, resulting in a misleading conclusion that married people are happier. However, divorced and widowed people are generally less happy than people who have always been single; the always singles are more similar to married people.

When people who are single are compared with people who are married at just one point in time, any differences that emerge may not be about marital status at all. For example, people who stay single and people who eventually marry may already differ in happiness even before anyone marries. One way to see whether marriage matters is to follow people over time and see whether, for example, they become happier when they marry than they had been when they were single. A large study showed that when people married, they became slightly happier around the year of the wedding. Then they went back to being about as happy as they were when they were single. Not all people who married experienced that small

increment in happiness around the time of the marriage; people who married and later divorced did not become any happier early on in their marriage. The same study showed that people who became divorced or widowed became less happy than they were before the loss of their spouse, but even they recouped much of their happiness over time.

The findings for health generally follow the same pattern as those for happiness. Although people who have experienced a loss of a marriage, either through divorce or widowhood, often experience poorer health outcomes than people who remain married, there is little difference between the health outcomes of people who have always been single and those who remain married.

Singlehood as Stigma: Negative Stereotypes and Discrimination

Stereotypes of Singles

Despite research showing that people who have always been single are just as happy as those who are married (and when there are differences, they are quite small), people tend to assume that singles are different from married and coupled people along many dimensions. Research on stereotypes of singles has shown that, in comparison with married people, singles are thought to be more socially immature, self-centered, poorly adjusted, unattractive, asocial, and disagreeable and to have lower self-esteem. The only ways in which singles are perceived more positively than married or coupled people is that singles are seen as more independent and career oriented.

Why might people hold predominantly negative stereotypes about singles? First, although singlehood is increasingly common, marriage is still considered the norm. Most people report wanting to marry, and about 90 percent do marry at some point in their lives. Because marriage is considered highly desirable and normative, people may feel the need to explain the lives of singles simply because they are counternormative. The stereotypes that people hold of singles may have developed to serve this purpose—to provide an explanation for why singles have not married (e.g., perhaps they are too independent, immature, or disagreeable). The stereotypes of singles may also follow from assumptions that people make about

the consequences of not marrying (e.g., perhaps singles have become more independent career-oriented or have experienced a decline in self-esteem in response to not having a romantic partner). However, as noted earlier, there is no research indicating that these stereotypes are accurate.

Because adults marry later in life than they once did, it is no longer so unusual to be single in early adulthood. Consistent with the counternormative explanation, then, one might expect that the stereotypes of singles would be stronger for older than younger adults. Research offers some support for this prediction: People perceive larger differences between 40-year-old single and married people than they do between 25-year-old single and married people. Still, younger singles are not exempt from the negative stereotypes. Even college students are perceived more negatively if they are not in a romantic relationship or have not demonstrated past romantic relationship experience. These findings suggest that the need to explain counternormative behavior is unlikely to be the sole explanation for stereotypes of singles.

The predominantly negative stereotypes of singles may also be a consequence of how highly valued marriage and romantic relationships are in our culture today. Not only is marriage seen as a signifier of adulthood, it is also considered to be the most important and fulfilling adult relationship. Contemporary adults often believe in “soul mates.” They look to one special person to fulfill all of their social and emotional needs, often expecting that if they find and marry the right romantic partner, they really will live happily ever after. From a historical perspective, this is quite unusual. In earlier times, marriage was valued for more practical reasons, such as protecting and expanding property and power or increasing the number of people who would be allies rather than strangers. Many people in addition to a spouse had important places in adults’ lives. Now, however, when so many hopes and dreams are invested into just one person—a romantic partner—people who do not have such a partner may be presumed to be unhappy or incomplete.

Some have argued that the increasing number of singles may be perceived as a threat to the highly valued institution of marriage. When people feel that an important belief or institution is threatened, they tend to derogate those who do not live

according to the same beliefs. The negative stereotypes of singles may serve to maintain the importance of marriage by reinforcing negative misconceptions about singlehood.

Finally, from an evolutionary perspective, the negative ways that humans respond to singles may be a vestige of our ancestral past. Back then, people who were unpartnered—particularly women of reproductive age—may have had what evolutionary psychologists call “lower mate value.” Our perceptions have not caught up with our current realities, in which people who are single may be just as likely as people who are married to be healthy and engaged in positive pursuits.

Discrimination Against Singles

The stereotypes that singles are less mature and conscientious than married people can lead to various forms of discrimination. Several studies have found that single men make less money and earn less frequent promotions than married men even when they are the same age, have the same level of seniority, and have demonstrated similar performance on the job. The stereotype that singles are more career oriented can have a negative impact on the way they are treated in the workplace. Singles report being asked to work overtime and during holidays more often than their married peers.

Singles also face discrimination in the rental market. Landlords prefer leasing properties to married couples over singles even when their ages and finances are identical. Even long-term, committed (but unmarried) romantic relationship partners are discriminated against in favor of married couples. People tend to regard discrimination based on marital status as more justifiable and acceptable than discrimination based on race, gender, sexual orientation, or weight. Many commonly accepted and institutionalized policies favor married couples over singles; they include employer-sponsored benefits for spouses, tax advantages for married people, insurance policies that are costlier for singles than for married couples, and two-for-one discounts for consumer products.

Research focusing on singles is fairly recent, and many unanswered questions remain. For example, are there benefits to being single, such as increased autonomy and solitude? Are there adaptive advantages to meeting one's social and

emotional needs through a number of important relationships, rather than investing predominantly in a single romantic partner? Are there unique challenges that single parents face? Might the experiences and stereotypes of singles vary cross-culturally depending on whether marriages are arranged or freely chosen and the differing cultural expectations for marriage as a path to economic security or emotional fulfillment? Perhaps these questions will be explored in the future.

SINGLE-PARENT FAMILIES

Single-parent families are comprised of one parent raising children without the other parent living in

the same household. Many factors have contributed to an increase in the proportion of single-parent households, including divorce, cohabitation, unwed births, teenage pregnancy, death of a spouse, or the decision to have or adopt a child without another parent or partner. Single-parent families are found throughout society and are not limited to particular social groups. Factors such as ethnicity, race, and social class can assist in our understanding of single-parent families. Changing societal attitudes toward single-parent families also help explain the greater acceptance of these households. This entry describes common types of single-parent families and explores the causes and consequences of these family arrangements for individuals and for society.

Description and Types of Single-Parent Families

Although the concept of a single-parent family is not new, there has been growth in such families since World War II. According to the U.S. Census, in the year 2000, 9 percent of households were headed by a single parent and 1 out of 10 children in the United States lived in a single-parent family. Children in single-parent households usually live in mother-only families, although the number of children living in father-only families has also increased. According to estimates, more than half of U.S. children will spend some or all of their childhood in a single-parent household.

In 2005, 9.9 million families in the United States were headed by single mothers, and more than 2 million were headed by single fathers. Part of the growth of single-parent households is due to increased numbers of children born to unmarried parents. By 2000, about one third of U.S. births occurred outside of marriage.

Overall, children in single-parent families are more likely to live in female-headed households. They are also more likely to live in poverty than are children in two-parent or father-only families. Although the fastest growing category of single mothers is comprised of White women, Black and Hispanic children living in single-parent, female-headed households are even more likely to live in poverty. Not only are children in single-parent families more likely to be poor, they also have a greater chance of becoming involved in criminal

activity, having health-related problems, and attaining lesser educational levels. They are less likely to experience consistent parental supervision and more likely to have disagreements with their parent. Children growing up in single-parent households tend to develop less stable family relationships as adults, are more likely to themselves divorce, and attain lower occupational status. Whether these outcomes are a result of being raised in a single-parent household or due to other factors, especially socioeconomic ones, are questions that are fiercely debated by researchers and policymakers.

Research shows that unmarried mothers and their children confront many obstacles. This is especially the case for children born to teenage mothers. Although teen birth rates have declined somewhat in the United States over the past 15 years, they remain high, especially when compared with other industrialized Western countries. About half of all nonmarital births occurred to women under the age of 20 in 1970, whereas less than one third of all nonmarital births were to teens by 1999. Still, the majority of teens who give birth are not married, and their children are more likely to grow up in single-parent families. These children are also more likely to experience multiple living arrangements during childhood, living in what is sometimes called subfamilies. *Subfamilies* are defined as single parents living within other households, often including other adult relatives such as parents. Estimates are that in the United States about one in five single parents (and their children) currently live in subfamily arrangements. Unmarried teens are also more likely to keep their babies, and fewer are getting married than in the past. Teen mothers are also more likely to have subsequent births outside of marriage, have lower educational levels, and be poor. Teen mothers are also likely to be sexually involved with men over the age of 20, who generally do not marry these teen mothers and often do not financially support their children.

Another significant change affecting the rise in single-parent families is related to increased divorce rates since the 1950s. In the United States, current estimates are that more than half of all divorces involve children under the age of 18, and approximately 4 out of every 10 children will experience parental divorce. By the year 2000, in the United States, the majority of single mothers (55 percent)

were either divorced or separated. The impact of divorce on families differs, but generally single-parent families headed by females do not do as well financially as their married counterparts. When noncustodial parents pay child support and have regular visits, the overall well-being of their children improves. The extent to which divorce brings emotional relief to conflict-ridden families is unclear. Stressful divorces can have lasting negative impacts on some children.

Divorce results in the formation of a single-parent family, at least for a period of time. Although there has been much debate on whether divorce causes damage to children, the alternative, staying in a bad marriage, may not be any more acceptable. Increased awareness on the part of many spouses that they have alternatives to marriage and greater societal acceptance of divorce are reasons for the rise in the number of single-parent families. Other reasons include later age at first marriage and increased societal acceptance of cohabitation and out-of-wedlock births. Although death of a spouse also results in single-parent families, increased life expectancy rates make it increasingly unlikely that children will be raised in single-parent households through parental death. For example, in 2000, only 4 percent of single mothers in the United States were widowed.

In the United States, cohabitation rates have been increasing, and estimates are that more than half of nonmarital births currently occur within cohabiting relationships. Cohabiting couples and their families may not experience the same financial and resource challenges as single-parent households. However, although many cohabiting couples expect to eventually marry, these relationships tend to be less stable and disproportionately result in dissolution compared to marriage. Estimates are that less than half of cohabiting relationships last 5 years or more.

The availability of new reproductive technologies and greater acceptance of premarital sex and single-parent adoptions may also influence the decision to become a single-parent family. Estimates are currently that about one third of children adopted from foster homes are adopted by single parents. Some adults choose to become single parents, rejecting the need to be in a committed relationship, but embracing parenthood and family life. For women who delay both marriage and childbearing,

single parenting may be seen as a reasonable option. When former Vice President Dan Quayle criticized the television show *Murphy Brown* for glamorizing single motherhood, he was accused of misunderstanding the plight of single mothers and underestimating the degree to which American society supported the right of single women to choose motherhood over marriage. Gay and lesbian single parenting has also become more common. Many states now allow single gay men and lesbians to be foster parents and to adopt children.

Racial and Ethnic Differences

In the mid-1960s, the *Moynihan Report* cited three features of Black family life: (1) almost one quarter of urban Black marriages were dissolved, (2) almost one quarter of Black births were to unmarried mothers, and (3) almost one fourth of Black families were headed by females. Although this report was criticized, 15 years later, out-of-wedlock birthrates among Blacks had more than doubled to 56 percent. By 2005, 65 percent of Black children were born to single mothers. Recent research on Black families continues to show higher proportions of unwed mothers, single-parent families, and poor single-parent households. Many factors contribute to racial and ethnic differences in single-parent households. Black children in the United States are more likely to live in single-parent families (65 percent) than are Hispanic children (34 percent), non-Hispanic White children (24 percent), and Asian children (16 percent). Although there has been an overall decline in the proportion of teen births in recent years, the percentage of births to Hispanic teens is growing rapidly.

Census figures show increases in the number of single-parent, female-headed households across all racial and ethnic groups. Single-mother households headed by Whites are more likely to be the result of divorce, whereas Black and Hispanic single-mother households are more likely to be the result of having never married. However, there is variation among Latino subgroups in terms of rates and types of female-headed households. Estimates are that more than 25 percent of American Indian families are single-parent, female-headed households.

Psychological Impacts

The psychological effects of growing up in a single-parent family vary. Single parents and their children can share some psychological outcomes, including loneliness, anxiety, fear, and feelings of abandonment. Single parents are more likely to suffer from higher levels of stress partly because they must take on the role of both parents even if they are uncertain about what the other role entails. Financial strains experienced by single-parent households add to psychological stress, as does the lack of emotional support experienced by many single parents.

Single-parent families often face especially high levels of stress. Compared with two-parent families, single-parent households experience more major life events, including job changes, decreases in income, moves, and illness. Single mothers in particular report lower levels of psychological support, higher amounts of depression, lower self-esteem, and greater pessimism.

The psychological impacts on children of single-parent families can be numerous. Children in single-parent families are often given more responsibilities than those from two-parent homes, and many report having social lives that differ from their peers raised in two-parent families. Often children in single-parent families feel as if they had to grow up more quickly and assume more responsibilities. They often report emotional strains related to being overloaded with responsibilities, tasks, and expectations. The absence of fathers in the lives of many female-headed households may deny children the opportunity for access to a male role model.

Finally, children of divorce who are subsequently raised in single-parent households may experience psychological effects even years after the divorce of their parents. Although some studies report that these children are more worried, angry, underachieving, and less likely to enter into healthy adult relationships, there is no agreement on this issue. Others suggest that children raised in single-parent divorced households are more resilient and adjust well.

Sociological Consequences

Children raised in single-parent families may experience lower educational achievement, increased

chances of dropping out of high school, and increased chances of drug or alcohol use and of committing delinquent acts compared with their peers from intact families. They also tend to experience greater difficulties in future occupational success. If they marry, they are more likely to do so earlier and to have children earlier. They are also more likely to divorce.

Although single-parent families are more accepted today, many single parents feel that their lifestyles are negatively labeled. Single parenthood and divorce are still seen by many as “failed familial life cycle stages.” Many family policies tend to favor two-parent families, and single-parent families are often seen as burdens to the state. In American society, a weak social welfare system, inadequate affordable child-care and health care options, and the erosion of strong extended families result in many single-parent families reporting high degrees of social isolation. Single-parent families in countries that place less emphasis on individualism as a social value do not report similar levels of isolation.

Due to financial strains, many single-parent families live in low-income areas and send their children to low-performing schools. They more often live in neighborhoods with high crime, unemployment, and poverty rates. Another significant concern for many single-parent families is health care because many single parents work in jobs that do not provide these benefits. Child care is another issue for many single-parent households, especially for those with lower incomes. Single parents often find themselves relying on family, friends, neighbors, and older siblings for child-care services. Children in single-parent households are less likely to have as much parental supervision. Single parents tend to be less involved with their children’s educational activities and are less likely to monitor their children’s friends and leisure activities.

SOCIAL ALLERGIES

A social allergy is an individual's tendency to experience a disproportionately intense emotional reaction in response to a social allergen. A social allergen is a behavior or situation that seems unpleasant or uncivil to onlookers, but may not warrant as intense a reaction as the individual displayed. Individuals who experience social allergies may recognize that their reactions are excessive, but describe the stimulus as something that "grates on my nerves," "rubs me the wrong way," "has gotten under my skin," "is making me sick," "is driving me crazy," or "is a pet peeve." Social allergens commonly produce annoyance or disgust, although rage, anxiety, or sadness also may occur.

Mechanisms of Social Allergies

A social allergy affects an individual emotionally in a manner that resembles how physical allergies function immunologically. The first experience with poison ivy generally produces a small negative reaction. With repeated contact with poison ivy, however, sensitivity tends to increase, and the negative response becomes stronger. The same repetition-sensitization response can occur in response to a lover or coworker's unpleasant behavior. Many unpleasant behaviors that occur occasionally are gracefully tolerated and quickly forgotten. But, through periodic exposure at regular intervals or through extreme or prolonged initial exposure, a social allergen may produce escalating sensitivity. Each instance of the unpleasant actions may

increase the recipients' socially allergic emotional response. Respondents recognize changes in their reaction over time by saying that they have become "tired of" or "fed up with" a social allergen.

The repetition-sensitization process may be based on the same learning dynamics that are responsible for Pavlovian conditioning and reinforcement learning, and it shares some features with post-traumatic stress disorder. Cognitive processes can accelerate the process. Negative emotions can be accelerated if the individual perceives that the perpetrator is uncivil due to indifference and does not care about causing unpleasantness or hurt feelings. Emotions can be further inflamed if the recipient has politely asked the perpetrator to curtail the unpleasant actions and they continue nonetheless. The escalating reaction may be adaptive to motivate further action to escape or suppress the allergen.

Types of Social Allergens

When university students were asked to specify people who caused social allergic reactions and drove them crazy without necessarily intending to do so, every respondent was able to name at least one person who got under his or her skin. The average was one relative and three nonrelatives. Based on studies conducted with undergraduate students in romantic relationships and a study of employees responding about work relationships, allergenic behaviors were divided into four categories. The categories differed in terms of whether the initiation of the action was intentional (even if the consequences may not have been), as opposed to being performed habitually, accidentally, or mindlessly. The factors also differed in terms of whether the behaviors were personally directed toward the individual or performed by the partner without focusing on the individual (although the partner might be offended or hurt). Examples of behaviors from love and work are offered.

Uncouth habits are behaviors that are unpleasant, but are not intentional or personally directed. A romantic partner could behave aversively through excessive informality, such as by noisily belching, showing a lack of concern for being clean, expressing a lot of profanity, or wearing old, tattered clothing. An uncouth coworker displays

poor grooming, frequently leaves things in others' work spaces, fails to share work information, or uses jargon that is difficult to understand.

Inconsiderate acts involve behaviors that are relatively unintentional, but nonetheless create a personal imposition. Romantic partners who are prone to inconsiderate acts demand attention by frequently asking for feedback about their appearance, take too many things when traveling (which require help), keep the individual out shopping too long, or express excessive needs for emotional support (which require pep talks). An inconsiderate coworker does not offer help when the individual needs it, often complains about mundane things, is vague and indecisive on task, or does not work hard on shared projects. Inconsiderate acts were the most frequent allergens among coworkers and had the greatest emotional impact.

Intrusive behaviors are actions that are both intentional and personally imposing. They include a romantic partner demanding that the individual do things, complaining about actions that caused disappointment or anger in the distant past, or being rude, insulting, impolite, or disrespectful to the individual. An intrusive coworker is critical, giving commands without having legitimate authority, does not allow the individual to take a turn in the conversation, or imposes his or her thoughts and opinion on the individual. Intrusive behaviors caused the strongest social allergies in romantic relationships.

Norm violations are behaviors that are intentional, but not personally directed. This includes a romantic partner who does not work hard at job or school, gambles excessively, goes out with friends instead of the individual, or flirts with members of the opposite sex. Norm violation also describes the actions of a coworker who does unethical things to get ahead, lies to other people, creates obstacles for more successful people, or criticizes people who are in a position of authority.

In research examining social allergies among dating couples, it was found that the longer a couple had been dating, the more that the individual perceived the partner to display uncouth habits, inconsiderate acts, and intrusive behaviors. The change in perception of negative behavior was not due simply to the loss of romantic illusions. The individual's increased perception of negative partner behaviors was related to the partner's own

self-reports of decreased effort to be proper, increased efforts to control the individual, and decreased disclosure to the individual.

Social Allergy Outcomes

A social allergy can develop whenever a partner or coworker repetitively performs an obnoxiously vulgar, insensitive, pushy, or proscribed behavior that adversely affects the personal boundary, comfort, dignity, or propriety needs of the individual. The frequency of occurrence of an allergen and the intensity of the emotion that it elicits both influence the impact of social allergies on the individual's life.

Personally focused allergens, such as inconsiderate acts and intrusive behaviors, have adverse effects on romantic relationship satisfaction, whereas intentional allergens, such as intrusive and norm-violating behaviors, predict relationship termination. In the office, the frequency with which a coworker performed each type of social allergen is associated with dissatisfaction with the social environment of work, which is correlated with turnover intention. Social allergens are stressors that may have an adverse impact on the immune system. They are related to an increased likelihood of illnesses.

Coping With Social Allergies

Individuals cope with social allergies in a variety of ways. In a study conducted by Michael Cunningham and colleagues, about half of people who experienced a social allergy spoke to the perpetrator, but most did not obtain relief. Perpetrators differ in their capacity and inclination to modify their allergenic behavior, especially the unintentional.

Individuals tried to cope by avoiding the perpetrator of social allergens. Due to the contact demands of work and relationships, this was seldom successful. Many people dealt with their social allergies by seeking support and advice from other people. This seemed to reduce some of the adverse impact, but did not neutralize the effect of social allergies on job or relationship satisfaction.

Accepting advice to adjust to certain social allergens, rather than resent them, may aid some people. But individuals who are neurotic and easily

upset may find it difficult to acclimate to social allergens, and some social allergens are simply intolerable. Systematic desensitization therapy may help in such cases. Strategies to alleviate social allergies may be an important part of an individual's emotional, relational, and physical health.

SOCIAL ANXIETY

Social anxiety is a fear of being evaluated negatively, embarrassed, or judged by others. It is a construct that overlaps significantly with the personality trait of shyness. When a person's social anxiety is associated with life interference or significant personal distress, he or she is diagnosed with social anxiety disorder (or social phobia, as listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* [2000]). It is important to acknowledge that nearly everyone experiences some degree of social anxiety in certain social or evaluative situations. Social anxiety is regarded as problematic when it is associated with avoidance of these situations and/or decreased life satisfaction.

According to the Self-Presentation Theory of social anxiety, described by Mark Leary and his colleagues, socially anxious individuals would like to make a favorable impression on others, but they

doubt their ability to do so. As a result, they behave in a submissive, conciliatory manner to avoid rejection. Unfortunately, this strategy often prevents them from achieving the pleasurable rewards that most people obtain from social engagement. Research has documented many deleterious interpersonal consequences of social anxiety. For example, data from large epidemiological studies indicate that people with social anxiety disorder experience mild to moderate impairment in their close relationships, and they are less likely to be married than people without this disorder. Other studies have demonstrated that socially anxious individuals report higher levels of loneliness, fewer friends, less dating experience, and fewer daily social interactions than nonanxious individuals. Some socially anxious people are unsatisfied with their social networks and the social support they receive from close others.

This entry discusses some of the specific cognitive, behavioral, and interpersonal deficits experienced by socially anxious individuals that have been identified in published research. It also describes psychosocial and pharmacological interventions that can be used to treat the symptoms of social anxiety that exacerbate these deficits. However, this entry also considers the manner in which social anxiety can be adaptive in forming and maintaining relationships.

Cognitive Deficits

Cognition refers to the manner in which people think about, judge, and interpret events in their environment, as well as the manner in which they process incoming stimuli. Socially anxious individuals experience more negative and fewer positive thoughts when they interact with others. Contrary to ratings by objective observers, they believe that they have performed poorly in social situations. Even when they judge that a social interaction has gone well, they continue to experience anxiety because they believe that others will increase their expectations for them. When a social error occurs, they perceive it as being costly or intolerable. After they have engaged in social interaction, they ruminate over their performance, a phenomenon called postevent processing.

Socially anxious individuals are quick to detect any indicators of poor social performance, such as

a frown from a member of the audience. Furthermore, they interpret neutral behaviors by others (e.g., an inadvertent yawn) as evidence that they are being rejected. Socially anxious individuals also exhibit self-focused attention, which is defined as excessive attention on internally generated information, such as emotions or physiological sensations. When they focus their attention inwardly during social interaction, they become consumed with indicators of anxiety and miss important social cues that would enhance their performance. As a result, they have difficulty remembering the information that is shared with them by others. Thus, socially anxious individuals have pessimistic beliefs about their ability to engage successfully in social interaction, and their style of information processing during social interaction puts them at risk for realizing their negative predictions.

Behavioral Deficits

Social skills are behaviors that enable people to be successful in social interaction and include verbal, nonverbal, and emotional expressions. A great deal of research designed to examine social skills in socially anxious individuals was conducted in the 1970s and 1980s; a typical study required socially anxious and nonanxious individuals to have conversations with standardized conversation partners (i.e., confederates who were part of the experiment), and their social skills were coded by objective raters. Surprisingly, this research suggested that socially anxious individuals tend to be as adept as nonanxious individuals in many types of molecular social skills, or skills that capture specific behaviors such as head nods and gestures. When socially anxious individuals were rated on the overall impression that they made on others during social interaction, they fared more poorly than nonanxious individuals, although ratings often indicated that they performed in the adequate range. Many scholars suggested that the degree to which socially anxious individuals demonstrate impaired social skills varies as a function of the circumstances surrounding the interaction. According to this explanation, socially anxious individuals are most likely to demonstrate social skills deficits in situations involving evaluation or

ambiguity and are least likely to demonstrate social skills deficits in situations in which they are comfortable, such as friendly interactions with close friends and family members.

More recent research has adopted the same type of experimental methodology, but in addition to coding observable social skills, it obtains ratings on the subjective impressions that socially anxious and nonanxious individuals make during their interactions. Findings from this line of research suggest that people who interact with socially anxious individuals report that they have difficulty forming a meaningful connection with them. Relative to their conversation partners, socially anxious individuals disclose less about themselves and speak for less time. As a result, conversation partners perceive that socially anxious individuals are dissimilar and uninterested in them. People who interact with socially anxious individuals do not experience the expected increase in positive affect by the end of the conversation and, at times, even express irritation toward them. After the conversation, conversation partners rate the quality of the interaction as low and indicate that they would not particularly look forward to future interactions with them. Although this summary paints a bleak picture of the impression that socially anxious individuals make on strangers, it should be noted that interactions between two socially anxious partners are associated with higher levels of closeness than interactions between one socially anxious and one nonanxious person, suggesting that characteristics of the conversation partner play a role in the amount and type of information that socially anxious individuals disclose.

Most of the research on the association between social anxiety and social skills deficits has examined skills in the context of meeting people for the first time. However, there is some evidence that socially anxious individuals demonstrate impaired skills in their partner relationships. When talking with their partner about a problem in their relationship, their communication style often escalates conflict, rather than resolves it. They often communicate defensiveness and a sense that they do not understand their partner's point of view. In addition, compared with nonanxious individuals, socially anxious individuals report a lower frequency of sexual activity with a partner, less sexual satisfaction, more apprehension about sex, and a

higher incidence of sexual dysfunctions, such as premature ejaculation (if male).

Interpersonal Style

Adult attachment style is defined as a cognitive, emotional, and behavioral way of responding in close relationships that stems from significant childhood relationships, especially the caregiver–infant relationship. Socially anxious individuals are more likely than nonanxious individuals to be characterized by both a fearful adult attachment style (i.e., discomfort with being close with others) and a preoccupied adult attachment style (i.e., anxiety about not being able to obtain a satisfying relationship). Socially anxious individuals characterized by a fearful style would be expected to avoid close relationships or approach them in a guarded, defensive manner, whereas socially anxious individuals characterized by a preoccupied attachment style would be expected to be submissive and dependent in their close relationships. Other work examining interpersonal styles associated with social anxiety has supported the notion that there is heterogeneity in the manner in which socially anxious individuals approach their relationships, with some socially anxious individuals presenting as friendly but unassertive and other socially anxious individuals presenting as hostile and mistrustful. Some research shows that the latter group of socially anxious individuals is particularly likely to experience other types of psychological distress and demonstrate a resistance to treatment.

Intervention

The most extensively evaluated psychosocial interventions for social anxiety fall in the broad category of cognitive behavioral treatments, which include interventions designed to help patients develop strategies to evaluate maladaptive beliefs about themselves and the world and/or develop behavioral strategies for managing social anxiety (e.g., relaxation, social skills, exposure to feared situations). In addition, some serotonin-reuptake inhibitors (e.g., paroxetine [Paxil]), monoamine oxidase inhibitors (e.g., phenelzine [Nardil]), and benzodiazepines (e.g., clonazepam [Klonopin])

are more effective than placebo in treating social anxiety. Research shows that both pharmacological and cognitive behavioral treatment approaches are equally efficacious in reducing symptoms of social anxiety. Although pharmacotherapy exerts its effects more quickly, patients who receive cognitive behavioral therapies are less likely to relapse. To date, most clinical trials that evaluate interventions for social anxiety focus on reductions in anxious symptoms as an outcome, rather than improvements in interpersonal functioning. However, there is preliminary evidence that cognitive behavioral approaches to treating social anxiety are associated with improvements in self-reported social functioning and social skills rated by objective judges.

Adaptive Significance

According to evolutionary theory, social anxiety inhibits people from behaving in ways that would threaten dominant others, which in turn ensure their place in a group. This was adaptive for our ancestors because it was nearly impossible for them to survive outside of a group and handle the multitude of environmental threats that they faced on a regular basis. In contemporary society, excessive social anxiety is unnecessary because the same threats no longer exist (or exist to a much lesser degree), and it often interferes with attaining interpersonal goals that many people aspire to achieve. As is evidenced in this entry, the majority of the theory and research on interpersonal functioning and social anxiety is geared toward identifying specific deficits that cause such life interference and developing strategies for modifying those deficits.

However, it is important to acknowledge that not all socially anxious individuals are dissatisfied with their interpersonal functioning. Many socially anxious individuals have a small, intimate circle of family and friends to whom they feel close. Socially anxious individuals are likely to be perceived by others as modest, agreeable, and polite, and they are unlikely to be perceived by others as arrogant and brash. It is possible for socially anxious individuals to learn to capitalize on these traits in their interpersonal functioning. There is also evidence that socially anxious individuals perceive their

mate value to be lower than nonanxious individuals, and they report that they would be less likely to pursue relationships with physically attractive people and more likely to pursue relationships with unattractive people. Although these findings sound like additional deficits associated with social anxiety, in actuality, this tendency could be adaptive because socially anxious individuals would not squander their resources on unattainable partners. Thus, there is no doubt that social anxiety is associated with interpersonal distress, but there are many avenues for socially anxious individuals to attain healthy close relationships.

SOCIAL CAPITAL

Social capital is the social ties and the norms of trust and reciprocity that underlie them. These ties

represent an often overlooked yet crucial asset for individuals and communities. In principle, this form of capital is as valuable to the productivity and well-being of individuals and communities as their financial assets, as well as their education and training. Like financial capital and human capital, social capital is a resource used to maintain and improve quality of life. It is a key unlocking a world of greater possibility. Indeed, it is through friends, colleagues, and acquaintances that individuals and groups receive opportunities to use larger pools of financial and human capital. This entry reviews the benefits of social capital, as well as some of the problems confronting social science in measuring and conceptualizing the value of these assets.

Like financial and human capital, the possessor of such ties must not just simply invest in them and build them over time to be beneficial; they must “spend” them as well. At a personal level, such ties give access to information, opportunities, and resources available only to the friends and acquaintances in our networks. With some personal effort, they can help us get a job, a loan, information, or just plain good advice. The community can benefit from social capital as well. A multiplier effect is realized when groups share their talents and resources. Partnerships have the potential to be stronger, more resilient, and more creative than their partners.

Functions of Social Capital

Social capital benefits individuals and groups in two ways. It *bonds* a collection of similar individuals together, producing “strong ties” between them. A strongly bonded group offers entrée to a community of persons with similar characteristics, influence, and resources. In contrast, social ties *bridge* or link differing groups of people, unlocking a wider array of resources and a wider span of influence. Bonding ties allow people with limited resources to maintain their current circumstances and lifestyles better than they might on their own. Bridging ties, in contrast, allow these same people to achieve a better way of life by providing admittance to groups with a greater variety of resources and power. These ties are sometimes referred to as “weak ties” because they represent the larger

acquaintance structure of individuals. Weak ties can help people and communities overcome structural barriers to advancement. For both individuals and groups, they offer chances for innovation and change by offering exposure to a range of new ideas, new resources, and diverse populations.

This understanding of the “value” contained in our social ties has led to research concluding that social capital has significant benefits for people’s physical and mental health and their overall sense of well-being. Life satisfaction, suicide ideation, depression, colds, heart disease, strokes, cancer, and premature deaths have been linked to reduced social capital, although the mechanisms connected with these relationships remain unclear. Indeed, although the concept of social capital has promoted interest in topics as diverse as the social causes of disease, work productivity, school performance, and the significance of civil society, the concept of social capital is not without its critics.

Problems of Measurement

Perhaps the most serious problem yet to be overcome is the challenge of measuring social capital. Too often social capital is assessed arbitrarily in social science research. Measures have included distinct forms: political, civic, and religious participation; workplace ties; informal social ties; Internet-based connections; volunteering and philanthropy; social support; and attitudes of reciprocity and trust. This scatter-shot approach to the concept of social capital has led to too many indices with no agreed-on scale, and that has made for confusion and overwrought claims of relevance. No agreement exists yet in the social sciences over what constitutes social capital, leaving the concept open to the critique that it is a catch-all term for a variety of social connections and normative circumstances. Substantial work, therefore, needs to be done to refine the measurement of social capital before much can be said definitively about its impact on quality of life. Perhaps the best example of this lies in the debate over whether social capital is declining in the United States. The answer appears to depend on how social capital is measured. When social capital is assessed by looking at more traditional social connections like voluntary associations, friendships, social supports, acquaintances,

religious participation, and so on, a good case can be made that social capital has declined in the United States since the late 1970s. However, when use of the Internet is factored into the equation, it is apparent that the ties that bind us together may have actually increased steadily with the use of blogs, Web pages, e-mail, online support groups, and so on.

Social Capital as a Fix

Social capital is also controversial because the concept implicitly suggests that it can fix deep-seated social problems. In essence, the term has both empirical and normative content—describing what is as well as what should be. Local problems are often blamed on shrinking social capital, rather than government inattention or an unjust social structure. Implicit in some writings on social capital is the idea that as voluntarism and group participation decline so goes the community and the society. There are two hidden assumptions in this approach to social capital:

1. This asset has the same uniform spending power as physical and human capital. Hence, possessing a unit of social capital tends to have the same consequences regardless of the individual’s position in the social structure. From this perspective, both the individual’s and the community’s capacity for problem solving must be reassessed because all fungible and measurable assets have not been counted.
2. Individuals and communities have the capacity to pull themselves out of poverty and dramatically improve their quality of life if they just invest in and spend their social resources wisely. In essence, social capital is capital, whoever has it and wherever it is located.

There is a serious problem with these assumptions. Social capital’s value for individuals and communities depends on resources embedded in social networks, hence not all social asset units are equal because the resources embedded in them vary by social position. The social position of the asset holder affects the value of his or her social capital. Social capital doesn’t spend the same way in every social position. People in poor, segregated communities, with fewer fiscal and human capital

assets, often find their social ties becoming obligations instead of resources.

Social capital offers a promising concept for thinking about how social networks can improve individuals' quality of life. Much work, theoretically and methodologically, still needs to be done before the field fully understands how to measure the "value" of these assets for individuals and communities.

SOCIAL COMPARISON, EFFECTS ON RELATIONSHIPS

Imagine a couple, Tony and Maria. Tony and Maria spend lots of time together, as many couples do, doing things together and sharing their victories and disappointments. But how do Tony and Maria affect each other's self-concepts? How will Tony feel when Maria wins a dance competition they both entered? Similarly, will it affect Maria's self-concept when Tony loses a fight? Self-concept shifts due to social comparison can either be contrastive (people's views of themselves become less similar to their views of the salient other; e.g., Tony compares himself to Maria and feels like a worse dancer because she is so good) or assimilative (people's views of themselves

become more similar to the salient others; e.g., Tony feels like a better dancer when he thinks about how his girlfriend is a great dancer). In addition, they can either have positive effects (improved feelings about the self and/or about a relationship) or negative effects (diminished feelings about the self and/or a relationship). For example, if Maria is attractive, Tony can either compare himself to Maria and feel less attractive (a contrast effect with negative implications for the self) or incorporate her attractiveness to himself and feel more attractive (an assimilation effect with positive implications for the self). Similarly, if Maria is a bad dancer, Tony can either compare himself to Maria and feel like a better dancer (a contrast effect with positive implications for the self) or incorporate her dancing to himself and feel like a worse dancer (an assimilation effect with negative implications for the self). Factors that influence the directions and effects of social comparisons within close relationships are discussed in this entry. The broader implications of social comparison within and between close relationships are also discussed.

Direction and Effects of Social Comparisons in Close Relationships

Relationship Closeness

Within close relationships, a key variable influencing whether assimilation or contrast effects occur is the closeness of the relationship between the perceiver and the target. When the perceiver has a close, intimate relationship with the target, assimilation effects are likely; when the target is not close to the perceiver, contrast effects become more likely. For example, when evaluating their own performance on a novel task, people tend to assimilate the performance of a close friend, but contrast the performance of an acquaintance. Similarly, the self-concept of the perceiver can moderate these effects. When thinking about the self as interdependent or connected to others (e.g., I am a mom, a sister, a friend, a teammate), people tend to assimilate relationship partners. Conversely, when thinking about the self as independent or unique and different from others (e.g., I am smart, funny, unique, different from other people), people tend to contrast relationship partners.

Attachment Style

Although all people form relationships, they differ in their desire to pursue closeness within those relationships. Attachment theory accounts for these differences by asserting that individuals enter relationships with well-developed cognitive representations of the self and others. One dimension of the attachment behavioral system is avoidance. Individuals who are low in avoidance (hereafter referred to as *nonavoidant*) are comfortable with closeness and seek it in their relationships. Conversely, avoidant individuals are not comfortable with closeness and try to create mental and physical distance between themselves and their relationship partners. In addition, avoidant individuals are often involved in relationships that are low in interdependence and commitment. Thus, avoidant and nonavoidant individuals differ in their desire for, and comfort with, closeness in their relationships.

These principles, together with social comparison research, suggest that nonavoidant individuals may be more likely than avoidant individuals to assimilate the characteristics of relationship partners into their self-concepts because of their greater comfort with closeness. However, avoidant individuals may be more likely than nonavoidant individuals to contrast their self-concepts away from the characteristics of relationship partners because of the mental and physical distance between themselves and their relationship partners. A priming study conducted by Shira Gabriel and her colleagues found that individuals with nonavoidant attachment styles define themselves as more similar to a friend (assimilation effect), whereas individuals with avoidant attachment styles define themselves as less similar to a friend (contrast effect). Priming refers to an experimental procedure that activates mental images of a particular concept or person. For example, thinking about a funny and extroverted friend led nonavoidant participants to describe themselves as more funny and extroverted than when not thinking about the friend. Conversely, thinking about a funny and extroverted friend led avoidant individuals to see themselves as less funny and extroverted than they normally would. Gabriel and her colleagues also found behavioral effects of thinking about friends. Thinking about a smart friend led nonavoidant

individuals to perform better on an ostensible intelligence task, whereas avoidant individuals trended to perform worse. The same effects have been found with romantic partners. Thinking about the ways in which a romantic partner is intelligent led nonavoidant participants to do well in an ostensible intelligence task, whereas thinking about the ways in which their romantic partner is stupid led avoidant participants to do better on the same task.

Relevance of Domain to the Self

Contrast and assimilation effects are also influenced by the relevance of the domain of comparison to the self (self-relevance). Abraham Tesser's Self-Evaluation Maintenance (SEM) model proposes that within close relationships contrast effects are likely within self-relevant domains, whereas assimilation effects are likely within domains of low self-relevance. For example, if singing is important to Maria's self-concept, then she is likely to contrast her singing to Tony's and feel threatened if Tony is a better singer. However, if singing is not central to Maria's self-concept, Maria is more likely to assimilate Tony's singing skills and feel proud of him and good about herself even when Tony outsings her. Thus, one implication of the SEM model is that the performance of a partner who shares the same interests can be threatening to the self, in particular when the partner excels in that area.

Thankfully, for all people who fall in love at work or in graduate school, there are exceptions to this corollary. Close relationships may serve as a buffer against negative social comparisons. For example, people in close relationships can moderate the negative impact of upward social comparisons (i.e., comparison to others who perform better than the self) by focusing on the strength of their relationship, rather than their own bruised egos. Furthermore, interdependently oriented individuals tend not to demonstrate contrast effects in close relationships, even on self-relevant traits. Rather, people who think of relationships as part of the self, either dispositionally or situationally, tend not to feel threatened by the good performance of a close friend; instead, the friend's success may be cause for celebration, rather than a blow to self-esteem.

Extensions of the SEM model have accounted for individual differences in close relationship quality. Married people, who tend to have a more interdependent or communal orientation and distinguish less between benefits to the self and to the partner, respond to outperforming (or being outperformed by) a partner by considering the partner's response to being outperformed by (or to outperforming) oneself. This may attenuate the standard responses. In other words, although Tony outsings her, Maria may feel happy because Tony has succeeded.

Broader Implications of Social Comparisons Within and Between Close Relationships

Implications of Attachment Style

Social comparisons have implications for self-esteem and partner preferences. The self-concept contains both positive components (liked and ideal attributes) and negative components (disliked and feared attributes). Because nonavoidants assimilate the characteristics of salient relationship partners into their self-concepts, relationship partners who embody liked and ideal aspects of the self-concept may lead nonavoidants to feel better about themselves by activating the more positive aspects of self. However, because avoidants contrast themselves to relationship partners, they benefit from having relationship partners whom they perceive as embodying more of their negative traits (i.e., their disliked and feared attributes). Comparing themselves to more negatively viewed relationship partners makes avoidants feel less similar to their feared and disliked aspects of self, which in turn helps avoidants feel better about themselves. Avoidants and nonavoidants also strategically favor different relationship partners when their self-esteem is threatened as a means of bolstering their self-esteem. After a self-esteem threat, non-avoidant participants favor relationship partners who are viewed as more similar to positive aspects of self. Conversely, avoidant participants favor relationship partners who are more similar to negative aspects of self.

Implications of the SEM Model

The social comparison processes involved in SEM also have implications for relationship processes. To

avoid the potentially painful consequences inherent in SEM, individuals have been shown to willfully bias the processing of social comparison by undermining, predicting poor performance for, or psychologically distancing themselves from successful close others. SEM processes also affect partner choice. In one study, middle-school children preferred friends whose performance (both actual and perceived) was better than their own on self-irrelevant traits, but slightly worse than their own on highly self-relevant traits. Thus, SEM effects can lead to different treatment of partners, feelings for partners, and even partner choice.

Between-Relationship Social Comparisons

Social comparisons are also used to evaluate the strength of a relationship by contrasting it to other relationships. Thus, Tony and Maria can feel better about their relationship by comparing themselves to other couples whom they perceive as less happy. For example, when evaluating their relationship problems, spouses tend to view themselves as better off than other couples, thus providing themselves with a downward comparison standard. Some individuals are more likely than others to engage in these between-couple social comparisons. Individuals high in Social Comparison Orientation (i.e., a strong tendency to engage in social comparisons) tend to be happier with their own close relationships after reading about people who have poor social lives or who have to work hard on their relationships to be happy.

SOCIAL EXCHANGE THEORY

The social exchange framework was formally advanced in the late 1950s and early 1960s in the work of the sociologists George Homans and Peter Blau and the work of social psychologists John Thibaut and Harold Kelley. Over the years, several exchange perspectives, rather than one distinct exchange theory, have evolved. The exchange framework is built on the combination of the central tenets of behaviorism and elementary economics. Within this framework, human behavior is driven by the desire to maximize rewards and minimize costs. The framework can be used to understand the constellation of factors contributing to the formation, maintenance, and breakdown of social relationships over time and the interpersonal dynamics found within them.

Core Assumptions of the Exchange Framework

Embedded within the exchange framework are core assumptions about the nature of humans and social or “exchange” relationships. The assumptions about the nature of humans are summarized as follows:

- Individuals seek rewards and avoid punishments.
- When interacting with others, individuals seek to maximize profits for themselves while minimizing costs. Because it is not possible to truly know the actual rewards and costs involved in interacting within another before the interactions occur, individuals guide their behavior through their expectations for rewards and costs.
- Individuals are rational beings and, within the limitations of the information that they possess, calculate rewards and costs and consider alternatives before acting.
- The standards that individuals use to evaluate rewards and costs differ from person to person and will vary over time.

The assumptions about the nature of exchange relationships are as follows:

- Exchange relationships are characterized by interdependence—that is, the ability to obtain profits in a relationship is contingent on the ability to provide others with rewards.
- Exchange relationships are regulated by norms like reciprocity, justice, and fairness.
- Trust and commitment result when relationships are consistently experienced as both rewarding and fair, and these help to stabilize relationships over the long term.
- Exchange relationships are characterized by the levels of attractions and dependence experienced by those participating in the relationship. It is the contrasting levels of attraction and dependence experienced by each partner in the relationship that determines the patterns of interaction found within the relationship and the stability of the relationship over time.

Core Exchange Concepts

The core exchange concepts can be classified as falling into the following broad categories.

Rewards, Costs, and Resources

Exchange theories make use of the concepts of rewards and costs (which were borrowed from behavioral psychology) and resources (which were borrowed from economics) when discussing the foundation of the interpersonal exchange. Rewards and resources refer to the benefits exchanged in social relationships. *Rewards* are defined as the pleasures, satisfactions, and gratifications a person enjoys from participating in a relationship. *Resources* are defined as any commodities, material or symbolic, that can be transmitted through interpersonal behavior and give one person the capacity to reward another. The costs of social exchange relationships can involve punishments experienced, the energy invested in a relationship, or rewards foregone as a result of engaging in one behavior or course of action rather than another.

Relationship Satisfaction

Satisfaction with an exchange relationship is derived, in part, from the evaluation of the outcomes available in a relationship. Outcomes are equal to the rewards obtained from a relationship minus the costs incurred. Although it is generally the case that the higher the level of outcomes available, the greater the satisfaction, these concepts are not equivalent. To account for satisfaction, both the experiences of the outcomes derived from the relationship and the expectations that individuals bring to their relationships are taken into account.

The concept of comparison level (CL) was developed by Thibaut and Kelley to explain the contributions that previous experiences and expectations make to the determination of how satisfied an individual is with a relationship. Individuals come to their relationships with an awareness of societal norms for relationships and a backlog of experiences. The CL is influenced by this information and thus reflects (a) what individuals feel is deserved and realistically obtainable within relationships and (b) what individuals feel is important for them to experience within a relationship. When the outcomes derived from a relationship exceed the CL (particularly highly valued outcomes or ones that are important to individuals), global assessments of a relationship are likely to be high.

Relationship Stability

The satisfaction that partners experience with their relationships does not solely determine the stability of the relationships. Thibaut and Kelley developed the concept of comparison level of alternatives (CL_{alt}), defined as the lowest level of outcome a person will accept from a relationship in light of available alternatives, to explain individuals' decisions to remain in or leave a relationship. The CL_{alt} is an individual's assessment of the outcomes available in an alternative to the present relationship. When the outcomes available in an alternative relationship exceed those available in a relationship, the likelihood increases that that person will leave the relationship.

Hence, staying in or leaving a relationship is not simply a matter of how rewarding that relationship is. Relationships that are rewarding are more likely to be stable because a high level of outcomes reduces, in terms of expectations, the likelihood of a better alternative existing. Unsatisfactory relationships, in turn, may remain stable for the lack of a better alternative. These relationships have been conceived of as nonvoluntary relationships by Thibaut and Kelley. Married individuals who stay in violent relationships can be thought of as participating in a nonvoluntary relationship—that is, the relationship stays stable despite the violence because of the absence of better alternatives.

The CL_{alt} is also related to the experience of dependence. *Dependence* is defined as the degree to which a person believes that he or she is subject to or reliant on the other for relationship outcome. The degree of dependence evidenced is determined by the degree to which the outcomes derived from a relationship exceed the outcomes perceived to be available from existing alternatives. Dependence may be experienced as one of the costs of participating in a relationship, but this is probably determined in part by the level of satisfaction experienced with the relationship. Dependence, in other words, is tolerated in highly rewarding relationships.

Dependence is further influenced by the barriers that increase the costs of dissolving an existing relationship. Two types of barriers (e.g., internal and external) discourage an individual from leaving a relationship by fostering dependence even if attraction is low. Internal barriers are the feelings of obligation and indebtedness to the partner that

contribute to dependence by increasing the psychological costs of terminating the relationship. Internal constraints might involve the moral belief that a marriage, for example, is forever or that children should be raised in a home with both parents present. External barriers are things like community pressures, legal pressures, and material or economic considerations that foster dependence by increasing the social and economic costs of terminating a relationship.

Normative and Cognitive Orientations

Exchange relationships are governed by both normative and cognitive exchange orientations that delineate acceptable and appropriate behavior. Normative orientations refer to the societal views on acceptable and appropriate behavior in relationships. These norms refer to the broader consensus that exists within a culture about how exchange relationships should be structured. Among the more prominent of these normative orientations in Western cultures are the norms of distributed justice or fairness, norms of reciprocity, and norms of equity. Each of these has to do with the expectation that, within a close and intimate relationship, the rewards experienced by partners should be more or less proportionately distributed. When these norms are violated, as when housework is unfairly distributed within a marriage, people are apt to complain more about the relationship and pressure their partners to restore a more just and fair pattern of exchange.

Cognitive orientations are conceptualized as a set of expectations and goals that guide individuals in setting up rules and patterns of interaction within their intimate relationship. A few assumptions derive from this definition of cognitive orientations. First, the individual's cognitive orientation is thought to function as an internal template or "cognitive structure" that shapes and directs his or her behaviors, perceptions, and experiences within intimate relationships. More specifically, this internal template of relationship standards serves as a guidance to establish rules and patterns of interaction with one's partner that determine: (a) how each person should contribute to the relationship, (b) what each person deserves to obtain from the relationship, and (c) how positive and negative outcomes should be distributed among partners.

Second, it is assumed that individuals vary in the type of cognitive orientation they hold vis-à-vis their intimate partners. Underlying such variability, there is a constant tension between taking into account what one (self-focused) or the partner (other-focused) needs and deserves to structure the relationship. That is, individuals' cognitive orientations differ in the extent and degree to which the interests of self or the interests of the partner take precedence when it comes to setting up rules to distribute outcomes and determine obligations.

Last, it is assumed that such cognitions are connected to a macrosystem of cultural beliefs and values. Individuals are embedded in a cultural system in which they internalize norms regarding what relationships are for and the appropriate rules to attain such goals and ideals. Thus, these cognitive orientations are closely connected to the normative orientations about gendered relationships existing in their culture and in the network of relations surrounding them.

Trust and Commitment

Trust refers to the belief on the part of individuals that their partners will not exploit or take unfair advantage of them. When relationships conform to the norms of reciprocity and when the pattern of exchange is perceived as being fair, individuals are more likely to come to believe that they will not be exploited. Trust is proposed to be important in relationship development because it allows individuals to be less calculative and to see longer term outcomes. Put another way, through trust an individual is able to expect fairness and justice in the long term and therefore does not have to demand it immediately.

Commitment is characterized as central in distinguishing social and intimate exchanges from economic exchanges. Commitment involves the willingness of individuals to work for the continuation of their relationships. Exchange theorists would expect commitment to develop within a relationship when partners experience high and reciprocal levels of rewards that facilitate the experience of trust. Commitment builds stability into relationships by increasing partners' dependence on their relationships—in part because the emergence of commitment is thought to be accompanied by a reduction of attention to alternative relationships.

Exchange Dynamics

The exchange framework also provides insight into the dynamics found within intimate relationships. In particular, the exchange framework has been used to explain the patterns of power and decision making found within relationships. Fundamental to the exchange views of power are the assumptions that dependence and power are inversely related and resources and power are positively and linearly related. This is to suggest that exchange theorists address the bases of power by focusing on the constructs of resources and dependence. The partners least interested in their relationships tend to have the greater power in large part because they are less dependent on the relationships. The partners with the greater resources also tend to be the ones with the greater power—here largely because they have relatively greater control over the outcomes available to the partners. In other words, the essential point of the discussion of the patterns of interaction observed within exchange relationships is that the relative levels of involvement, dependence, and resources contribute importantly to the different patterns of interaction observed within relationships.

SOCIAL IDENTITY THEORY

Social Identity Theory (SIT), originally developed by Henri Tajfel and John Turner, suggests that people maintain or boost self-esteem by valuing groups in which they are a member (*ingroups*) and by devaluing groups to which they do not belong (*outgroups*). SIT starts with the widely accepted principle that all individuals are motivated to maintain a positive self-image. When evaluating the self, people assess information such as their talents or physical appearance; however, group membership is also an important part of the self-concept (e.g., race, sex, political party, school affiliation). In other words, individuals have several “social selves” that reflect who they are within various groups. To maintain a positive self-esteem, individuals therefore must evaluate both the groups and membership in the groups, or their “social selves,” in a favorable way. This entry describes the classic experimental procedure used to test SIT’s basic predictions, as well as a review of recent research and critiques.

Minimal Groups

SIT posits that people maintain a positive view of their ingroups as a way of maintaining positive self-esteem. Once people identify with a group, they begin to display ingroup favoritism, in which they seek what is known as *positive distinctiveness* by evaluating their group more favorably than the outgroup on some valued dimension, and outgroup distancing (avoiding the outgroup) or outgroup derogation (negative attitudes toward the outgroup).

Whereas several other theories of intergroup relations suggest that people may be prejudiced against outgroups due to historical conflicts, social hierarchies, or previous injustices, in contrast, SIT predicts that people will favor ingroups and become prejudiced against outgroups as soon as and only because group categorization exists. Because group membership makes salient categories of “us” versus “them,” group identification may cause prejudice and discrimination due to people’s motivation to affiliate with and protect their group. An example can be seen in traditional school rivalries. Typically, rival schools are similar in aspects such as region, size, and type of student; despite these similarities, students at the schools maintain a negative view of each other, often via direct comparison.

This prediction led to the classic experimental procedure known as the *minimal group paradigm*. In this procedure, participants are divided into groups using arbitrary, meaningless categories. Examples of specific groups used in this research are underestimators versus overestimators, in which people are told that their group membership was determined by how they incorrectly estimated a large series of dots on a piece of paper given limited time, groups based on art preferences, or even groups decided by the flip of a coin. Participants are divided into groups such as these specifically because the groups are basically meaningless (or minimal). Despite the lack of meaning behind categories such as these, SIT hypothesizes that the participants will feel a certain affinity to their own group, as part of their social identity, and thus will engage in behaviors designed to protect and advance the group.

The common outcome that is measured in this paradigm is how individuals will distribute some type of desirable resource, such as points or money, between their group and at least one other outgroup. In several studies, including participants of different ages and cultures, the results are consistent: People demonstrate ingroup favoritism by providing them with a higher amount of resources while depriving the outgroups. In short, discrimination against an outgroup is elicited easily and quickly even when group assignment and categorization are random and meaningless.

Recent Research and Critiques

An important aspect of SIT is intergroup comparison. As noted, positive self-esteem is maintained by the belief that one’s ingroups are superior to one’s outgroups. Because prejudice and outgroup derogation are the result of this comparison, SIT argues that these prejudiced tendencies should occur more when an individual is feeling insecure, anxious, or inferior. In other words, if individuals feel that their groups are in danger of appearing inferior, they should be increasingly motivated to lash out against other groups. However, if individuals feel secure about their group’s superior status, less prejudice should result. This insecurity may also apply to individual standings within the ingroup. Recent research suggests that it is, in fact, lower status group members who are more likely to discriminate against outgroups.

Other recent research on SIT has examined factors that influence when social identity motives and categories, compared with individual aspects and facets, are activated. As previously noted, one factor is an individual’s status within the group. A second factor is the group size: Smaller groups are more likely to display ingroup favoritism than larger groups. Additional factors include strength of group identification, a prejudiced personality in general, and how similar or different two groups are.

Some criticisms of SIT exist. For example, although there is much evidence that group categorization can lead to ingroup favoritism, which can, in turn, bolster self-esteem, evidence that outgroup derogation actually boosts self-esteem is harder to find. There is evidence that people with low self-esteem will sometimes identify more with a low-status group instead of trying to affiliate with a high-status group (e.g., because “fighting against the status quo” can bring individuals a sense of power and a role of importance in their minority ingroup). In addition, people with high self-esteem sometimes feel more comfortable identifying with low-status groups because they can maintain their positive self-evaluation through other routes. One possible conclusion could be that, although bolstering self-esteem is not a primary motivation for outgroup derogation and prejudice in all cases, it is more important for social identity formation. Finally, one of the original creators of SIT, John

Turner, has recently stated that the theory was originally designed to explain the social status of the group as a whole and was not intended to focus as much on individual-level self-esteem. Despite its criticisms, SIT has had a major impact on social relationships research and has guided the field in directions it would not have achieved without this theory's tenets.

SOCIAL INEQUALITIES AND RELATIONSHIPS

The structure and quality of human relationships experienced by adults vary across differences in social status based on social stratification in society. Socioeconomic status (SES) is a major social status factor that results in social inequalities in individuals' experience of relationships, usually advantaging persons of higher SES. SES is typically indexed by differentiation across levels of education, income, occupational status, and wealth. In addition, measurement of SES is sometimes extended to consideration of parents' SES, spouse's SES, and/or neighborhood SES. Most

societies also make social status distinctions across gender, race/ethnicity, and age. This entry focuses on describing inequalities in the structure of relationships (e.g., quantity, differences in timing of relationship entry and exit, geographic proximity) and quality of relationships (e.g., satisfaction, stability, responsiveness, exchange of support) with partners, children, other kin, and nonkin in adulthood that are linked to differences in SES.

Social Inequalities in Partnership Relationships

SES and Structural Aspects of Partnership Relationships

The likelihood and timing of entering into marriage varies across SES. Individuals whose parents achieved higher educational attainment, higher income, and higher occupational status tend to marry later than those whose parents attained lower education, lower income, and lower occupational status. These social inequalities in age at marriage have further life-course impact: Lower age at marriage is associated with higher rates of marital disruption, resulting in higher rates of separation and divorce among those with lower SES.

Before 1950, it was more common for women with more education to remain unmarried throughout their lives than it was for women with less education. Among more recent birth cohorts of young women, this pattern has reversed such that women with the least education now are the most likely to remain lifelong singles.

Overall, there has been a historical trend during recent decades toward experiencing a smaller proportion of adult years in a marital relationship due to demographic trends over time toward longer lives, later ages at first marriage, higher rates of never marrying, higher rates of divorce, and lower rates of remarriage. This smaller proportion of the life course spent married is particularly pronounced among individuals with lower SES. Partnership absence among those with lower SES is accentuated further by the fact that lower SES is consistently associated with higher rates of mortality (as well as both psychological and physical morbidity) and incarceration, particularly among men, at all ages.

Rates of cohabitation have increased in recent decades. Historically, cohabitation was most common among persons with lower SES (income and

education). In the 1960s and 1970s, cohabitation also became more popular among more SES-advantaged young adults going to college—often as a prelude to marital commitment. The prevalence of cohabitation, however, remains highest at lower levels of education and income. Cohabitors' reports that they expect their union to evolve into marriage varies by the male partner's SES, such that individuals in cohabiting partnerships that include a man with lower education and income report less expectation of transitioning the relationship into marriage.

SES and Quality of Partnerships

Longitudinal as well as cross-sectional assessments of marital quality relatively consistently indicate that persons with higher education and higher income report better quality marriages, including higher marital satisfaction, greater marital happiness, less marital discord, less intimate partner violence, and lower expected likelihood of separation. Some research during the 1970s and 1980s suggested that one exception to these associations was that higher wives' individual income was linked to poorer marital quality and greater likelihood of separation. Scholars speculated that women's relative independence due to higher earning capacity might undermine the dependency of wives on husbands, and that this, in turn, might undermine marital quality and stability. Research on more recent cohorts of marriages has not supported this idea, however; by contrast, both husbands' and wives' higher incomes are now found to be associated with better marital quality.

Cohabitation, which is more common among persons with lower SES than persons with higher SES, is associated with more partner violence than marriage.

Social Inequalities in Parent–Child Relationships

SES and Structural Aspects of Parent–Child Relationships

Women with lower education and income are more likely to experience a nonmarital birth or a premarital pregnancy than women with higher education and income. Women with higher SES

are more likely to postpone having a first child and limit their ultimate number of children (although the gap in family size by SES as well as race/ethnicity has been narrowing in recent years). The fact that marriages and partnerships among individuals who experienced lower SES in their families of origin are more unstable results in a greater likelihood that persons with lower SES will become single parents—either custodial or noncustodial. The higher likelihood of having a nonmarital birth and divorce among those with lower SES also results in individuals from families with lower SES reaching adulthood more likely to have experienced disrupted coresidence and/or absence of contact with a parent (typically a father).

In midlife and older age, persons with lower SES may experience more proximity to adult children (including coresidence) due to the greater likelihood of children with lower SES to remain geographically closer to their family of origin. A larger number of children may provide some persons with lower SES more children in their social network—both to provide help to and from whom they might receive help.

Viewed from the adult child's perspective, the health and mortality differentials noted previously across SES result in the fact that adult children with lower SES tend to be less likely to have living mothers and fathers—and the emotional, instrumental, and financial resources that living parents provide—at any given age.

SES and Quality of Parent–Child Relationships

The economic stress experienced by low-income parents can have considerable detrimental impact on parent–child relationship quality. Economic stress is often linked to maternal depression, which is, in turn, linked to less responsive parenting. Attachment patterns (i.e., internalized schemas regarding how trustworthy others are and how worthy of care the self is), which have their antecedents in the responsiveness of a primary attachment figure (usually the mother), are therefore influenced, in part, by poverty and family instability; poverty is associated with less secure attachment among children. Persons with insecure (vs. secure) attachment styles are at a disadvantage in relationship quality across all types of relationships.

Parents with less education and less income also tend to provide less consistent discipline, less consistent monitoring, and less complex and growth-fostering social interaction for children. Psychological and physical violence toward children is more common among parents with lower SES. Adults with lower SES are more likely to be single parents, a parenting status additionally linked to high levels of stress and depression among parents, and greater challenges for high-quality parent-child interaction.

In adulthood, individuals with low-income parents are less likely to receive parental financial support, emotional support, and child-care help than those with parents who have higher income.

The SES differential in psychological and physical morbidity leads parents with lower SES to develop chronic conditions that limit functioning at younger ages than parents with higher SES. Therefore, adults from lower SES backgrounds are more likely to be called on to provide caregiving for their parents at younger ages. Individuals with lower SES also tend to live geographically closer to parents, increasing the likelihood of providing hands-on care when there is a need for care. Individuals with higher SES are more likely to focus on providing financial support and arrangement of social service support for parents in need of care. Interestingly, caregiving research has suggested that persons with lower SES report less negative impact on mental health from caregiving possibly due to a greater relative valuing of caregiving activity among those with lower education, income, and occupational status.

Social Inequalities and Other Kin Relationships

Overall, persons with lower SES tend to report a smaller number of kin other than spouses, children, and parents in their social networks than those with higher SES. Yet individuals with lower education and income report a higher *proportion* of kin in contrast to nonkin in their extended social networks. Persons with lower education and income are more likely to live geographically closer to other kin and emphasize extended family relationships in their everyday lives than are persons with higher education and income.

Individuals with lower SES are more likely to become a grandparent at a younger age due to earlier ages at childbearing for themselves and their children. Grandchildren are likely to be more geographically proximate among those with lower SES; they may also have more need for help from grandparents—including the need for custodial grandparenting—due to the greater likelihood that they are being reared by poorer, often single parents who tend to have more stress, depression, and severe problems. Custodial grandparenting, in contrast to noncustodial grandparenting, has been linked to mental and physical health risks; yet custodial grandparents also report gains from this role—such as increased purpose in life and closer relationships with grandchildren.

Social Inequalities and the Nonkin Relationships

Overall, individuals with lower education and income report fewer nonkin (friends, neighbors, coworkers) in their social networks than those with higher education and income. Sociologists have documented the importance of nonkin “weak ties” (i.e., acquaintances, in contrast to close friends and family), who are most likely to be resources for novel information, and therefore particularly valuable in extending potential contacts for employment leads, housing leads, and other instrumental information that is crucial for expanded life-course opportunities and upward mobility. Persons with more education report broader, deeper, and richer friendship networks that include many more such weak ties, as well as close friendship and family ties—all of which contributes additionally to the intergenerational transmission of SES (i.e., tendency for continuity of similar SES across generations). Those with higher education also report more normative obligation to support friends.

Recent research has suggested that neighborhood SES (specifically, rates of poverty in a neighborhood) contributes additionally to the relative isolation from potential helpful weak nonkin ties that persons in high-poverty neighborhoods experience. In addition, poverty and divorce (more prevalent among lower SES groups) often lead to more frequent residential mobility,

which in turn can disrupt neighborhood social networks.

Some research in the 1960s and 1970s emphasized the ways that lower SES groups use “fictive kin” (i.e., persons not biologically related, but persons who are nonetheless considered to be similar to biological kin in terms of bonds of enduring connection and mutual support) to supplement biological kin network needs. More recent research has questioned whether such strong compensatory networks truly exist for individuals at the bottom of the SES hierarchy, and has indicated that rich compensatory fictive kin networks are not typical. Scholars have documented how the social networks of low-income families can actually result in “stress contagion” as much as support.

SOCIAL ISOLATION

Social isolation refers to the separation of individuals from others, especially a lack of strong social ties. It may be defined in terms of behavioral or perceived isolation or as a combination of the two. By any of these definitions, older, single, and less educated individuals have a higher probability of being socially isolated. Having few close connections to others has serious negative effects. Those people who are socially isolated have a higher mortality and morbidity rate and are more likely to suffer from psychological disorders. Researchers have offered a number of explanations for the negative health outcomes of the socially isolated. These explanations link biological functioning, stress, and social support.

Measurement

Researchers who employ behavioral definitions use relational characteristics to define social isolation. For example, one may say that a relation exists between two people if they discuss important matters. Under this definition, a socially isolated individual is someone who has no one with whom they discuss matters that are important to them personally. Similarly, some researchers have defined social isolation as a lack of specific types of relationships—friends (for adolescents), caregivers (for the elderly), or someone who you could ask to watch your children in an emergency (for young parents). In a general population, measures of one type of close tie tend to overlap with others so that the specific question does not matter much. Claude Fischer has pointed out that having just one close connection makes one dependent on that one relationship; he argued that someone with only one tie still has inadequate social support. Therefore, social isolation may not be a qualitative distinction, but a matter of degree. Other researchers refine measures of social isolation by looking at the frequency of contact or the degree to which one’s connections are connected to each other in a tight social group.

In contrast to these behavioral definitions, some researchers have measured isolation in terms of perceived isolation. Such definitions capture

whether individuals feel socially isolated. Perceived social isolation is theoretically independent of actual social ties, although the two are correlated.

Finally, some researchers combine perceived and behavioral connection, arguing that individuals are socially isolated only when they lack interaction partners *and* feel socially isolated. With this view, those who are lonely (high perceived social isolation) but have social ties are not socially isolated (although they may suffer mental distress). Similarly, those who have no social ties but do not feel lonely are not socially isolated. Thus, it is not only the nature or existence of one's relationships that matter, but also one's interpretation of these relationships. In the end, all of these definitions attempt to capture the same thing: whether an individual has operative, sufficient, close social connections to other people.

Characteristics of the Socially Isolated

Socially isolated individuals tend to be older, be unmarried, and have less education than the socially integrated. Those with lower incomes also have a higher chance of being isolated. Thus, a privileged social position is linked to a healthy social environment. Researchers have also found that ethnoracial minorities are more likely to be socially isolated than Whites. There are few gender differences in the likelihood of being socially isolated, although some research suggests that single males may be more socially isolated than single females (because males often depend on a spouse for connection, whereas single females often look to female friends).

Consequences of Social Isolation

Social isolates are more likely to experience a high number of negative life events. This fact is important because close social connections tend to provide help and social support in both routine and emergency circumstances. Oddly, however, social isolates are no less likely than those who have social connections to experience positive life events.

Social isolation constitutes a significant health risk—on the same order as smoking, obesity, and lack of physical activity. Researchers have found, even after controlling for physical

health, demographic characteristics, and health behaviors (e.g., smoking and alcohol use), that those with more social ties are less likely to die over time. Studies have linked social integration with lower rates of cardiovascular disease and stroke, higher rates of survival from heart attacks, and lower chance of cancer recurrence. The relationship between social connections and physical health is distinctly nonlinear. The mortality risk for the completely isolated is high relative to those with at least one close social tie. However, there is little difference in mortality risk between those with average and high levels of social connectivity.

Researchers have also found that social isolation has detrimental effects on psychological well-being. Socially isolated individuals are more likely to have low esteem, have high anxiety, and suffer from depression. They are also more likely to have suicidal thoughts and to attempt suicide.

Underlying Mechanisms

Many mechanisms help explain the deleterious consequences of social isolation. First, the effect appears to be real. Although some researchers have argued that the health patterns arise from selection (e.g., healthier, more physically attractive, happier individuals attracting more friends), there has not been much evidence to support this hypothesis. More research links the effect of social isolation to stress and stress management. Social isolation causes stress, which leads to an increased likelihood of disease. In addition, close social ties act as a stress buffer, lessening the negative effects of stressful life events. These buffering effects can be both direct and indirect. Close confidants offer emotional support and physical help in stressful situations. In addition, those with social ties are more likely to believe that close associates will be there in difficult times, and this expected support decreases one's stress response in dealing with negative life events.

Researchers have also studied the effect of social control on health outcomes. Socially integrated individuals experience social pressure from close others, which may lead to the adoption of more healthy behaviors. Social ties may also offer resources, such as information and finances, which decrease the probability of having health problems.

In conclusion, older, single, and disadvantaged individuals are more likely to be socially isolated. Social isolates suffer from poorer physical and psychological health. The most important mechanisms for this important relationship are: (a) Social isolation is associated with negative life events and directly causes stress; (b) the socially isolated have fewer stress buffers; and (c) the socially isolated have fewer resources to draw on in dealing with routine and emergency needs.

SOCIALIZATION

One of the most fascinating domains of study in sociology involves the process of socialization, or the process by which we learn the ways of a specific society so that we can function within it. The process of socialization is essential for our unique development as human beings. We learn to think, reason, control our emotions, and have relationships through the process of socialization. In short, all of these social behaviors are shaped according to the guidelines given in a particular culture or

society. Multiple forces including parents, family, peers, schools, neighborhoods, the media, as well as the broader culture shape social behavior.

Family has the strongest influence on children's socialization, while peers also exert a strong influence on socializing children and adolescents. The peer group is a social group whose members are the same age, share interests, and share social positions. Further, the mass media may also shape children's ideas about what behaviors and values will help them to fit into society. The mass media are interpersonal communications aimed at a vast audience, including television, newspapers, the Internet, radio, books, as well as other forms of mass communication. Last, broader forces such as social class and gender also influence the socialization process. Social class shapes the process of socialization by influencing values and occupational goals within families. For example, depending on social class, parents may shape their children's behavior toward conformity (necessary for most blue-collar jobs) or independence (necessary for most white-collar jobs). This entry focuses primarily on the role of parenting in the socialization process of children and the ways in which social class and gender influence socialization.

Socialization and Parenting

Parental socialization refers to the process by which parents transmit knowledge and values related to culture to their children. Parents and family are the primary individuals who provide love and nurturance to children so they can develop a foundation of trust in human relationships. Parents also train children with knowledge and skills to become autonomous individuals within a specific culture or society (e.g., parents may train children to be polite to facilitate children's acceptance into social groups). Parents also provide discipline and control necessary for children to develop self-regulation of emotions and to guide their rational decision making as children make the transition from childhood to adolescence and young adulthood. For example, parents train children to control their impulsive emotions so that they can think clearly and make good decisions. Consequently, an adolescent may decide to control her desire to go out with her friends until she has finished her homework.

Parental Support and Control

Parents typically shape children's behavior through the use of two broad dimensions of behavior: emotional support and parental control. They provide emotional support through affection, love, warmth, and acceptance. Parental warmth is essential for children to develop feelings of self-esteem, competence, and a positive orientation toward human relationships. For example, nurturing parents provide positive feedback and love to their children on a consistent, daily basis. This positive feedback, in turn, helps children to develop trust in their parents and promotes self-confidence. When children have these positive, warm interactions with their parents, they develop positive feelings toward others in their own relationships with peers and others.

Parents also exert control over their children's behavior. There are two types of control that parents utilize in the socialization process. These types of control are important because each deals with a different type of child behavior. Parents use upper limit controls to reduce and redirect behavior that exceeds parental or societal standards of intensity or frequency. For example, if a child is running through the supermarket, parents may redirect the child to walk inside the store. A child running through the store exceeds parental standards because the child may get hurt or may hurt others by knocking over a display. In contrast, parents may use lower limit controls to stimulate child behavior that is below parental or societal standards. For example, if a child is not spending enough time on homework, parents may use positive controls or incentives to stimulate the child to focus on academic work. A parent may tell the child that if he does his homework, he will have time to play with a friend before dinner. In this way, parents guide the child's behavior toward standards that are likely to ensure success and competence with culturally appropriate developmental tasks.

Studies also suggest that parental controls can be inductive by setting appropriate limits (e.g., children need to be at home in time for dinner), providing reasons for the limits, and praising the child for observing the limit. Parental controls also may be used in the form of threats or use of punishment (e.g., a parent may tell a child that he will have to go into time-out if he or she continues to

shout at another child). Sometimes parents may even withdraw emotional support as a way of attempting to bring their child's behavior into compliance (e.g., ignore a child's attempts to get attention).

Styles of Parenting

Much research has examined the various combinations of control and support that parents utilize with their children. Diana Baumrind has distinguished three types of parental behavior styles. In the authoritative style of parenting, parents utilize high levels of emotional support with moderate levels of consistent and firm control. With this type of parenting behavior, children experience much positive affection and nurturance combined with firm, clear limits on inappropriate behavior. The limits are explained in rational ways rather than demanded in the context of threats of punishment. For example, if a parent wanted their child to finish a homework project before going to a friend's house, the parent may state that the child will first need to finish the schoolwork and then he or she will be able to go to a friend's house for an hour. In this way, the parent is stating the positive behaviors that are expected of the child while also providing a positive reward for the child when the schoolwork is completed. Research suggests that this style of parenting is characterized by extensive verbal exchange within the family. Longitudinal studies report that this style of parenting leads to more positive, socially competent behavior in children. Children who experience this parenting style also are more likely to be independent, have higher self-esteem, have more positive cooperation with others, and have a strong sense of morality. This positive orientation toward human relationships eases the transition to adolescence as adolescents become more self-reliant and independent in decision making.

In the authoritarian style of parenting, parents use strong levels of coercive control with low levels of emotional support and nurturance. The authoritarian style is associated with a highly restrictive and punitive parenting style. Parents tend to utilize many limits and use excessive control with their children. For example, a parent may become angry and shout at the child that he or she needs to finish

homework, do dishes, and clean the room. This type of parenting style tends to be associated with immature child behavior. Children are likely to be less socially competent, have more behavioral problems, and experience more anxiety in their own relationships.

In the permissive parenting style, parents provide emotional support and nurturance, but are low on control. This occurs because parents are either overly indulgent of their children (e.g., a parent may “spoil” the child while having few expectations of the child’s behavior) or neglectful of their children’s needs (e.g., a parent may be depressed and unable to respond to the child on an emotional level). This style tends to be associated with socially incompetent child behavior later in life. For example, children are not likely to make independent decisions and accomplish goals later in life.

Thus, the authoritative style of parenting is the most optimal style that tends to produce mature, socially competent children and adolescents. As children make the transition from childhood to adolescence, the authoritative style remains the most effective parenting style because it offers sufficient autonomy necessary to foster internal control among adolescents while also offering sufficient controls to foster responsibility. Children exposed to the authoritative parenting style also develop more mature and stable relationships later in life.

Social Class and Gender

The family’s social class also influences socialization. Researchers report that parental social class influences parental childrearing values. Interestingly, the type of work that parents do shapes expectations that they have for their children’s behaviors. Specifically, working-class workers must often perform simple tasks in a repetitive way and tend to be supervised closely. Thus, working-class parents are more likely to emphasize the values of conformity, obedience, or characteristics that individuals need to be successful in working-class positions. In contrast, middle-class parents, such as professionals, are less closely supervised and work with a variety of different people and tasks. Middle-class parents are more likely to encourage independence, creativity, and individualism to help their children be successful

in future middle-class jobs. Thus, the social class of one’s family affects the way children think and the values they have regarding school, work, relationships, and lifestyles (e.g., children from middle-class families may be likely to be more independent and self-reliant in relationships).

More recent research reports that social class is influential in childrearing practices. For example, middle-class parents utilize “concerted cultivation,” or providing lessons, sports activities, active discussion and solicitation of children’s opinions, and much individual attention. Working-class and poor parents tend to focus on a safe environment and promoting the “accomplishment of natural growth” for children. Over time, middle-class children develop advantages because they may be more assertive and independent in school and work settings as a result of these early childrearing experiences.

The gender of the child also may influence the socialization process. Although socialization is considered to be a two-way process in which parents influence children and children influence parents, certain characteristics of the child may be important in parental socialization practices. For example, parents may select stereotypically male toys for boys or female toys for girls, thus reinforcing stereotypical gender differences. As children grow older, peers may further reinforce stereotypical male or female behaviors. Although a broad base of research exists on gender socialization, parents may choose to emphasize stereotypical gender-based behaviors or they may choose to encourage boys and girls to engage in a broad range of behaviors that are not anchored in gender stereotypes, but in autonomous choices regarding roles.

Conclusion

Researchers in the future may need to address the important task of examining the interplay of various influences such as parenting style, social class, and gender in understanding the process of socialization over time. For example, it may be important to assess the relative importance of parenting style within a particular social class or social context, such as whether an authoritarian parenting style may be more powerful than social class in shaping relationships. Or, in what ways does

gender interact with parenting style to influence the development of future relationships with peers and romantic partners? Perhaps girls and boys respond differently to parenting styles. Finally, it is important to assess the relative importance of each of these factors in predicting the quality of relationships that develop over time. So, does the parenting style one experiences in childhood influence the choices one makes in romantic relationships in adolescence and early adulthood? These are all important issues to consider in understanding the process of socialization of relationships over time.

group contexts and that are a consequence or an antecedent of characteristics of the individual. These experiences have been conceptualized according to a three-level model that includes the individual, the dyad, and the group. According to this model, the level of the individual refers to the characteristics that children bring with them to their experiences with peers or that they take away from these experiences. These characteristics include more or less stable characteristics of the person, such as social orientations, behavioral patterns, temperaments, social skills, forms of social perception, cognition, and social problem solving. Dyadic experiences refer to the properties and characteristics of the interactions and relationships that a child has with a specific peer. The best-known example of a dyadic experience is friendship, but other types exist, such as bully–victim pairs or mutual antipathies. The group context refers to the structure and features of the set of peers in which the child and the child's relationships are embedded. Groups are distinguished from each by their internal structures (e.g., levels of cohesion among members) and by their “content” as manifested by the behavioral norms, attitudes, and values. This entry discusses the theory and current knowledge base about the role of peers in socialization processes, showing how experiences with peers affect development and adjustment.

Phenomena from each of these three levels of experience are interrelated in the sense that individual, dyadic, and group variables influence one another. For example, when individuals enter into a relationship (i.e., a dyadic experience), they bring with them particular behavioral tendencies, as well as a range of expectations and needs derived from their own relationship history. These factors, in turn, combine and interact with those of their friendship partner to determine the characteristics and effects the friendship will have. Moreover, the broader group provides a particular climate that may either favor or disfavor particular characteristics of individuals, thus making a particular child more or less popular.

SOCIALIZATION, ROLE OF PEERS

The term *peer relations* refers to a set of interrelated experiences that take place in either dyadic or

Theoretical Accounts

Theoretical accounts of the developmental significance of peer relations have ascribed socialization

effects to both dyadic and group experiences. That is, they have claimed that peer relations affect basic forms or aspects of development. Studies conducted in the 1960s and 1970s often used concepts from social learning theory that emphasize the role of peers as sources of reinforcement and modeling. These studies showed that children's behavior could be shaped by the rewards given by peers, especially by friends, and by their exposure to peers who modeled either positive (e.g., pro-social) or negative (e.g., aggressive) behavior. According to this approach, peers function as agents of control over each other's behavior. Peers can punish or ignore behaviors that are nonvalued or non-normative just as they can reward behaviors that are desirable or regarded as appropriate. As a result, insofar as children behave in a socially appropriate manner, they are rewarded by receiving further opportunities for interactions with their peers; insofar as they act in ways that transgress norms, standards, or expectations, they risk being excluded or rejected by them. In this way, a peer group is a developmental context that functions as a miniature culture with its own norms, expectations, opportunities, and practices that will, in part, shape or direct the functioning of the children within the group.

Aside from these behavioral approaches, constructivist accounts of development have pointed to the role of peer interaction as a context for the development of social skills and cognitions. Jean Piaget claimed that the balance and egalitarian characteristics of interactions with a peer, especially in contrast with relations with one's parents or other adults, is an ideal context in which children could examine conflicting ideas and explanations, negotiate plans, consider multiple perspectives, and decide to compromise with or reject the perspectives held by peers. Piaget believed that discussion and negotiation in the context of conflict with peers was critical for the development of basic social constructs, such as fairness, care, and justice. In a similar way, Lev Vygotsky proposed that cooperative, rather than conflictual, discussions with peers would promote a shared understanding of social events that would lead to the formation of basic social constructs, such as ideas about the causes and consequences of events. In these ways, experiences with peers are essential for all forms of social cognitive development.

Other theories have also emphasized processes at the level of the dyad. Harry Stack Sullivan's theory emphasized the impact that dyadic experience can have on the formation of the self-concept. Sullivan proposed that the friendships that develop at the beginning of adolescence include experiences of closeness and mutual regard that differ from the hierarchical relationships that children experience with their parents and from the play-based interactions of childhood. Sullivan argued that this close relationship was a child's first true interpersonal experience of reciprocity and mutual exchange and that it was within what he called "chumships" that children had their first opportunities to experience a sense of self-validation. According to Sullivan, this validation results from the internalization of the positive regard and care that their chums provided to them. Sullivan went so far as to propose that the positive experiences of having a chum in adolescence would be so powerful as to enable adolescents to overcome problems that may have resulted from prior family experiences. Sullivan believed that the experience of being isolated from the group during the school-age period would lead a child to have concerns about his or her own competencies and his or her acceptability as a desirable peer. Consequently, Sullivan suggested that children who are unable to establish a position within the peer group would develop feelings of inferiority that could contribute to psychological distress.

A related approach to the study of peer relationships emphasizes the provisions that are available in interactions and relationships with peers. According to this perspective, peers offer each other opportunities for experiences that are critical for well-being and healthy development. These include companionship, help, protection, closeness and intimacy, enduring affective alliances, and ego reinforcement. From a developmental perspective, it is known that the levels of some provisions vary with age, especially with an increase with age for the provisions of intimacy, closeness, reliable alliance, and loyalty. It is expected that the effects that particular provisions (e.g., intimacy) have on development will increase with age as well, although empirical studies of this developmental effect are limited.

Patterns of Attraction

Children differ in the extent and quality of their experiences with peers. Two theories have been proposed to explain why some children are more likely to be liked by their peers than are others. One model emphasizes the importance of particular features or characteristics. A large number of studies have shown that children tend to like peers who are helpful, competent, and engaging and who possess good looks and have lively but well-regulated temperaments. It is well known also that children tend to dislike peers who are disruptive, withdrawn, and possess obnoxious habits and values that contradict group norms and processes. Much of the literature on the factors underlying different children's status in the peer group has adopted this emphasis on features and characteristics. Although some consistent findings have been observed, some developmental differences have also been observed. For example, aggression becomes a less negative predictor of liking at the beginning of early adolescence.

A second model emphasizes the fit between a child and the child's peers. According to this model, children prefer to associate with peers who are like them rather than with dissimilar peers. There is evidence that friends tend to be more similar to each other than they are to other peers. Some of this similarity drives attraction, whereas some of it results from the mutual effects that friends have on each other's behavior. Further evidence for the importance of the fit comes from studies that have shown that attraction varies across contexts, with the attractiveness of a particular feature being higher when it is normative for the immediate peer content than when it is less normative. For example, aggression can be a positive predictor of attraction in contexts where aggression is normative.

Effects of Peer Relations

Studies of the effects of peer relations have taken three general forms. One concerns the effects of peer relations on internalizing problems (e.g., anxiety and depression); a second concerns the effects of peers on behavior, especially disruptive behavior; and the third assesses the extent to which peer relations can protect at-risk peers from

the negative effects of experiences in the family or with other persons.

The effects of peer experiences on internalizing problems have been well documented. The most general findings are that children who are disliked by peers, who are friendless, or who are victimized by peers are more likely than others to show elevated levels of depressed affect. It appears that the lack of positive experiences in any of these domains increases one's risk for internalizing difficulties because these experiences challenge one's sense of validation and one's desire for inclusion. Beyond provoking the negative cognitions that can result from being rejected, friendless, or victimized, these experiences also mean that children will receive limited amounts of provisions from peers. The experience of being rejected by one's peers seems to be especially problematic because it increases the risk of increases in subsequent victimization and friendlessness.

Beyond the effects of friendlessness on internalizing problems, it is also known that some forms of interaction between friends can promote depressed affect. Specifically, the practice of some early adolescents, especially early adolescent girls, to use their opportunities for interaction with a friend to discuss the challenges or negative features of their lives has been shown to increase feeling of depressed affect. Beyond its direct effect on depressed affect, this "corumination" has been shown to help explain why early adolescent girls show higher levels of depressed affect than are shown by boys.

In regard to the effects of peer relations on behavior, a large number of well-designed longitudinal studies have shown that association with aggressive or disruptive peers will lead to an increase in a child's own level of behavior in these areas. These effects, which have also been shown in laboratory-based studies, are typically explained via two processes that were alluded to earlier. One process, known as deviancy training, emphasizes the rewards and encouragement that peers can give to each other for performing acts that are disruptive or harmful. This process of reinforcement has been shown to account for increases in both mild and extreme forms of disordered behavior. Another explanation is related to the typical level of similarity seen between friends. Insofar as the strength of one's relationship with a friend may be manifested in similarity, peers might be motivated to become

like their friends so as to solidify a friendship or to strengthen the ties between them and their friend. In some cases, this means taking on the deviant or disruptive characteristics of one's friend.

Aside from these negative effects that peer experiences can have on affect and behavior, friendships are known to have protective effects. Consistent with the ideas of Sullivan, friendships have been shown to protect children from the negative effects on affect and self-perceptions that can result from being in a nonoptimal family context. Similarly, friendship appears to protect at-risk children from victimization by peers. Specifically, children who are at risk for being victimized because of their individual characteristics, such as being aggressive or withdrawn, are less likely to be victimized if they have a friend than if they do not. Beyond this protective effect against being victimized, friended children who are victimized are less likely to show the negative effects of victimization than are victimized children who are friendless.

SOCIAL LEARNING THEORY

Social learning theory is a school of psychology that views personality as being shaped by the

interpersonal environments in which people are raised. Initially, social learning referred primarily to learning through imitation of others' actions. However, social learning now refers more broadly to any kind of influence our relations with others have on our behavior, beliefs, and values. Social learning theory sees social goals, such as getting approval from others, dominating others, or depending on others, as powerful motives that direct our behavior. Important psychologists associated with social learning theory are Julian B. Rotter, who began his work in the early 1950s, and Albert Bandura and Walter Mischel, whose work started in the 1960s. This entry reviews the development of social learning theory during the 20th century.

The first social learning theorists were the team of John Dollard and Neal Miller in the early 1940s. Dollard and Miller posited that humans have an innate desire to imitate the behavior of others. Dollard and Miller's work was primarily focused on children; however, they also examined group behavior seen in crowds. Although Dollard and Miller's was an important first step in explaining social learning, their theory was hampered by its reliance on now-discredited *drive theory* to explain human motivation.

During the mid-20th century, there were two competing explanations for what motivates people's behavior. Initially, drive theory dominated. Drive theory posits that behavior is motivated by an uncomfortable internal state (drive), brought about by deprivation, that propels people to satisfy and reduce the intensity of the drive. Thus, psychologists talk about a drive-reduction theory, in which people are motivated to return to a neutral, driveless state that feels optimally comfortable, known as *homeostasis*. The disadvantages of drive theory are, first, that drives are internal, physiological states that cannot be measured. If they cannot be measured, they cannot be used to predict future behavior. Second, if people's ultimate goal is the neutral state of homeostasis, then all behavior is considered an attempt to avoid discomfort. But people are not satisfied just with avoiding discomfort. Therefore, drive theory is inadequate to explain humans' goal-driven behavior, particularly when social motivations conflict with physical comfort.

The most prominent alternative to drive theory is the *empirical law of effect*, which proposes that

people not only seek to reduce negative stimulation, but also to enhance positive stimulation. All behavior is seen as an attempt to obtain desired outcomes, called *reinforcement*. Traditional learning theorists, such as B. F. Skinner, are known as stimulus–response psychologists. They believe that to predict behavior it is only necessary to know what stimuli are in the environment and what the individual’s overt responses are.

The advantage of learning theory is that it gives a scientific framework for conducting psychological research on behavior. However, Skinner was opposed to considering anything mental—thoughts, feelings, or beliefs—when predicting behavior. Skinner’s stimulus–response approach may work reasonably well when applied to such relatively simple organisms as rats and pigeons. However, it has shortcomings as a way of understanding the complex behaviors of human beings.

Rotter’s Social Learning Theory

In the early 1950s, Julian B. Rotter developed his social learning theory, which was a vast departure from Dollard and Miller’s approach. First, Rotter eschewed drive theory. He believed a psychological theory should only include psychological motives, not physiological motives such as drives. Second, Rotter went beyond simple imitation as social learning. Rotter created a model of human behavior that maintained the scientific rigor that Skinner advocated while including aspects of people’s minds that cannot be directly seen. Rotter, like most people, believed our ideas, hopes, and feelings influence our behavior.

Rotter’s motivational principle is the empirical law of effect. Thus, all behaviors are attempts to maximize reinforcement. As a social learning theorist, Rotter viewed social reinforcers—the rewards and punishments we experience in our interpersonal relationships—as powerful influences on our behavior. Much of our behavior can be seen as attempts to obtain love, praise, or approval from others or to avoid criticism, embarrassment, or ridicule.

Rotter proposed four main variables needed to predict behavior. These are expectancy, reinforcement value, behavior potential, and the psychological situation. *Expectancy* represents one’s

subjective probability that a behavior will lead to a particular outcome. If one’s expectancy is high, one is confident that one’s behavior will result in reinforcement. The desirability of the outcome is its *reinforcement value*. The higher the reinforcement value, the more we want to obtain the outcome. *Behavior potential* represents the likelihood that one will engage in a particular behavior. If behavior potential is low, one is unlikely to exhibit the behavior.

According to Rotter, behavior is jointly determined by the desirability of the outcomes of the behavior and the perceived likelihood that the behavior will obtain those outcomes. If both expectancy and reinforcement value are high, then behavior potential will be high. This means one is likely to exhibit a behavior if one is confident that the behavior will lead to a desired result. However, if either expectancy or reinforcement value is low, behavior potential will be reduced. Thus, even if a person desires friendship, he or she will not try to make friends with others if those attempts seem likely to meet with failure.

The fourth variable, the *psychological situation*, is used to point out that it is the subjective environment, rather than objective reality, that determines people’s behavior. The psychological situation explains why different people behave differently in the same circumstances. In any given situation, different individuals identify different reinforcers as available, place different values on those reinforcers, and have different expectancies about the likelihood of obtaining those reinforcers. For many children, being yelled at by their parents would be punishing; thus, they try to avoid this consequence. However, other children may prefer being scolded over having their parents ignore them. In this case, punishment has a higher reinforcement value than neglect.

Rotter proposed that our expectancies and reinforcement values develop over time. In particular, our social relationships shape our likes and dislikes, as well as our beliefs about our ability to obtain reinforcement. If we have been rewarded in the past for a particular behavior, we will have a high expectancy of being successful in the future. In addition, Rotter believed that not only do the consequences we personally experience influence our expectancies, but also the consequences we observe others experiencing. Thus, if we observe

someone being rejected by others for a particular behavior, our expectancy for being rejected for that behavior will go up without our personally needing to experience rejection ourselves.

Rotter coined the term *generalized expectancies* to refer to our cross-situational beliefs about the likelihood of being reinforced. The most widely known of these is generalized expectancies for internal versus external control of reinforcement, also known as *locus of control*. Locus of control refers to people's beliefs about whether the results they achieve in life are largely due to their own efforts (internal) or due to luck, chance, or powerful others (external). People who are more internal tend to actively attempt to change their circumstances. In contrast, those who are more external tend to be more passive in life because they believe they have little influence on the consequences they experience. Thus, a battered woman may stay in an abusive relationship because she has little expectation that she will be able to leave or that leaving will better her circumstances.

As a clinical psychologist, Rotter was concerned with how people develop mental disorders and how those disorders are treated. Rotter did not view mental problems as illnesses. Rather, because all behavior is *learned* behavior, symptoms of mental disorders stem from faulty learning experiences. People either have not previously learned adaptive ways to deal with life stress or they have developed irrational expectancies regarding the likelihood of obtaining reinforcement for certain behaviors. For example, a man may not be assertive with his partner either because he has not learned how to be assertive or because he has been raised to believe that attempts at assertiveness will lead to disapproval. Rotter viewed the therapist-client relationship as essentially a teacher-student relationship, in which irrational beliefs are corrected and adaptive behaviors are taught. His ideas have influenced contemporary cognitive-behavior therapy.

Overall, Rotter's social learning theory has a positive view of humanity. People are drawn forward by their goals and their desire to maximize the positive experiences they have. Rotter's social learning theory explicitly connects personality, pathology, and clinical methods that therapists use to treat mental disorders.

Bandura's Social Cognitive Theory

In the early 1960s, Albert Bandura began work on his own social learning theory. His early work focused on sources of aggressive behavior in children, particularly imitation. Bandura conducted a famous series of studies, in which children observed adults attacking a blow-up Bobo doll and then exhibited this behavior toward the doll themselves. This type of observational learning is known as *vicarious* learning or *modeling*. Bandura also did research on how direct experience with reinforcement shapes children's aggressive behavior over time.

In the 1970s, Bandura broadened his social learning theory. (Later, he would change the name to *social cognitive theory*.) Like Rotter, Bandura believed that personality, behavior, and environment all influence one another. He called this interaction of factors *reciprocal determinism*. Thus, like Rotter, Bandura believed personality develops through both direct and vicarious experience in our interactions with others and the environment.

As Rotter had, Bandura rejected Skinner's position that mental factors should not be considered in a personality theory. He believed that one's thoughts, one's *cognitions*, have an important role in determining behavior. Bandura postulated two primary cognitive variables: (1) efficacy expectations, more commonly known as self-efficacy, and (2) outcome expectancies. *Self-efficacy* is the subjective probability that one can execute a particular behavior. If one has learned the set of skills needed to engage in a behavior, one's self-efficacy will be high. *Outcome expectancies* refer to one's beliefs about the results of our behavior; will they result in reinforcement or not? These variables resemble Rotter's concept of expectancy, but they have the advantage of separating the two components of expectancy—beliefs about one's ability to accomplish the behavior (self-efficacy) and the anticipated results of the behavior (outcome expectancy).

This distinction is important because a low expectancy from Rotter's perspective could be due to either a lack of skills (low self-efficacy) or an environment that will not reward even a skillfully executed behavior (low outcome expectancy). For example, parents may not discipline their children either because they have not learned effective disciplinary techniques or because they worry that

children will love them less if the parents impose limits. Like expectancy, self-efficacy is seen as a product of our experiences, both direct and vicarious.

Mischel's Cognitive Social Theory

Cognitive social theory was developed by Walter Mischel, who was a student of Rotter's in the 1950s. Like Rotter and Bandura, Mischel saw the interaction of the person and the environment as crucial to understanding behavior. Unlike Rotter and Bandura, however, Mischel more heavily emphasized the environment, suggesting that stable personality characteristics are an illusion. Rather, behavioral consistency is largely determined by stability of the environment. What appear to be personality traits really represent habitual ways of responding to certain situations. If the situation changes, so do our responses.

Mischel has also incorporated emotion into his model of behavior, showing that our interpretations of events differ depending on whether we are experiencing mild or intense affect at the time. This explains why our interpretation of a loved one's behavior is different when we are angry than when we are feeling calm. A major focus of Mischel's work has been delay of gratification, which is one's ability to forgo immediate reward in favor of more desirable longer term outcomes.

SOCIAL NETWORKS, DYAD EFFECTS ON

The traffic between dyadic (two-person) relationships and the larger networks in which they are embedded always runs in both directions. Although researchers have traditionally emphasized ways that networks influence what goes on inside relationships, there are many ways that dyadic events flow outward to affect the behavior of others and the structure of social networks as a whole.

Deliberate Efforts to Change the Perception and Behavior of Network Members

Relational partners often deliberately seek support or resources for their relationship from other members of their social networks. Researchers have found that, during the initiation of relationships, network members are regularly recruited to make introductions, facilitate meetings, relay information, and promote a positive image of one prospective partner in the eyes of the other.

Deliberate attempts to enlist or influence network members continue as relationships develop. Leigh Leslie and her colleagues found that 85 percent of young people in romantic relationships had attempted to influence one or both parents. They used multiple strategies (e.g., emphasizing the partner's good points, talking about how well the partner treats them, reassuring their parents that they are still valued). At the other end of the relational life cycle, participants in troubled relationships commonly enlist network members as confidants, supporters, and even coconspirators in efforts to end the relationship. But these intentional, self-interested attempts

to “work the network” only hint at the myriad ways in which events inside a given relationship spread outward and affect other relationships and the overall structure of the network.

Unintentional Effects on Perception and Behavior of Network Members

Many of the effects of dyadic relationships on networks are beyond the vision of the relational participants. For example, regardless of whether they know it, their relationship provides others with a point of comparison for evaluating their own relationships. Married couples commonly compare their marriages to the marriages of their friends. Thus, the friends’ marriages become reference points that influence perceptions and behaviors within the network.

Individuals will also be influenced in more diffuse ways. As they observe others and as they hear gossip, they will infer rules and norms to be applied to their own relationships. Social-psychological research on conformity in group settings demonstrates that people will adjust their attitudes and perceptions in response to perceived consistencies in what others think or do. Face-to-face interaction enhances these effects, but researchers have found similar, although less robust, conformity effects in computer-mediated settings where face-to-face contact was absent.

Other subtle effects on the perceptions of network members occur as well. For example, research in settings where there are sharp intergroup differences, such as between Catholics and Protestants in Northern Ireland, demonstrates that people will be more tolerant of those in the opposing group when they discover that their close associates have friends in that group.

Dyads may become the critical nodes in a larger process of diffusion or contagion. The decision of whether to discuss a topic with a partner is not just a dyadic event. It also functions as an information gate structuring the flow of information through a network. Those who disclose may attempt to limit retransmission of the information to others, but research suggests that these efforts are rarely successful. People promise not to tell, but they do. Nor are these effects limited to information. In a study in a U.S. high school, for example, Peter

Bearman and his colleagues found that more than 50 percent of sexually active students were linked to each other in a single sexual network. Nearly half of these students reported that they had been sexually monogamous—having sex with just one person and no one else—but they were nonetheless linked to everyone else in the network by virtue of their partner’s less monogamous behavior. Findings such as these obviously have implications for the spread of sexually transmitted diseases, but they also illustrate how choices made within dyads embedded in networks extend to affect the network as a whole.

Dyadic Effects on Network Structure

Network Distance

The concept of network distance refers to the number of links needed to connect any two network members. The distance separating any two individuals will change as other individuals within the network initiate, develop, and dissolve dyadic relationships.

When two previously unacquainted people meet, the members of their network who were not already connected are shifted closer in social space, thus increasing the chance that they will meet. Studies in the United States and the Netherlands show that most relational partners already had some friends in common by the time they met for the first time. As their relationship grows closer, romantic partners typically reprioritize their interactions with network members in order to make more time for each other. They spend less time with their friends and relatives. Yet the degree of withdrawal is usually relatively small and occurs chiefly in the less intimate sectors of the network. More important, the withdrawal from one’s own contacts is usually more than matched by the new contacts and interactions with members of the partner’s network. Thus, the overall process is not so much a process of withdrawal as a process of realignment and reprioritization.

Realignment and reprioritization of relationships with network members also occur when dyads experience difficulty. Divorce typically ruptures the network that has assembled around the partners. Less dramatic changes in network structure occur when people disengage from particular

friendships or business relationships. These changes fan out to stimulate changes in surrounding relationships and alter the relative distances of network members from one another. Some may become more distant as a dyad dissolves (e.g., the former in-laws on each side of a divorce). Others may become closer as the relational partners realign and reprioritize. Indeed, the circle of relational life becomes complete as the demise of some relationships hastens the formation of new ones. If we could visualize the entire network in motion, we might see new partners moving toward one another even as one or both are still involved in their present relationships.

Network Centrality

Changes in our individual relationships not only affect the distance between particular network members, but also ripple out to influence the prestige and influence of others, including those whom we may know only slightly or not at all. Central members of the network have more favorable positions, more opportunities, and greater influence owing to their position relative to others in the network. Being directly connected to more people generally increases one's centrality, but it matters even more how one is linked to them. Network theorists commonly distinguish between prestige and influence. You gain prestige when a large number of others identify you as one of their contacts, but your influence depends on the number of people you contact. Prestige and influence need not balance—an individual may, for instance, have a great deal of prestige, but relatively little influence.

Centrality, and hence power, in networks flows not only from one's direct contacts, but also from how those individuals are linked to others. One might think that being directly connected to others who are highly connected would confer power or prestige. But if the people to whom we are connected are also well connected, then they are less dependent on us. Ironically, we are in a more powerful position when those to whom we are linked are not well connected.

The concept of centrality in its many forms gives us a way to recognize how changes in individual relationships may yield changes in others' relationships and in their prestige, influence, and power. New romantic partners, for instance, are not only

creating a connection with each other, but are also stimulating the formation of links between members of their networks. This alters the power or influence of network members, as in the case of the man who becomes friends with his brother's girlfriend's brother. The same occurs when relationships terminate. The friend who maintains contact with both former spouses, for example, may find herself in a particularly influential position as other contacts are dropped. The same might be said for those who are successful in retaining contact with each side of failed friendships or busted business relationships. In each case, the centrality of the individual has been increased because other linkages have dissolved and others are now more dependent on him or her for information. By the same token, those who were once in central positions may find themselves relegated to the backwaters of the network as changes in key relationships around them reduce others' dependence on them and their connections.

Network Density

Density refers to the overall degree of interconnectedness among network members. It is typically calculated as the ratio of actual links to total possible links. In low-density or loosely knit networks, relatively few network members are linked to one another. In high-density or tightly knit networks, members are highly interlinked, often in multiple ways.

As relational partners develop their relationship, they typically increase contact with the members of each other's networks and develop overlapping networks. This cross-network contact increases in the density of linkages between the partners' networks and the overall density of the larger network. As the dyadic relationship becomes more interdependent and more stable, the connectedness of those around it is likely to increase. Researchers have found that both dating and married couples whose relationships are closer, more satisfied, and more stable tend to have more friends in common and more contact with each other's friends and family.

Conversely, when a dyadic relationship begins to deteriorate, the network surrounding it may unravel. Members of the network who were brought together by virtue of their relationship

with the dyadic partners often lose incentive to stay connected. The demise of a friendship, romantic relationship, or work relationship may force members of the surrounding network to choose sides. Even in the absence of loyalty conflicts, however, network members may begin to question their own relationships as the dyads around them begin to deteriorate. They may lose access to resources. The barriers to alternative relationships may be raised or lowered. The termination of a business partnership, for example, creates options for network members to form new collaborations. The demise of a romantic relationship loosens other bonds within the network, freeing network members for new associations.

Conclusion

To appreciate the effects that dyads can have on networks, we only need consider two questions: How could events inside my relationships affect others? How are my relationships affected by my responses to what others do in their relationships? These questions differ only in perspective, and both point toward ways that dyads influence networks. These include the deliberate attempts of dyadic partners to secure support or other resources from network members, as well as a series of less direct effects on the behavior of network members, the distance between them, their prestige or influence, and the overall structure of the network.

SOCIAL NETWORKS, EFFECTS ON DEVELOPED RELATIONSHIPS

It is often said that when we marry, we marry our spouse's family as well. As it turns out, there is truth to this statement. In fact, each time we enter a romantic relationship, we not only "marry" the family, but friends as well. Romantic relationships do not exist in a vacuum, but are embedded in a network of interdependent relationships. This social network affects not only marital relationships, but also has been shown to affect romantic relationships at all stages of development. The present entry addresses the current research highlighting the impact of social networks on relationship initiation, maintenance, and termination.

Defining Aspects of Social Networks

The global social network is a collection of all individuals with whom we are personally acquainted. Social networks can vary in structure in a number of ways. For instance, the size of a social network varies for individuals, with some people having smaller networks and others having more expansive ones. Further, some networks are considered higher in density because they are more closely knit, with many members of the network being directly acquainted with each other. Often these networks are higher in intensity, meaning members are more willing to respond to the expectations of their social network. Meanwhile, others are lower in density, with fewer within-network associations, and may be higher in distance, such that associations within the network are more indirect (e.g., Andrea knows of Vincent because Vincent is friends with her sister). Alternatively, it may only be that subsets of individuals within a network may be closely linked with each other, whereas others are not. This is referred to as clustering or the development of cliques within one's network.

Each social network is typically composed of family members as well as nonfamily members, such as friends, neighbors, and coworkers. As such, within the global network, there are subsets of individuals who constitute

- The psychological network—people to whom one feels close (e.g., one's significant others).
- The exchange network—those who are important to the individual because they provide resources or are those to whom the individual provides support.
- The interactive network—those with whom one regularly communicates.

These categorizations are not mutually exclusive. Rather, it is common for there to be overlap across these different networks. In fact, much of the research on social networks has focused on the inner circle of significant others who are exchange and interactive network members, in addition to members of the psychological network. Personal relationships with these individuals can significantly impact one's physical and mental well-being. In addition, these social network relations can influence one's relations with others within the network, such as the development, quality, and fate of one's romantic relationships.

Social Network Influences

There have been four primary avenues of research examining the influences of social networks on romantic relationship dynamics:

1. Studying how networks contribute to relationship initiation by facilitating introductions of potential partners (e.g., "matchmaking")
2. Examining how aspects of global network structure (e.g., size, density, intensity) contribute to relationship quality
3. Investigating how the provision of resources (e.g., finances, advice) from the social network affects different relationship aspects
4. Exploring associations between social network perceptions (e.g., approval, disapproval, perceptions of the likelihood of the relationship succeeding) and relationship state and fate

Within each of these foci, one theme is consistent: Social networks are important for a variety of romantic relationship variables, from the beginning of the romantic relationship to its end.

Relationship Initiation

Social networks can exert influence in a number of ways during the early stages of relationship formation. Research has shown, for example, that it is often through social networks that we find potential romantic partners. In one national study, 35 percent of married couples claimed to have met their partner through mutual friends, 15 percent met through family, and another 13 percent reporting to have met their spouse through other work or school acquaintances. Sometimes these third parties help through direct matchmaking attempts and blind dates, but friends and family also assist in introducing one to a date through parties, through joint dating (e.g., double dating), and by couples meshing their social networks so that, say, friends from Erika's network come to meet friends of her new husband.

Within Western cultures, there is some evidence that friends can have more influence than the family at these initial stages of relationship formation. After all, it is at this courtship stage that one is essentially making the decision about who to integrate into one's existing peer network. Whereas it is at later stages of relationship development—namely, when deciding whether to commit to a partner for life—that the individual is making a decision about including a partner in his or her family. As discussed earlier, friends of friends make up one of the primary sources of long-term partners. Also, in younger groups of mixed-sex acquaintances, it is not uncommon for friends to date multiple friends within their network. In some instances, literature within developmental psychology has also reported that adolescents even feel pressure to date exclusively within their own social networks and thus limit their choices of romantic partners to avoid exclusion from their peer group. Further, recent experiments in social network research have shown that when weighing potential dates in a dating game study, between 60 and 80 percent of participants chose the bachelor(ette) that was approved for them by their friends. In contrast, participants

were equally likely to choose the candidate they were told their parents disliked as they were to choose the match their parents approved. Last, research on individuals using personal ads shows that if anyone is consulted to help the individual choose among their options, it is friends.

Relationship Maintenance

Once the courtship commences, social networks continue to play a role in affecting the relationship state (e.g., the levels of satisfaction, love, commitment, and overall quality within the romantic relationship). For instance, work by Robert Milardo and colleagues has shown that the more the networks of the couple overlap (i.e., the more they share mutual friends), the lower the likelihood of relationship demise. The social network prevents breakup because the more overlap there is in the network, the more a breakup would cause turmoil—in one's romantic relationship, as well as with one's friends, perhaps forcing them to choose sides.

Another interesting finding is that cross-network contact also plays a significant role in relational development. As the number of individuals one meets in one's partner's network increases, a greater amount of time is spent with the partner. Also, as a result of greater cross-network contact, individuals also report feeling more understanding and predictability in their relationship. Additionally, people report greater disclosure and emotional attachment and generally become more committed to continuing their relationship with greater cross-network contact.

There are a number of possible reasons that cross-network contact yields these positive outcomes. First, meeting the partner's network can be seen as an important step in a developing relationship. Thus, the partner simply being willing to integrate the partner into his or her social network could be indicative of him or her being more committed to the relationship. Second, if individuals are willing to spend time with their partner's social network, this allows them to spend more time with their partner. After all, one would not feel like she or he has to choose between spending Friday night with the partner or his or her friends. Third, meeting individuals from one's partner's network can provide more insight into one's

partner, thus building understanding. For instance, stories of one's partner's past would emerge, perhaps accompanied by an embarrassing photo or two. During these interactions, an individual can get a better sense of a partner's character (e.g., how does she or he react to that embarrassing photo) and his or her approach to relationships. Last, greater disclosure may come about as partners share their experiences from interacting with cross-network associations. Plus, emerging research has shown that if the cross-network contact involves intimate disclosure with other couples, this disclosure not only enhances feelings of trust and love between couples, but within couples as well. It is as if the other couples serve as models, giving couple members training in intimacy building.

Aside from network structure, much of the research examining links between social networks and relationship state has focused on the role of social network support for the romantic relationship. One could define network support of a romantic relationship as the actions, feelings, or expressed opinions of third parties that romantic relationship members perceive as conveying that the network member is validating of the romantic relationship and facilitating of relationship development. Support from one's social network can be expressed in a variety of ways. Emotional support is that which reassures the couple of the value of their relationship, such as when third parties express liking for the partner, include the partner in events (e.g., holidays, parties), and otherwise approve of the relationship. Network members may also serve as sources of advice about the relationship, lending appraisal support. In fact, research suggests that once a couple marries, the social network, particularly friends for women, become the primary source of "relationship work" (e.g., help "make sense" of relationship issues). Last, these friends and family may lend instrumental support through providing material and financial resources to help facilitate relationship development. For instance, friends may throw a baby shower or parents may lend the new couple a down payment for a new home.

In studies of the association between social network support and relationship state, degree of support has been assessed through a variety of measures. Many use single-item indices that ask

individuals in the couple how much they agree that: "My friends/family support my romantic relationship" to which couple members respond from *completely disagree* (1) to *completely agree* (7). Others use scales with multiple items asking about the perception of social approval or about behaviors that third parties engage in to indicate support. Most studies ask about the perceived social support, asking the couple members about the opinions of their social network, rather than asking the third parties. Studies that have inquired about actual social support in addition to perceived social support find that the latter is actually a better predictor of relationship state. Indeed, most studies find that perceived social network support is a positive correlate of satisfaction, love, commitment, investment, and general relationship quality.

This correlation is likely bidirectional. On one side, the better the relationship, the more the network approves. After all, people want the best for their friends and family and would be more approving of a relationship that makes their child or friend happy. On the other side, the more the social network supports the relationship, the more positively one comes to view one's relationship. The positive social network opinion reaffirms one's choice, and the social network likely actively provides resources to help maintain the relationship (e.g., positive advice, encouraging commitment).

By and large, the focus in the literature has been on the influence of social network opinions on the romantic relationship, rather than vice versa. Emerging experimental evidence shows that social network approval is causally linked to greater commitment and affection in a romantic relationship. Also, some longitudinal studies have found the social network support indices to be a stronger predictor of relationship continuation than the perceptions of the couple about how satisfied or committed they are to the relationship. Further, although the majority of this research has been conducted with surveys of primarily White college students in heterosexual dating relationships, this finding about the influence of social network opinion has been replicated in studies of long-term married couples, in experimental surveys, in longitudinal designs where couples are followed for months or years, in studies in non-Western cultures with racially diverse samples, and in relationships with a history of societal disapproval (e.g., intergroup, Internet, or homosexual).

Relationship Termination

Perhaps it is not surprising, then, that lack of support, interference, or other forms of disapproval from the social network are linked to a higher risk of relationship dissolution. Couples coping with the lack of social support for their relationship tend to show lowered levels of commitment and increased risks of infidelity and breakup. Further, new research shows that the impact of the social network extends even beyond breakup, as disapproved couples are less likely to even remain friends postdissolution.

However, the research findings on the impact of disapproval have been less consistent than those assessing approval. Although many research studies examine disapproval and approval as opposite poles on a continuum, increasingly, evidence suggests that disapproval is not merely the inverse of approval. After all, approval largely indicates that the social network is in agreement with the couple about their perception of the relationship. Disapproval, however, indicates disagreement. This difference is important because one doesn't need to stop to question why it is that one's friends and family agree with him or her, but disagreement causes one to stop, think, reconsider, and sometimes choose between the relationship with the disapproving friend/relative and the romantic relationship.

As such, although a number of studies show links between disapproval and relationship failure, there are exceptions. Most notably, early research on the Romeo and Juliet effect found that, in some instances, parental interference was linked to increased love for one's partner. Limited support for the Romeo and Juliet effect has been found in subsequent studies. However, other studies have failed to find a link between disapproval and relationship outcomes. Given the array of findings, it is difficult to pin down the impact of social disapproval. Likely, some respond to disapproval with reactance—whereby they interpret the disapproval as attempts of third parties to interfere in their life and thus respond by doing the opposite of what the third party would like them to do. In contrast, others could not imagine being in a relationship disapproved of by their parents, particularly if they are from a more collectivistic culture where family bonds are considered to be of the utmost importance. Additional individual, relationship, cultural,

and situational variables probably come into play as well and are currently being investigated.

An additional challenge facing the interpretation of results regarding the association of disapproval and relationship outcomes is the lack of a clear and consistent definition of *disapproval*. Most often disapproval is measured with the same instruments used to assess approval, and relationships low in approval are considered disapproved. However, the measurement of disapproval has varied in terms of

- Type of disapproval—Active versus Passive: Some studies ask about the active attempts of third parties to end the relationship (e.g., such as parents forbidding children to see a boyfriend or girlfriend). This type of active disapproval may be more likely to trigger rebellion because third parties are actually interfering in the relationship. In contrast, more passive forms of disapproval—whereby the third party simply doesn't provide as much support for the relationship (as opposed to, say, threatening the withdrawal of resources for remaining in the relationship)—likely elicits a different reaction.
- Target of disapproval—Partner versus Relationship: Other studies ask about dislike of the partner as opposed to disapproval of the relationship, and yet one may like the partner but disapprove of the relationship, perhaps feeling the couple members are too young.

Other aspects of disapproval may also be important to consider. For instance, the third party's reasons for disapproval have yet to be examined in the field. Yet in some cases, the reasons one's parents or friends object may be seen as biased or otherwise invalid, such as if one's parents object to one being in a cross-race relationship. However, in other instances, it could be that the network members disapprove because the relationship is indeed an unhealthy one, perhaps abusive. In this case, the individual may be dependent on the romantic relationship. Dependency on one's romantic relationship has been shown to decrease the impact of social network opinion on the likelihood of relationship termination. Otherwise, it could be that the individual still sees their partner with rose-colored glasses. These idealized perceptions of the partner—called positive illusions—can prevent the individual in the

relationship from seeing flaws evident to outside observers. Indeed, when Diane Felmlee asked participants how members of their social network had affected the breakup, it was evident that third parties played a significant role in helping them see what their partner “was really like.”

Given the more realistic views of the relationship that third parties are credited with having, perhaps it is not surprising, then, that recent research has found that certain social network members are better able to predict whether a romantic relationship will last than are the members of the couple. However, a competing alternative may be that the opinions of the third party regarding relationship quality becomes a self-fulfilling prophecy, whereby if third parties perceive a relationship as doomed to failure, they may bring about this outcome. For instance, their opinion would influence the feedback they gave their friends/family whenever that person sought them out for relationship advice. Thus, the disapproving third party may be more likely to assign blame to the partner and encourage break up in the face of relationship difficulties, rather than help the couple member forgive his or her partner. How the social network facilitates relationship sense making is one of the newer avenues of study in social networks research. It is but one path currently being pursued by researchers as they move from establishing that social network opinions have an impact on trying to understand how and why it is that third parties affect relationship dynamics.

SOCIAL NETWORKS, ROLE IN RELATIONSHIP INITIATION

Social network perspectives have much to contribute to our understanding of why some people meet and others do not and why some who meet go on to develop a personal relationship and others do not. Although the forces that bring people together are often treated as a matter of chance or destiny, research has shown that social network factors play two important roles in this process.

First, they help determine who meets whom. Second, they provide a set of resources or affordances that people employ to create first meetings and facilitate the initial development of relationships. To set these network factors in context, it is helpful first to consider the cultural notion of chance and choice in relationship initiation and, second, the adequacy of traditional social scientific approaches to relationship initiation.

Choice and Chance in Relationship Initiation

Human cultures vary in the degree to which they attempt to regulate contact between strangers. The clearest examples of this can be found in the regulation of contact between unattached men and women who might become sexual partners. In many cultures and groups, relationship initiation is heavily regulated by norms about contact between opposite-sex strangers, as well as mechanisms for sexual segregation and surveillance. When young women and men meet, they meet in a relatively “closed field” that is actively managed by the families and institutions to which they belong.

In other cultures, particularly contemporary European-American cultures, relationship initiation is widely presumed to occur in an “open field,” in which individual choice is maximized and larger social influences are minimized. The romantic literature of these cultures celebrates the role of chance or “destiny” in human encounters, although it frequently contains cautionary tales regarding the risks of consorting with strangers as well.

Two things are apparent when we look across the continuum from “closed” to “open” relational fields. First, although cultures differ, all are concerned to one degree or another with regulating contact between strangers, and all have complex literary and cultural traditions regarding the virtues and risks of such meetings. Second, although some cultures regulate relational initiation to a greater degree and more explicitly than others, there is no such thing as a pure “open field” when it comes to relational choices. That is, whom we meet and who is judged to be a potential relational partner is never solely a matter of chance or choice. There are other factors at work even in the most open of cultures. Before looking at those, it is useful to consider how the myth of

the open field has limited our understanding of relationship initiation.

Blind Spots in the Study of Relationship Initiation

Until recently, researchers typically sought to examine relationship initiation by asking arbitrarily selected strangers to interact in a laboratory setting. Sometimes they were not even asked to interact. In one popular technique, for example, subjects were asked to form impressions or make relational choices based on extremely limited information—such as pictures or brief printed descriptions of others' attitudes. This was called the *phantom-other* technique because there wasn't actually another person with whom subjects interacted. Subjects in these stripped-down situations naturally used the few scraps of information they were given, but how they did so probably tells us little about how people seek and use information in real settings.

Studies that track naturally occurring relationships over time or compare relationships at different stages of development are more informative. Unfortunately, nearly all of these studies start with established relationships because participants usually elect to report on their more established relationships, rather than on their more tentative, early stage relationships. If we are to understand how relationships begin, we must therefore catch them as early as possible and in their natural setting. Fortunately, there is research that speaks to these issues of timing and context in a general way. This is the research on social norms and physical proximity.

Norms of Relationship Initiation

Researchers view relationship initiation as a screening process—winnowing a comparative large “field of availables” to a narrower “field of eligibles” and then to a still narrower “field of desirables.” Some aspects of the selection process are idiosyncratic, but others reflect broader social norms within the individual's group regarding who is an appropriate and desirable partner.

The most powerful of these is the norm of similarity or homogamy. When it comes to selecting mate or friends, selection favors those who are

similar in terms of age, ethnicity, socioeconomic status, education, and religion. These factors are not equally important in every relationship, but research has consistently demonstrated that people draw on norms of similarity when selecting partners for interaction and when deciding whether they wish to pursue a closer relationship.

Norms have influence because they are widely diffused throughout the individual's social group. The more frequently a norm is referenced or enacted within the group's social network, the more influence it will have. Conversely, if the network becomes fragmented or the opportunities to enact norms are restricted, then the impact of the norm on relationship initiation is diminished. Thus, the power of social norms in relationship initiation implicitly depends on the activity and structure of the group's social network.

Physical Proximity and Relationship Initiation

Physical proximity is undoubtedly the most widely recognized factor accounting for why some people meet and others do not. Put simply, one is more likely to meet and begin a relationship with someone nearby than with someone not so near. Research dating back to the 1930s has consistently documented the effects of physical proximity. Apartment dwellers are more likely to become friends with others who live on their floor than with those who live on other floors. Homeowners are more likely to become friends with the neighbors who live next door than with those who live several houses away. Workers are more likely to strike up a relationship with those who work in close proximity than with those who work in other areas of a plant or office.

Physical proximity offers such a commonsense account for why people meet that researchers rarely question it. However, there are a number of problems with physical proximity as an explanation for relationship initiation. First, the findings of the early research were often not as conclusive as we might think. Although they showed that people who lived within a few blocks of each other were more likely to become friends or marry, a large minority of the relational partners examined in these studies were not in close proximity. In some cases, researchers overestimated proximity

effects because they did not count people who met while living in different cities.

Second, physical proximity cannot account for differences within the same geographic radius. Demonstrating that many of those who become friends or romantic partners live within a few blocks of one another does not explain why those particular people connected while others within the same area did not.

Finally, advances in transportation and communication technology over the past 50 years have steadily reduced the importance of proximity as a basis for relationships. In many cases, physical proximity is no longer even a necessary condition for relationship initiation. Computer-mediated communication now makes it possible for people to establish relationships, often close ones, without reference to physical location.

Social Proximity and Relationship Initiation

In social networks, people are directly linked to those they know, but indirectly linked to many others. In fact, nearly everyone is linked to nearly everyone else, although a relatively small number of indirect links. This has been called the “small world” effect, and it accounts for why total strangers often find that they have common acquaintances.

The pattern of social linkages among any large group of people is in a constant state of flux. Some people are pushed further from one another in social space as the number of links separating them increases. Others are carried toward one another as the number of links separating them decreases. Being carried toward one another in social space during the time before individuals actually meet defines a sort of prehistory of relationships. Imagine, for instance, that we could go back in time to visualize changes in the networks containing two individuals who will someday meet and marry. Early on, they might be separated by many links, but as time moved forward, we would see that the number of links separating them steadily decreased. At some point, they were separated by just one or two links. They probably have now become members of at least some of the same groups and have started to share at least some of the same values, attitudes, and expectations. They

may become aware of each other through their common contacts and at some point meet for the first time.

These shifts in network structure create “social proximity effects.” As the number of links separating any two people decreases, the probability of meeting increases. Although it is difficult to document social proximity effects in large social networks, several lines of research point to their existence and illustrate the role they play in relationship initiation. Structural sociologists have shown that patterns of liking tend to be transitive in groups. That is, if A likes B and B likes C, then A will come to like C. Other researchers have shown that this transitivity of liking helps predict friendships over time. Two people are more likely to become friends if they already have a friend in common.

Social proximity effects imply that people who become friends or romantic partners should have had one or more common contacts prior to meeting for the first time. Using a national sample of married and cohabitating couples in the Netherlands, Matthijs Kalmijn and Henk Flap found that almost 50 percent had common friends before they met, and a bit more than 14 percent said that members of their immediate families had known each other before they met for the first time.

Further evidence of social proximity effects comes from a series of studies by Malcolm Parks, who examined the relational prehistories of 858 individuals involved in opposite-sex romantic relationships or same-sex friendships. Respondents were asked which of their partner’s 12 closest friends and family they had met prior to meeting their partner for the first time. Two thirds (66.3 percent) had met at least one member of their partner’s network of family and close friends prior to meeting their partners for the first time. Close to half (47.3 percent) had met between one and three members of the partner’s close circle before meeting the partner, and nearly 20 percent had met more. Social proximity effects occurred equally for men and women and across age groups. Interestingly, however, people in romantic relationships reported that they had prior contact with almost twice as many people in their prospective partner’s network as people in same-sex friendships. It appears that young people tend to select romantic partners from those who are socially

close, but are willing to develop friendships with those who are not quite so close in social space.

Direct Involvement of Network Members in Relationship Initiation

Network members are often actively involved in the initiation of personal relationships—far more often than is acknowledged in the social scientific literature. Some attention has been devoted to those in formal roles such as marital matchmakers. The formal role of matchmaker can be found in a number of non-Western countries and in a variety of ethnic enclaves in the United States and Europe. Yet focusing on such formal roles leads us to overlook the many informal roles played by network members in everyday life.

Network members rarely describe what they do as “matchmaking,” but people agree that they have often given or received “help” in initiating romantic relationships. In one of the few studies to address this phenomenon, Malcolm Parks found that more than half of those in a sample of young adults in the United States said that they had helped at least one other couple “get a romantic relationship started” in the last year. Those who had helped reported helping an average of nearly three couples during the previous 12 months. Among those who had initiated a new romantic relationship themselves during that time, almost two thirds said that they had assistance from at least one person in their social network. In many cases, they reported having received help from multiple parties. Thus, even in a culture that emphasizes personal choice in romantic relationships, the active involvement of network members in relationship initiation appears to be the rule rather than the exception.

The findings of this study also challenged popular gender stereotypes of women as relational specialists and men as less relationally oriented and probably in greater need of help. Men and women were equally likely to help others begin romantic relationships. They are also equally likely to be recipients of help.

The helper’s location within the social network was critical. Helpers were more likely to be unmarried—perhaps reflecting the fact that married people tend to have married friends and are thus

less likely to be in a position to know people who require assistance. People also did not generally give or receive help from relatives, although this may have been a reflection of the fact that most of the study participants were college students away from home and so relatives were perhaps less available. From a network perspective, however, the most interesting finding was how helpers and recipients were related. Cases in which the helper was close to both recipients were rare. The most common cases were those in which the helper was much closer to one of the recipients than the other. Thus, helpers functioned as “network operators” who were not just bringing potential romantic partners together, but who were also bringing together previously unconnected parts of their own social networks.

Contrary to the common stereotype of informal matchmakers operating behind the scenes, most of the people who received help were aware of what the helper was doing on their behalf. More important, in nearly half the cases reported in the Parks study, one or both of the recipients had sought help from the third party. Instead of being passive receivers of third-party influence, then, many people actively enlist the resources of their networks to assist with relational initiation.

The activities of third-party helpers fall into three broad categories: attraction manipulations, direct initiations, and direct assists. Attraction manipulations attempt to increase the prospective partners’ attraction to each other by making positive comments about one person to the other, downplaying or reframing less positive attributes, or noting and reinforcing similarities between the prospective partners. Direct initiations include all those activities intended to facilitate meetings between the prospective partners—arranging for them to be at the same place at the same time, making introductions, and arranging social events intended to bring the prospective partners together. Direct assists range from coaching one or both prospective partners to acting as information relays between the prospective partners. Again, these activities are frequently done with the person’s knowledge and often at their request.

The availability of help from network members often has a profound influence on relationship initiation. In Parks’s study of third-party assistance in the initiation of romantic relationships, just over half of the helpers believed that

they had been successful. More important, the majority of those who had received assistance from network members believed that it had been beneficial. Those who received third-party assistance had more active social lives than those who did not.

SOCIAL NEUROSCIENCE

Social neuroscience is the study of the associations between social and neural levels of analysis and the biological mechanisms underlying these associations. Neuroscientists have tended to focus on single organisms, organs, cells, or intracellular processes. Social species create relationships and organizations beyond the individual, however, and these emergent structures evolved hand in hand with neural and hormonal mechanisms to support them because the consequent social behaviors helped animals survive, reproduce, and care for offspring sufficiently long that they too reproduced. Human relationships represent a particularly important social structure that serves these functions. Social neuroscience is concerned with how biological systems implement social processes and behavior, capitalizing on concepts and methods from the neurosciences to inform and refine theories of social-psychological processes, and using social and behavioral concepts and data to inform and refine theories of neural organization and function.

Consider the recent evolutionary development of the brain, which has grown substantially larger than needed to maintain life. According to the social brain hypothesis, deducing better ways to find food, avoid perils, and navigate territories has adaptive value for large mammals, but the complexities of these ecological demands pale by comparison to the complexities of social living. The latter include (a) learning by social observation; (b) recognizing the shifting status of friends and foes; (c) anticipating and coordinating efforts between two or more individuals; (d) using language to communicate, reason, teach, and deceive others; (e) orchestrating relationships, ranging from pair bonds and families to friends, bands, and coalitions; (f) navigating complex social hierarchies, social norms, and cultural developments; (g) subjugating self-interests to the interests of the pair bond or social group in exchange for the possibility of long-term benefits; (h) recruiting support to sanction individuals who violate group norms; and (i) doing all this across time frames that stretch from the distant past to multiple possible futures. Accordingly, cross-species comparisons suggest that the evolution of large and metabolically expensive

brains is more closely associated with social than ecological complexity, at least in primates.

Even within anthropoid primates, the achievements of *Homo sapiens* are notable. Humans were not the first bipedal creatures or the first to use tools, but humans, apparently uniquely, contemplate the history of the earth, the reach of the universe, the origin of the species, and the genetic blueprint of life. Estimates among biologists at the dawn of the 21st century were that 100,000 genes were needed for the cellular processes that are responsible for complex human behavior. It appears that humans have only about a quarter this number of genes, but as a species we have been faster than other animals to acquire new genes and to discard unnecessary ones. The frontal cortex is particularly important for critical behaviors such as executive function and working memory, yet the ratio of frontal to total cortical gray matter is about the same in humans as in nonhuman primates. Although humans may have more cortical neurons than other mammals, whales and elephants are not far behind on this count. The specialized capacities of humans may depend less on the number of neurons than the number of synapses in the brain, the greater cell-packing density in the brain, and the higher neural conduction velocities, which together raise the overall capacity for abstraction, representation, and information processing.

A biological approach that treats the individual organism as the broadest legitimate unit of organization may help illuminate some aspects of development and behavior, but it is unlikely to provide a comprehensive account. Nevertheless, from the perspective of many biological scientists during most of the 20th century, the contributions of the social world to biology and behavior were thought best to be considered later in time, if at all. Accordingly, social factors were viewed as of minimal interest with respect to the basic development, structure, or processes of the brain. To the extent that social factors were suspected of being relevant, their consideration would so complicate the study of brain and behavior that they were not a priority. The approach of social scientists throughout most of the 20th century was no less narrowly focused than that of biologists. World wars, a Great Depression, and civil injustices made it amply clear that social and cultural forces were too important

to address to await the full explication of cellular and molecular mechanisms. Thus, biological events and processes were routinely ignored.

Despite this historical independence of biological and social sciences, evidence for a social brain has continued to accrue. Individuals with frontal variant frontotemporal dementia have relatively normal general cognition and intelligence, but exhibit severely impaired social cognition such as empathy and self-regulation. Individuals with Alzheimer's dementia, in contrast, whose disease first manifests in the entorhinal cortex and hippocampal regions, are characterized by severely impaired memory and cognition, but aspects of social cognition such as empathy and theory of mind are relatively intact. Prosopagnosics, who typically have bilateral lesions in the occipital lobes near the temporal lobes, do not undergo a change in personality, but they no longer recognize the faces of those whom they once knew (e.g., spouses). The Capgras syndrome, typically associated with bilateral lesions in the temporal and right frontoparietal cortices, is characterized by an indelible belief that others who are emotionally close to the affected individual have been replaced by physically identical imposters. In contrast, Fregoli syndrome, typically associated with right hemisphere dysfunction, is characterized by a belief that strangers (i.e., people who are perceived to be physically different) are in fact familiar individuals (i.e., psychologically identical to familiar individuals).

In addition to the impact of the brain on social behavior, social behavior has a substantial impact on the brain and genes. Social factors such as loneliness are heritable and affect genetic expression in white blood cells. For example, early work by Harry Harlow and colleagues suggested that tactile contact is a stronger determinant of mother–infant attachment than feeding. In rodents, early tactile deprivation reduces the number of glucocorticoid (a class of stress monitoring and dampening hormones) receptors (sites at which neurotransmitters act on neurons) in the hippocampus and frontal cortex. These changes can be long-lasting, and, as a consequence, stress reactivity is elevated in both the pup and the adult. Intentional action and the observation of intentional action by another individual activate the same neurons—the so-called mirror neuron system—thereby providing a shared

neural notation that promotes positive social interactions, synchrony, and communication. Positive social interactions promote the release of oxytocin in the brain, which in turn promotes social recognition and bonding and down-regulates reactivity to stressors. The release of testosterone in nonhuman male primates not only promotes sexual behavior, but the availability of receptive females—a social factor—influences testosterone levels in these male primates.

In summary, mounting evidence for the importance of the relationship between social and biological events has prompted biological scientists, cognitive scientists, and social scientists to collaborate more systematically, with a common view that the understanding of mind and behavior could be enhanced by an integrative analysis that encompassed brain, cells, and genes. The growth in this research suggests that linking the neurosciences and social sciences is indeed practical and indicates potential for a common scientific language that can establish bridge principles needed to connect the theoretical terms of these sciences. Social neuroscience is the interdisciplinary scientific field that emerged to bridge these different levels of organization.

Social neuroscience assumes that all human social behavior is implemented biologically. This does not mean that the concepts of biology can provide an adequate description or explanation of social behavior, or that “molecular” forms of representation provide the only level of analysis for understanding social behavior. Reductionism is a focus on the component parts of a whole to understand these parts and how they function together, but reductionism should not be conflated with substitutionism. Reductionism is one of various approaches to better science based on the value of data derived from distinct levels of analysis to constrain and inspire the interpretation of data derived from others levels of analysis. Emergent social structures and molar constructs, in turn, provide a means of understanding highly complex activity without needing to specify each individual action by its simplest components, thereby providing an efficient approach to describing complex systems. By analogy, chemists who work with the periodic table on a daily basis use recipes rather than the periodic table to cook, not because a particular food preparation cannot be coded by complex

chemical expressions. However, efficiency of expression is not the only issue: The concepts defining fine cuisine are not part of the discipline of chemistry. The theoretical terms of the behavioral and social sciences are similarly valuable in relation to those of biology, but can be informed and refined through integration with theories and methods from the neurosciences.

Research in social neuroscience has grown dramatically since the term was introduced in 1992. The most active areas of research in social neuroscience include brain-imaging studies in normal children and adults, animal models of social behavior, studies of patients with brain lesions (e.g., stroke patients), imaging studies of psychiatric patients, and research on social determinants of peripheral neural, neuroendocrine, and immunological processes. These areas of research have important implications for a wide range of issues in human relationships that are only beginning to be investigated.

SOCIAL PENETRATION THEORY

What happens as individuals move through the different stages of a personal relationship—from being strangers, to acquaintances, to close friends, or, perhaps, to romantic partners? Social penetration theory, developed by Irwin Altman and Dalmas Taylor in 1973, provides a theoretical framework for understanding the thoughts, feelings, and behaviors of two people as they establish a close relationship. This entry summarizes the behavioral and subjective processes that occur in the development of a close relationship according to social penetration theory.

Social Penetration Processes in Relationship Development

Social penetration theory predicts that partners become more open with one another verbally (e.g., self-disclosure of thoughts and feelings), nonverbally (e.g., smiling, direct eye contact), and environmentally (e.g., moving chairs in order to be closer) as a relationship develops. In particular, social penetration theory has influenced research on self-disclosure during the different stages of a relationship. The theory assumes that people gradually reveal more personal information about themselves as a relationship progresses, allowing partners to assess how rewarding it is to interact together and to forecast the likely success of a closer relationship.

Self-Disclosure and Relationship Development

What exactly are the changes in self-disclosure as partners become more open with one another as their relationship develops? Social penetration theory assumes that the personality of the person making a disclosure is composed of numerous “items” (including facts, opinions, values, and emotions). These characteristics of personality are organized into a series of concentric circles (akin to the structure of an onion), reflecting layers of the personality. Self-disclosure is expected to increase in breadth and depth as a relationship progresses. *Breadth category* refers to the number of topic areas (e.g., family, religion, sex, hobbies) about the self that an individual talks about with another person. *Breadth*

frequency refers to the number of items within a topic area (e.g., views about having children; growing-up experiences with parents, grandparents, and siblings) that someone might talk about, whereas *depth* refers to the level of intimacy of information about the self that might be disclosed. Greater depth of disclosure is associated with disclosing about inner layers of personality, reflecting central, emotionally sensitive, and potentially vulnerable information about the self (e.g., fears, values, and closely held beliefs). Finally, *breadth time* refers to the amount of time spent talking about various topic areas to the other person.

Wedge-Shaped Model of Disclosure and Social Penetration

Changes in the breadth and depth of self-disclosure can be represented as a series of wedges penetrating into one’s personality. At each stage of a relationship, breadth of disclosure (i.e., how much information is revealed about the self) is expected to be greater in outer than in inner layers of personality. But as a relationship develops, these wedges widen and deepen as individuals reveal more information about themselves to the partner and at a deeper level of intimacy.

Several features of this wedge-shaped model of social penetration should be noted. First, people are expected to move only gradually from superficial to more intimate areas of disclosure as a relationship develops. People may not want to plunge too quickly into intimate exchanges (i.e., disclosing about highly personal and vulnerable information about the self early rather than later in a relationship’s development) because the potential costs of rejection and being hurt are much greater at more intimate levels of exchange. People will gradually increase the disclosure of more intimate information to another person based on their subjective assessment that outcomes (rewards vs. costs) have been favorable in earlier interactions and based on a forecast that rewards are likely to be greater than costs in more intimate interactions.

Second, people are expected to continue disclosing as well as to expand the breadth of disclosure at levels of intimacy that already have been attained. For instance, self-disclosure in a developing relationship may be a blend of talking about the old and the new at a particular level of intimacy: continuing to exchange information about

previously discussed topics (where favorable outcomes are known to occur), but also expanding disclosure to related topics that might be at the same level of intimacy. Social penetration theory predicts that the exchange of self-disclosure continues at already achieved levels of intimacy because of the certainty of rewards at these levels of intimacy. Self-disclosure (including an assessment of the other's reactions to the disclosure input) also continues at these previously accessed levels of intimacy to improve the accuracy of the mental picture of the other person. This information is used, in turn, by a "central memory reservoir" to infer whether it is worthwhile interacting with the other person in more intimate areas, as well as to decide whether developing a relationship with this person compares favorably (in terms of reward/cost outcomes) with starting a new relationship with someone else.

A third major feature of the social penetration process is that self-disclosure (and social interactions generally) may occur in *any* area that has been previously accessed. Partners in a relationship are open and flexible in exchanging information that has been associated with positive outcomes. Conversely, self-disclosure about certain topics may be taboo because the information is perceived as "too private" to disclose or as a potential source of conflict and/or negative outcomes in interactions with the other person. Social penetration theory is often associated with the notion that relationships develop unidirectionally and cumulatively as individuals reveal more and more information about themselves to their partner. But this "ever-increasing" openness is qualified by an individual's decisions to revisit previously explored areas of self as well as to restrict and perhaps deny access about certain areas of self to the other person.

Social penetration theory acknowledges that there are other possible models besides the wedge shape to describe changes in openness as a relationship develops. For instance, akin to a summer romance where partners sweep one another off their feet quickly, partners might accelerate depth of disclosure in just a few areas as they get to know one another. But this pattern of relationship development, according to social penetration theory, is atypical. People are expected to be cautious in exchanging information about central layers of self. They are unsure about the likelihood of reward/cost

outcomes at more intimate levels of interactions without more information about what it is like to interact with the other person at less intimate levels of interactions. People may be cautious about developing a relationship too rapidly to avoid unanticipated costs (e.g., losing the other's respect, being rejected as a relationship partner) associated with disclosure about central areas of self.

Unresolved Conflict and Reversal of the Social Penetration Process

What happens to a relationship when there is disagreement and maybe irresolvable conflict? First, there should be considerable conversation surrounding the conflict issues and/or disagreement. But if the conflict is not settled, then a reversal in the social penetration process (i.e., depenetration) is predicted as interactions decrease in breadth and depth of disclosure. Interactions may regress to more superficial levels to reduce conflict and to minimize costs that are incurred at more intimate levels of communication. The depenetration process is generally expected to be gradual in responding to an unresolved conflict, but it may occur rapidly if the conflict is associated with sensitive areas of personality.

Contributions of Social Penetration Theory

Social penetration theory has made several contributions to the field of personal relationships. Social penetration theory provided the first systematic framework to describe the multiple behaviors associated with the development of a close relationship. Although this entry focused on changes in verbal behavior (especially self-disclosure) that occur as a close relationship develops, social penetration theory and research have examined how people become more open on a range of interpersonal behaviors in a developing relationship, including how they communicate, how they share joint activities, how they show mutual consideration, and how they display affection toward one another. Altman and Taylor also pioneered in conducting longitudinal research among college roommates and U.S. Navy personnel on changes in self-disclosure and social penetration in the development of a close relationship.

More recently, researchers have used social penetration theory as a conceptual and empirical framework for studying changes in openness in the development of online relationships. Although social penetration theory predicts that relationship development is associated with a gradual increase in openness about the self, it has also stimulated the construction of privacy and dialectical theories of communications by its emphasis on the spiraling or cycling nature of disclosure (as relationship partners revisit previously explored areas of social exchange), as well as the idea that certain areas of personality may be closed off to disclosure. Although changes in self-disclosure may be linked to the progression of a close relationship, social penetration also anticipated transactional theories of relationship intimacy by the suggestion that it is the reaction of the disclosure recipient, not the disclosure, that influences the experience of rewards and costs in a social interaction and, in turn, whether a relationship will develop.

SOCIAL RELATIONS MODEL

David Kenny's Social Relations Model (SRM) allows researchers to study patterns in the thoughts, feelings, and behavior of individuals across relationships, as well as to examine the uniqueness of each relationship. Additionally, the model addresses the most important statistical challenge for relationships research that involves dyadic data—data collected from more than one person in a relationship. Specifically, the model accounts for nonindependence, the situation in which responses from persons in a relationship are related to each other. For example, a husband's marital satisfaction is likely related to or influenced by his wife's satisfaction. Nonindependence is more than a statistical nuisance because relationship research is often explicitly concerned with the degree of nonindependence between individuals and the processes that explain nonindependence, how one person's thoughts, feelings, and behavior influence another person. Designed explicitly for the analysis of dyadic data, the SRM offers researchers an important tool to understand relationships. This entry reviews the SRM and illustrates its application to different relationships, including friendships and families.

Although the SRM applies to dyadic data, the analysis requires information from groups of at least four individuals. Thus, the model is most easily applied to the study of work groups, friendship groups, and families. The most commonly used group design is a round robin. Consider a study of self-disclosure among a group of mutual friends. In a round-robin design, each person would rate how

much he or she discloses to each other friend. Similarly, if actual self-disclosure is measured, each person would interact one on one with each friend, and the disclosures of each person in every interaction would be recorded.

The SRM proposes that any dyadic measure (one person's report about or behavior toward another person) may reflect three important effects: actor, partner, and relationship. To illustrate, imagine that Mike reports trusting his friend Susan. Mike is the actor and Susan is the partner. The actor effect measures the degree to which Mike generally trusts or distrusts his friends. The partner effect assesses whether all of Susan's friends tend to trust or distrust her. Finally, the relationship effect indicates whether Mike especially trusts Susan beyond his general tendency to trust and the tendency for others to trust Susan. The presence of actor effects indicates individual differences in the tendency to be trusting, whereas partner effects point to something about the target person that elicits trust from others. The relationship effect reflects either the unique combination of two persons or a relationship property that emerges over time. These effects are interpreted in a similar manner for actual behavior. For example, consider the tendency of individuals to compliment friends while doing a cooperative decision-making task. An actor effect indicates that some individuals tend to compliment everyone, whereas others are less complimentary. A partner effect would demonstrate that some individuals are complimented more than others. The presence of a relationship effect would indicate that compliments are particularly prevalent in some friendships and less prevalent in others.

Recently, the SRM has been applied to families. In a family analysis, each family role (e.g., mother) has an actor and a partner effect. Relationship effects refer to the particular role combinations. For example, consider a study that examines criticism in families consisting of a mother, a father, and a daughter. The actor effect for mothers would indicate whether mothers tend to criticize all family members to a similar degree. The father partner effect would reveal whether fathers tend to be criticized to a similar degree by both mothers and daughters. The mother-father relationship effect would show whether criticism is especially pronounced in that particular relationship.

Although the presence or absence of actor, partner, and relationship effects may address important questions about relationships, the SRM is particularly helpful in understanding phenomena such as reciprocity. If Susan likes Mike, does Mike like Susan? With an SRM analysis, reciprocity can be examined at the individual and relationship levels. Reciprocity exists at the individual level if Mike generally likes others (actor effect) and others generally like Mike (partner effect). At the relationship level, reciprocity would exist if Susan especially likes Mike and Mike especially likes Mike.

Additionally, to understand the determinants of each effect, researchers can assess aspects of the individuals or relationships such as the individuals' personalities. For example, if everyone tends to think Joe is extroverted (Joe's partner effect), is Joe actually extroverted measured with a personality test? Similarly, researchers can assess whether a person's personality is related to how he or she is generally viewed by others and generally views others. For example, is an individual with high self-esteem generally trusted by others and does he or she generally trust others?

Much of the research using the SRM has examined personality judgments among unacquainted individuals. Do individuals agree in their perceptions of the same person and are those perceptions accurate? This research has shown remarkable levels of accuracy at least for some judgments. Research on acquainted individuals and friendship groups has focused on whether increased acquaintance improves accuracy, revealing some improvements in agreement and accuracy. Research on well-acquainted individuals also examines other aspects of relationships, including liking and self-disclosure. Not surprisingly, both liking and self-disclosure among acquainted individuals are characterized by strong relationship effects and somewhat weaker actor effects. Thus, some individuals tend to disclose to all their friends and others disclose relatively little, but the amount of disclosure still varies considerably depending on the particular friendship. Several studies have been conducted with family data, but clearly there is a need for more research in this area.

Results of recent SRM studies of friendship groups, families, and important relationship phenomena, such as self-disclosure, suggest that the

model has considerable promise as a tool for understanding relationships.

SOCIAL SKILLS, ADULTS

Adult social skills (also referred to as *interpersonal skills* or *interpersonal* or *social competence*) consist of a wide range of interpersonal abilities and competencies that help people function effectively in social situations. Social skills are particularly important in the initiation, formation, and maintenance of adult interpersonal relationships. Rather than being a clearly defined area of research on human relationships, research on adult social skills is progressing in many disciplines and subdisciplines on a variety of fronts. Scholars in clinical psychology, communication, social/personality psychology, and human development have all contributed to what we know about adult social skills. Moreover, the complexity and variety of adult social skills is enormous. This entry explores how and where adult social skills have been investigated in the social science literature, reviews models for understanding and measuring adult social skills, and discusses their implications for effective human relationships.

Social Skills in Adult Clinical Work

Research on adult social skills has its roots in clinical psychology as a means of helping hospitalized and discharged patients, as well as participants in a variety of outpatient programs, develop interpersonal skills to help them cope with problems stemming from family and other interpersonal conflicts. Social skills training typically consists of providing strategies for initiating and maintaining conversations, resolving interpersonal conflicts, avoiding inappropriate statements or nonverbal behavior, and understanding and adhering to appropriate social rules and conventions. Social skill training uses a variety of methods, ranging from simple instruction to role-playing, to homework assignments that have participants use their newly developed skills in actual social settings. Using a behavioral approach, social skills training typically relies on behavior modeling, live and video-recorded feedback, and rehearsal of effective social behaviors in simulated (and sometimes actual) social settings. Some research has demonstrated that social skills training is superior to traditional psychotherapy in effecting positive outcomes with certain clinical populations, particularly those suffering from chronic social anxiety or difficulty coping with social relationships. Social skills training has been a component of a number of psychological interventions, including conflict management training, anger management, family and marital therapy, assertiveness training, and in programs to treat severe shyness and social anxiety.

Perhaps the most impressive and well-organized social skills training program has been the work of John Gottman and his colleagues on marital relationships. In Gottman's program, couples are taught to recognize problematic aspects of their marital communication (e.g., criticizing, displaying anger and defensiveness, etc.); they are then taught appropriate social skills to deal with marital disagreements and conflict, such as learning how to tactfully discuss a conflict, avoiding negativity in interactions, and the like. These skills consist of both learning appropriate verbal interchanges and dealing with the nonverbal and emotional aspects of marital conflict.

Social Skills, Social Intelligence, and Social and Communicative Competence

In the early 20th century, psychologists studying intelligence proposed that, in addition to academic intelligence (i.e., the construct of Intelligence Quotient [IQ]), there existed another form of “everyday” intelligence: social intelligence. The domain of social intelligence consists of knowledge of appropriate behavior in common social interactions; the ability to understand others’ communications, intentions, and emotions; and knowing how to act wisely and tactfully in social encounters. Unfortunately, this line of research was nearly abandoned because of the complex variety of social abilities that composed social intelligence and difficulty distinguishing social intelligence from academic intelligence. Instead, scholars began investigating these constructs with research that examined various social skills, abilities, or competencies, usually without an organizing theoretical framework.

For example, social/personality psychologist Mark Snyder proposed a construct that he labeled *self-monitoring*, which is the ability to monitor and control one’s social behavior in order to manage impressions and behave appropriately. Although representing only specific aspects of the broad domain of social skills/competence, self-monitoring has been used by some scholars as a substitute for social competence.

Similarly, communication scholars have focused on *communicative competence* as a theoretical construct to capture abilities to exchange information in social situations and in the context of interpersonal relationships. Often communicative competence is broken down into a number of sub-components, such as effective listening behavior, abilities to plan and execute communication in social settings, adapting to social or cultural conventions, and regulating the flow of communication, and these are examined individually or in combination in research. In addition, there are certain skills that are less focused on building social relationships and more instrumental in nature, such as persuasion skills, arguing/debating, public or informal speaking ability, and skills in providing emotional support and comfort. Other communication scholars view communicative competence as a more global construct, similar to

social competence/intelligence, and examine how it impacts social behavior and outcomes.

Nonverbal and Emotional Skills

Another line of research has focused on nonverbal and emotional communication skills as a specific subset of more general social skills/competence. Specifically, research has examined people’s abilities to identify or “decode” nonverbal cues, such as facial expressions of emotion, gestures, or tone of voice. A parallel line examines individual differences in the ability to send or “encode” nonverbal messages accurately and appropriately. This is related to the concept of empathic accuracy—the ability to understand what another person is feeling or thinking. Finally, some scholars have studied ability to regulate and control the expression of emotional messages or other nonverbal cues, abilities that are important when a person is trying to cover up nervousness in social situations or anxiety and guilt when lying.

Nonverbal skills associated with emotional communication, particularly abilities to decode emotional messages and regulate one’s felt emotional states, have been included as components of the new and quite popular concept of *emotional intelligence*. In addition to nonverbal/emotional communication skills, emotional intelligence also includes knowledge about how emotions are involved in social interactions and human relationships, awareness of one’s own emotional states, and ability to regulate those states.

One model that is aligned with both the communication perspective and research on nonverbal and emotional skills focuses on the core, basic skills involved in interpersonal communication. According to this framework proposed by Ronald Riggio, social skills are broken down into three types: skills in encoding or expressing messages; skills in decoding, referred to as sensitivity to others’ messages; and skill in regulating or controlling communication. These three skills—expressiveness, sensitivity, and control—operate in both the emotional and the social/verbal domains, leading to six basic social skills: emotional expressiveness, emotional sensitivity, emotional control, social expressiveness, social sensitivity, and social control. Although the emotional skills include abilities to

send, receive, and regulate the display of nonverbal and emotional messages, social expressiveness is a verbal speaking skill and the ability to engage others in conversation, social sensitivity is the ability to decode and understand the elements of social situations, and social control is sophisticated social role-playing skill, somewhat similar to self-monitoring. Research has demonstrated that well-developed social skills, such as emotional expressiveness, emotional sensitivity, social control, and self-monitoring, are predictive of the quality of social relationships and the effectiveness in a variety of social situations, and are predictive of the ability to play complex social roles, such as formal leadership positions and ability as a public speaker.

Measurement of Adult Social Skills

In clinical settings, adult social skills are most commonly measured through observational coding of behavior or by having trained evaluators rate the possession or absence of particular types of social skills (or make an overall rating of social competence). Observational coding is used, for example, in Gottman's work on marital communication, where couples are allowed to interact with each other, and specific behaviors are used as indicators of good or poor communication processes.

In much of the research on social skills, performance-based assessments are used routinely. Individuals being assessed are asked to perform in some sort of actual or simulated social environment, and inferences are made about their possession of particular social skills based on their performance. In research on nonverbal encoding skills, individuals are asked to enact specific emotional expressions through face or tone of voice. These expressions are then shown to judges who try to decipher which emotions are being conveyed. The percentage of judges who correctly identify the emotion communicated represents the encoder's possession of emotional encoding skill. Likewise, to assess nonverbal decoding skill, individuals are shown video-recorded emotional expressions or social scenes and are asked to interpret the expressions or scenes. Accuracy at the decoding task represents the possession of nonverbal decoding skill. A number of standardized performance-based tests of decoding skill have

been developed and are used frequently in research on nonverbal skill. Some of these tests measure ability to read basic facial expressions of emotion or from voice tone, whereas others assess skill in reading the nonverbal and verbal/social cues in actual human interactions.

Another strategy for measuring social skills is the use of self-report instruments that ask individuals to report on their own social successes, strengths, and weaknesses. Although there is some concern over whether respondents are able to report their possession of skills or will report accurately their skill in communication and in social interactions, there is good evidence that many aspects of social skill can be validly assessed through carefully constructed and validated self-report instruments. Rather than simply asking people whether they possess certain social skills, these self-report measures focus on asking respondents about social outcomes and success in social situations. For example, the Social Skills Inventory measures the six basic social skills outlined earlier in Riggio's model. Similarly, although performance-based measures of emotional intelligence are the preferred method of measuring aspects of emotional skill, there has been some limited success with self-report assessments of emotional intelligence, although performance-based assessments of social skill and emotional intelligence are preferred and likely more accurate.

Research Findings and Implications for Human Relationships

Social skills training is an extremely common component of many clinical interventions, with patients suffering from chronic shyness, social anxiety, or difficulties in family and interpersonal relationships. There is substantial research that supports its effectiveness as a therapeutic tool.

There is also general agreement that social skills are critically important in everyday social interactions, in developing and maintaining high-quality human relationships, and in good relationships in the work setting. Research on social skills in nonclinical populations suggests that possession of social skills is positively related to the size and quality of social support networks, positive initial impressions, greater social self-efficacy,

self-esteem, and even life satisfaction. There is even evidence that suggests that socially skilled persons are evaluated more positively as potential dating partners, leaders, and job applicants; holding physical beauty constant, socially skilled persons are rated as more attractive than their nonskilled peers. Possession of high levels of social skills is also negatively related to self-reported shyness, loneliness, and social anxiety.

Although common sense and research evidence suggests that social skills are important for everyday social functioning and for the quality of human relationships, there has been relatively little research on adult social skills. Part of the problem is the lack of agreed-on theoretical models for social skills and no consensus on methods for measuring social skills. Another difficulty is that the research on social skills is scattered across a number of disciplines and in different areas of focus within those disciplines, as has been outlined. The emphasis and even the language of the topic vary depending on the discipline. The construct of adult social skills goes by many names—communicative competence, social and emotional intelligence, nonverbal skill, and interpersonal skill. However, regardless of the label, social skills are critically important for effective human social functioning and for relationships.

SOCIAL SKILLS IN CHILDHOOD

The term *social skills in childhood* refers to behaviors that enable children to elicit positive responses from others and establish positive relationships with others. Normal acquisition of social skills during childhood is a critical developmental task that fosters healthy adjustment across time and life domains. Children with good social skills generally enjoy positive relationships with peers and adults, which, in turn, serve a wide range of supportive functions. In contrast, children with poorer social skills may experience social rejection or neglect, and they face higher risk for maladjustment across social and psychological domains. In this entry, childhood social skills are conceptualized as multidimensional (i.e., behavioral, cognitive, emotional, and biological systems are involved), and social skills are contextualized within developmental (i.e., age group) and social circumstances.

Integrative Conceptualization of Social Skills

To conceptualize social skills, some scholars emphasize the capacity to elicit positive responses from peers and to forge positive peer relationships (e.g., friendships), whereas others focus on the attainment of social goals (e.g., establishing a position of leadership). Positive or desired peer responses are established by enacting behaviors

that are sensitive to specific demands across diverse social settings (e.g., classroom vs. playground) and situations (e.g., dyadic vs. group interaction). However, most scholars agree that social skills involve more than possessing a particular behavioral repertoire. The social behaviors that children display in a given social situation are shaped by cognitive and emotional capacities, such as an ability to “read” social situations accurately, an understanding of effective solutions to social problems, and well-controlled experiences and expressions of emotion. Thus, social skills are dynamic and multidetermined, not simply “mechanical” behaviors that function equally well across social contexts.

Several conceptual models have been formulated to explain how children’s social behavior is influenced by the ways in which they interpret social information (e.g., the facial expressions or behaviors of others during social interactions). Children’s interpretation of social information is often referred to as social information processing. Generally, these models propose that children process social information, first, by noticing and interpreting social cues and by selecting goals for the situation; next, by generating, evaluating, and selecting potential social responses; and, finally, by enacting the chosen response. Numerous studies have provided compelling evidence that social information-processing tendencies are associated with children’s social behavior and social status. For example, a well-replicated finding is that aggressive or peer-rejected children are more likely to attribute hostile intent to others in social situations (e.g., interpret an accident as an intentional attempt to harm), compared with nonaggressive or accepted children.

Likewise, emotion is tightly intertwined with children’s social information processing and social behaviors. Children’s interpretation of social cues and their selection of social responses is associated with the valence (i.e., positive or negative) and intensity of their emotions. For example, aggressive children are more likely to attribute hostile intent to peers after negative emotions (e.g., anger, frustration) have been primed, compared with neutral emotional conditions. Furthermore, emotion can be directly related to children’s observable social behavior. For example, to invite peers to interact with them, it is important for children to

experience appropriate emotion (e.g., happiness at the prospect of interaction), send appropriate emotional messages (e.g., facial expressions such as smiling), and receive emotional messages appropriately (e.g., read the other child’s emotion to assess whether she is also inclined to interact).

Socially skilled behaviors have emotional and cognitive determinants, and the evaluation of social skills cannot be judged apart from the child’s age, cultural norms, or situation-specific demands. Moreover, the development of social skills is affected by other child characteristics (e.g., temperament or personality, which have genetic roots) and numerous environmental factors, such as opportunities to learn social skills via peer interaction, as well as experiences in the family context (e.g., parental social coaching, observations of interparental conflict) and peer context (e.g., reinforcement for prosocial behavior, victimization by peers). Although social skills have multiple determinants and involve more than behavior alone, social behaviors are the most proximal determinants of peer responses and attainment of social goals.

Socially Skilled Behaviors

The “competence correlates” approach is one method for identifying socially skilled behavioral strategies. According to this approach, social behaviors can be classified as social skills to the extent that the behaviors are empirically associated with peer liking or peer acceptance. A vast array of discrete social behaviors has been linked to positive or problematic peer relationships during childhood. Thus, the competence correlates approach focuses on general social interaction strategies with multiple behavioral exemplars (e.g., fair-play skills), rather than specific social behaviors.

Karen Bierman distilled the literature on competence correlates in childhood and identified seven social skill domains. *Social participation* involves initiating or entering ongoing peer activities or conversations, attending to and responding to peers, and displaying positive affect in the context of peer interactions. *Emotional understanding* involves recognizing one’s own feelings and expressing them appropriately, detecting the feelings of others, and responding sensitively to the

feelings of others. *Prosocial behaviors* refer to playing or interacting cooperatively in dyadic or peer-group settings and include behaviors such as helping, sharing, and taking turns. *Self-control* refers to inhibiting impulsive behaviors and instead coping with upset feelings (e.g., anxiety, anger) in a way that promotes problem solving and does not escalate conflict situations. *Communication skills* involve appropriate self-expression, listening attentively and respectfully to others, and asking and answering questions in conversation. *Fair-play skills* refer to following rules during games or play activities and winning or losing games in a graceful manner. *Social problem-solving skills* involve the abilities to identify problems, generate and evaluate solutions and plans, and negotiate and compromise when disagreements arise. These behavioral strategies can be viewed as social skills based on their empirical associations with positive dyadic (e.g., friendship) or peer-group (e.g., overall acceptance by the peer group) relationships. Despite their general effectiveness, the optimal manifestation of these behavioral strategies varies depending on age and activity context (e.g., fantasy play in early childhood, rule-based games in middle childhood, and conversations in late childhood and adolescence), as well as gender and cultural norms.

Steven Asher and colleagues proposed a complementary approach for understanding social skills. This approach outlines six core issues that help determine whether peers will be inclined to like or accept a child: (1) whether peers find the child entertaining, (2) whether peers think they can trust the child, (3) whether peers believe that the child influences them in acceptable ways, (4) whether peers find that the child facilitates their personal goals, (5) whether the child makes them feel good about themselves, and (6) whether peers feel that the child shares their values and priorities. Thus, peer interpretations of social behaviors, as well as the actions in their own right, have implications for the social skillfulness of children.

Whereas a variety of social behaviors have been linked with peer success, many other behaviors have been associated with peer disliking or rejection by peers. Exhibiting relatively low rates of these “problem” behaviors may be necessary, but not sufficient, for social skillfulness. Aggressive

behavior has received the most attention. Direct (e.g., bullying, hitting, calling names) and indirect (e.g., spreading rumors) forms of aggression have been associated with lower peer liking across age, gender, and ethnic groups, as well as across peer, teacher, and observations of peer relationships. Oppositional, annoying, or hyperactive behaviors that disrupt peer-group interactions or classroom activities are also correlates of peer dislike. Another class of social behavior linked with peer relationship problems is anxious-withdrawn behavior.

Despite the relatively robust association between these problem behaviors and peer rejection, it is increasingly evident that the overall profile of behavior is more important than any particular behavior per se. For example, aggressive behaviors that are concomitant with a broader pattern of emotionally reactive (e.g., angry) and annoying or disruptive behaviors are highly predictive of peer rejection. In contrast, peer rejection is not necessarily associated with instrumental aggression that is executed to attain specific social goals or to gain access to resources when accompanied by prosocial skills (e.g., taking a valued toy from one group of children and then sharing it with another group of children).

The acceptability of behaviors is also shaped by characteristics of the peer context or peer culture, including the age range and normativeness of the behavior in question. For example, aggressive behavior is more normative and acceptable in early childhood before children have mastered emotional and cognitive skills that allow them to inhibit impulses and solve problems verbally. Likewise, social withdrawal predicts peer rejection better during late childhood and early adolescence than during early childhood, when playing alone and object-centered activities are more common. Furthermore, research by Xinyin Chen, Kenneth Rubin, and colleagues suggests that shy or withdrawn children are less rejected and more accepted in collectivist cultural contexts, such as in China. Thus, even behaviors that are generally associated with peer relationship problems can be adaptive (or at least not maladaptive) at certain times or under certain circumstances. Social skills are best viewed as a profile of behaviors that are exhibited flexibly depending on the context, rather than as the presence or absence of discrete behaviors.

Social Skills Training

Group-based social skills training programs have been designed to remediate children's social skill deficits and, in turn, improve their peer relationships. In general, effective programs promote social skills that are empirically associated with peer liking (i.e., competence correlates), target specific skill deficits exhibited by participants, and attempt to transfer skills from the intervention setting to naturalistic settings (e.g., school, playground, neighborhood). Such programs present *skill concepts* through verbal instruction or modeling, provide multiple *skill practice opportunities* for children in both structured settings (e.g., role-play with group leaders or group members) and more naturalistic settings (e.g., activities involving peers without social skill deficits), and provide *reinforcement and corrective feedback* on the basis of children's performance during practice sessions. Social skills training programs have made significant progress toward meeting several key challenges, such as generalizing skills to the naturalistic peer context, establishing skill improvements and increases in peer acceptance, and promoting sustained improvements over time.

SOCIAL SUPPORT, NATURE OF

Social support is a term that is understood by most people, but what is meant by it? Often it means that others understand a person's feelings or that someone seems caring or encouraging in times of trouble. Sometimes people use the term to refer to help with tasks when overburdened at home or work. Occasionally, what is meant is just being present and spending time together. Research definitions match these lay conceptions pretty well. Furthermore, the forgoing indicates clearly that social support is not one thing, but many things. In other words, it is multifaceted. How do we untangle the multiple facets or aspects of this complex concept? Luckily, research for more than 25 years has given us some ideas.

Perceived and Enacted Support

Two primary conceptions of social support exist. *Perceived support* refers to an individual's perception that social support is available if needed. Individuals high in perceived support believe that there are people in their social network on whom they can depend to provide various kinds of resources in times of need. Perceived support is associated with many different health benefits, including longer life, lower likelihood of disease, and better mental health and well-being (see Social Support and Health). This form of support is fairly stable or unchanging and is related to other characteristics of individuals. For example, people who perceive that

they have a lot of support available are also more likely to have high self-esteem; be optimistic, extroverted and socially competent; and be secure in their attachment to important figures in their life. Perceived support can be measured reliably with several questionnaires such as the Social Support Questionnaire (SSQ), the Interpersonal Support Evaluation List (ISEL), or the Social Provisions Scale (SPS). Questions might ask whether there is anyone available to provide caring and comfort, to provide advice, or to provide assistance if needed.

In contrast, *enacted support* refers to actual social exchanges or interactions in which one person behaves in a manner meant to meet another's needs. Enacted support (also known as received support) is experienced as specific acts of caring, assistance, and guidance. Intuitively, it seems that perceived and enacted support should be closely related, but research has demonstrated otherwise. For example, in stigmatizing circumstances such as HIV or following a sexual assault, expected support is not always forthcoming. Although perceived support has been consistently linked with positive mental and physical outcomes, enacted support has not always appeared to be beneficial. This is most likely a result of the fact that support exchanges usually coincide with ongoing stressors, which makes it difficult to disentangle the benefits of enacted support from the adverse effects of stressors on adjustment. In addition, the mere attempt to provide social support does not guarantee that it will be effective.

Some theorists argue that the type of support provided must match the needs of the recipient to be beneficial. Evidence is largely supportive of this intuitively attractive "matching hypothesis," but it is difficult to test because it calls for a detailed analysis of support needs and provisions over time, which is rarely done. In addition, matching the type of social support to needs does not capture the quality of support. For example, a family member may provide advice when needed, but do so in a controlling, critical, or domineering manner.

To assess whether enacted support meets a recipient's needs and the quality of it, Chris Rini and Chris Dunkel Schetter developed the Social Support Effectiveness (SSE) interview to assess the effectiveness of enacted support. In a sample of pregnant women who were interviewed in depth about their supportive interactions with a partner

or spouse, SSE was shown to be multidimensional and reliably assessed, and higher SSE scores were associated with reduced anxiety in mid-pregnancy and over the course of pregnancy. The SSE is now being used in further research, such as studies with bone marrow transplant patients, and has applicability to other contexts.

Types of Support

Similar to lay definitions, scientific definitions of social support include different functions or types such as *emotional*, *instrumental*, and *informational* resources. *Emotional support* refers to acts such as listening, providing empathy and understanding, and showing affection. The simplest of all forms of support is *instrumental support* (also known as tangible support), which refers to the provision of material resources or task assistance. For example, an individual might receive instrumental support in the form of a loan or help in moving residences. Finally, *informational support* refers to information, guidance, or advice as a form of support in problem solving. Advice is difficult to give because it is frequently considered unhelpful by recipients, yet sometimes this type of support can be quite effective.

In addition to these three core types, researchers have studied other specific types of support. *Appraisal support* (also known as *esteem support*) is defined as the provision of information that one is worthy and valued. Such affirmation is closely related to emotional support and is often subsumed into the same category. It may also be considered as a form of validation. In addition, belonging and companionship have been viewed as separate types of support. *Companionship* includes both the mere presence of others and engaging in activities with others, such as seeing a movie when someone needs relaxation or distraction from a problem. *Belonging* involves the support experienced when someone is a member of a group that provides an identity and perhaps other resources.

Normal Adaptation Versus Adjustment to Stress

A further wrinkle in understanding the nature of support is distinguishing the everyday presence of

support from the extra support received when something unusually stressful occurs. Perceived support is fairly constant for those who are fortunate enough to possess it. It tends to be relatively unchanging regardless of whether a crisis is occurring. Perceived support can be thought of as adaptive beliefs that function to protect people in numerous ways, not only in times of stress. Their stability is what has led some theorists such as Barbara and Irwin Sarason to refer to perceived support as more of a personality characteristic. It has also been conceptualized as cognitive structures or mental working models, sometimes called support schemas. Such schemas shape people's views of the world and everyday experiences. In contrast, enacted support is transactional and is therefore much more dynamic or fluctuating. It is most commonly observed in the context of stress, whether minor or cataclysmic. Because there are many forms of stress, there are many examples of enacted support that may be experienced or observed. For example, a parent might provide emotional support by hugging a child when he or she is upset, or a friend might provide instrumental support by cooking meals following the death of a family member.

In 1987, the UCLA Social Support Interview (SSI) was developed to study the complexities of enacted support. This questionnaire measures support of three types from each of three sources (e.g., partner, friend, professional) and, within these, the need for support, the quantity and quality of support received, and various negative aspects of interactions. It serves as a subjective and multidimensional view of a person's support exchanges over a specific time period (e.g., 3 months), and the questions can be adapted for specific research needs. The UCLA SSI has been used in research on HIV, heart disease, cancer, and many other stressful diseases. Other assessments of enacted support, such as the Inventory of Socially Supportive Behaviors, are available, but they typically do not distinguish sources of support.

Who Provides Support Matters

Individuals may receive support from any number of sources—friends, parents, romantic partners, extended family, siblings, colleagues, neighbors, or

acquaintances—and who provides support is an important determinant of its effectiveness. Certain people are most likely to be called on to provide specific types of support. For example, married couples tend to rely on spouses for support, and spousal support is especially beneficial, whereas its absence can be especially detrimental. In general, people tend to seek and receive many types of support from their closest relationships. Not surprisingly, however, they do not report *receiving* equal amounts of support from all relationships. Although social support varies from person to person, particular relationships, such as one's mother or spouse, may provide the most support over a person's lifetime. In short, the provider of support matters a great deal in many ways. Intriguing is the finding that giving support is beneficial to the provider as well as the recipient.

What should be sought from whom? This question has not yet been well addressed by research, but some findings suggest that experts or professionals are the best sources of advice or guidance. Skillful listeners and empathic people are probably the best sources of emotional support. Friends are often sources of companionship, and parents can be excellent sources of affirmation. Yet this is clearly a bit simplistic because myriad other factors matter too, including the support provider's personality, support capability (such as interpersonal skills and available time), and the nature of the relationship between provider and recipient (e.g., extent of trust and degree of interdependence). These and other factors contribute to who would be the best person to rely on for support in a given situation. If people operated as highly skilled seekers of support, they would tend to express feelings to others who listen attentively and keep confidences, to seek advice from those who are good problem solvers, and to ask for assistance with tasks from those who have the necessary skills and resources to help and no tendency to create feelings of indebtedness. However, research has not delved into support seeking this much nor have support interventions tried to teach support seeking skills or selectivity as yet.

Clearly, social support is intricately embedded in our interpersonal relationships, and the quality of those relationships influences from whom support is sought and received, as well as how we feel about it afterward. Although the earliest social support

researchers did not take into account a relationships perspective, recent work has emphasized the importance of understanding close relationships as the context in which social support occurs. As relationship science has progressed, research on social support has been progressing also. For example, Nancy Collins and Brooke Feeney have extended our understanding of enacted support by showing that anxious or secure attachment styles predict perceptions of support in couples and, further, that the quality of the relationship and of the couple's interactions have implications for physiology and health. Findings on intimacy and relationship satisfaction are among other areas where there has also been progress in linking relationship processes to understanding social support.

Relationships as Double-Edged Swords

Just as interpersonal and close relationships are not uniformly supportive, neither is all support beneficial or positive. Supportive transactions are not always perceived by the recipient as helpful. Some researchers have characterized close relationships as "double-edged swords" to refer to the fact that relationships can be both helpful and harmful. Paradoxically, the people who are one's strongest allies can be the strongest sources of stress and aggravation. Social support research has shown that people may be disappointed in the support received from others, which may not meet our expectations in strength, consistency, or quality. In addition, if support is not enacted skillfully, it may make us feel indebted, stupid, or unworthy. Support attempts may be selfishly motivated, intrusive, or controlling. If excessive, support can create feelings of anger, a loss of autonomy, and unhealthy dependency. Finally, as Karen Rook and others have clarified, the negative aspects of interactions such as social conflict can reduce the benefits of social support for health and well-being.

Niall Bolger's research suggests that support is most beneficial when it occurs outside the recipient's awareness or is delivered with such subtlety that it is not even noticed or perceived as social support. These invisible support acts are thought to be effective because they allow the recipient to enjoy the benefits of support without the emotional costs and threats to self-esteem (e.g., feelings of

dependence or indebtedness) that highly visible support acts can endanger. Thus, in examining the nature of social support, it is imperative to consider a complete picture of close relationships, incorporating both negative as well as positive aspects.

Gender, Ethnicity, and Culture Within Support Processes

Gender, ethnicity, and culture are other interesting determinants of the nature of support. Women and men differ in how often and how skillfully they provide support and in how beneficial it is. In the words of one scientist, "Women make the potato salad and men eat it," referring to findings that women more often provide support and men benefit more. Possible genetic, neural, and biological bases for gender differences are now garnering a lot of attention. For example, the role of oxytocin in predisposing women to be more affiliative and caregiving—to *tend and befriend*, a term used by Shelley Taylor—is under investigation. Changes in gender roles and their implications for support is another topic of interest. One review suggests that women and men may differ not so much in the ability to provide support, but in responsiveness to a partner's support needs, with women being more responsive than men.

Interesting cultural differences are also emerging in how people perceive, seek, provide, and receive support. For example, some cultures emphasize independence and individual problem solving, some emphasize reliance on the social group in times of need, and still others appear to discourage support seeking, but not necessarily the acceptance of support when offered. Furthermore, cultures differ in the behaviors seen as supportive and the ways they should be enacted. Providing assistance in tasks of everyday life to someone who is struggling is an insult in some places in the world, whereas not providing assistance is an insult in others. Also, cultures differ in who should be relied on for support. For example, in Asian cultures, families feel that it is inappropriate to talk to people outside one's family about problems because family problems are considered to be private. It has been suggested by Taylor and colleagues that group-level perceptions of support, referred to as

implicit support, are helpful in Asian cultures, whereas individual-level enactments of support, called explicit support, are helpful to European-Americans. Much is left to do to understand the interplay of gender, ethnic, and cultural differences in the nature of support. With time the field may have a better understanding of universal patterns of support as well as their cultural variations.

In summary, although it may seem simple at first glance, the nature of social support turns out to be a multifaceted and complex topic. Two primary aspects are *perceived support* and *enacted support*. Orthogonal to this are three core functional types of support: (1) emotional support, (2) informational support, and (3) instrumental support. Other types have also been delineated, such as affirmation, companionship, and belonging. The nature of support may differ in various ways depending on whether it is normatively occurring in the absence of a major stressor or occurring as a result of an identifiable stressor. Furthermore, the person who is providing the support matters very much. Some providers are more able to meet specific needs than others due to skills and resources. Beyond this, support is embedded in our interpersonal relationships, and the study of them enhances our understanding of support greatly. For example, research on attachment style, intimacy, and interdependence has already led to advances in our understanding of the nature of social support. Relationships are not only sources of support, however. They also contribute to social conflict, overdependence, and feelings of indebtedness and unworthiness. These negative aspects of close relationships both influence the effects of support on health and well-being and enhance a broader understanding of our supportive relationships. Finally, gender, ethnicity, and culture are important factors contributing to understanding the nature of social support. Although this is a relatively seasoned area of research, there is much left to discover. As a result, the study of the nature of social support is alive and well.

SOCIAL SUPPORT AND HEALTH

Social support is a variable based on the concept that resources provided through social relationships can enhance psychological adjustment and assist coping with problems. This entry discusses the relation of social support to physical and mental health. This topic is relevant to human relationships because research has shown that persons with higher support have lower rates of illness, and theory on how social support operates to reduce risk for illness involves concepts from research on human relationships and health psychology. In this entry, we discuss the conceptualization of social support, summarize evidence on the relation of social support to health outcomes, and outline possible mechanisms for the protective effect of social relationships. In addition, we highlight concepts from relationships research that may be useful for understanding social support processes.

Conceptualizing Social Support

There have been two approaches to conceptualizing and measuring social support in health outcome research. One approach examines how many persons an individual knows and/or considers as friends (i.e., the size of his or her social network). This measure of network size is often termed *social integration* because these structured relationships reflect the degree of a person's integration in the community. Other aspects of network structure include the existence of particular social roles (e.g., marriage, children, member of a community organization), the proportion of network members who know each other, and an individual's participation in regular activities with other persons.

Another approach involves determining the extent to which a person's relationships (irrespective of number) provide particular supportive functions. Typical questions ask whether a person would have a particular function available if needed. One function measured in many studies is emotional support—the perception that an individual has persons available who can provide confiding, sympathy, and understanding in times of trouble. Other functions include instrumental support, defined as providing tangible goods (e.g., providing tools, loaning money) or services (e.g., transportation, child care) when needed, and informational support, defined as providing useful advice and guidance. Data show that network size is not highly correlated with availability of supportive functions; a large social network may provide relatively little emotional and instrumental support, whereas a few relationships may provide a great deal of these. Hence, these two aspects of social relationships are measured separately.

Social Support and Health

In typical studies of mortality, social relationships are measured at one point in time in a large sample; researchers then determine whether each person is living at a subsequent time point, typically 5 to 10 years later. Results have shown that persons with larger social networks are less likely to die over the study period. This protective effect has been observed in more than 80 studies, conducted with samples including different ethnic groups and national populations, and has been found for mortality from several diseases, including heart disease and cancer. The effect of social integration on mortality is found with statistical control for a number of variables, including gender, socioeconomic status, and initial health, so this effect is not just attributable to certain types of persons (e.g., males, poor people) having larger or smaller networks. Some data have suggested that women may derive more benefit from close relationships that involve confiding and intimacy, whereas men derive more benefit from a looser network of worksite and community alliances (e.g., work mates, sports and outdoor activities, voluntary organizations). However, significant effects for social integration

and social support have been observed across groups, and overall the similarities are more striking than the differences.

With regard to other outcomes, longitudinal studies with samples of persons showing early symptoms of disease have linked social support to disease progression for several conditions. For example, higher emotional support is related to lesser progression of coronary artery disease among persons with some initial level of arterial occlusion. Social support is also related to recovery from serious illness. In such studies, persons who have suffered a major disease episode (e.g., heart attack) are identified shortly after the occurrence and are then followed over time. Results have shown that persons with larger networks or higher levels of functional support have longer survival times and fewer new disease episodes. For example, heart attack patients who have high emotional support are less likely to have a subsequent heart attack, compared with those with low support, and these findings are independent of demographic characteristics and initial severity of disease. In addition, support from others may enhance quality of life among persons with illness. Emotional support helps to maintain feelings of physical attractiveness and self-esteem, whereas instrumental support helps to increase mobility and feelings of control.

Some research has focused on the role of social support for reducing the impact of acute negative life events or chronic strains such as job pressure. This is termed a *stress-buffering effect* because support serves to buffer (protect) the individual against stressors that could present risk for disease. For example, studies of job-related stress have shown that men with high stress and high support have lower rates of mortality, compared with those with high stress and low support. Such findings have been demonstrated for measures of both social network size and availability of supportive functions, including emotional and instrumental support. Stress-buffering effects of social support have been found with various outcomes, including depression/anxiety, substance use, and physical health indices.

Several mechanisms have been suggested for the health-protective effect of social support. Persons with larger networks or more functional support are less likely to smoke cigarettes or engage in heavy use of alcohol; hence, a behavioral mechanism is

implicated because social support influences these health-related behaviors. Other studies have shown that persons with higher support show smaller increases in blood pressure under stress and have more healthful blood levels of biological markers for heart disease (e.g., clotting factors and inflammatory markers), so a direct biological mechanism has been suggested. Affect states associated with social relationships have been linked to measures of the functioning of the immune system, which protects persons from infectious bacteria and conducts surveillance for cancerous cells; supportive relationships are related to higher positive affect and better immune-system function, whereas conflict in relationships is related to worse immune-system functioning. In addition, studies indicate that persons with higher support tend to show better adherence to medical treatment programs. No single mechanism totally accounts for the health-protective effect of social support, and it may be that all mechanisms contribute to some extent, possibly under different conditions.

Social Support and Human Relationships Research

Findings on social support and health raise several questions for human relationships research. One issue concerns the question of how social networks and functional support can both be related to health. Research on mortality is clear in showing that having a larger number of established social connections is protective. These connections are by definition fairly stable, and the implication is that their protective effect derives in part from personal feelings of stability and the kind of self-esteem that derives from feeling that one is a valued member of a larger community. Social networks have also been shown to serve as agents of social control through communicating reminders about obligations to others (e.g., not smoking in order to protect family members). At the same time, emotional and instrumental support are activated in times of stress and help to reduce the impact of negative events, serving a protective role in this way. However, the availability of supportive functions is not strongly correlated with the size of one's network. Both aspects of social relationships (i.e., structure and function)

have been shown to be protective, so the implication is that different mechanisms are involved: one relying on stability and permanence of relationships, the other relying on the ability of spouses, friends, and relatives to be responsive in times of stress and to facilitate optimism, coping, and problem solving in response to challenges.

Another issue concerns the concepts of support and strain in relationships. Every relationship (e.g., parent and child, husband and wife, supervisor and worker) contains elements of supportiveness together with elements of conflict (e.g., arguments and disagreements). The latter elements have been termed *negative support* or *social strain*. Research has shown that supportive aspects of relationships are health-protective, but social strain can be detrimental to health. Although data show that people tend to perceive their primary relationships as relatively supportive, the existence of strain in relationships (e.g., marital conflict, job dissatisfaction) cannot be ignored, and the balance (or ratio) of support and strain should be considered for prediction of psychological well-being.

A special case of strain derives from the context of long-term caregiving, where one individual has primary responsibility for caring for a chronically ill person. In this context, the rewards of giving support to a close friend or relative may be offset by the burden of providing continual care to a person who may not be socially responsive (e.g., someone with Alzheimer's disease). Research has suggested that caregivers are at risk for health problems if the recipient is disabled and not actively helping with caregiving. Thus, the act of being supportive to another person has potential costs for the caregiver, and caregivers who are at risk may need support from others as well as alternative activities and breaks from caregiving.

Given the demonstrated health benefits of social support, interventions have been conducted to increase perceived support among persons with chronic illness (e.g., education and support groups for patients with cancer) or social isolation (e.g., visitors and telephone contacts for elderly persons with few network members). The results of these interventions have been more mixed than was originally expected, and questions have been raised about how the context of these interventions may differ from that of naturally existing social relationships. One difference is that these

interventions are often temporary, compared with the relative stability of natural relationships. Another possible difference is that social support typically involves ongoing communal relationships, a concept developed by Margaret Clark, in that supporters are motivated primarily to enhance the other person's welfare, and recipients will have many opportunities to subtly benefit the supporter in return. The challenge for support interventions has been to re-create the conditions of communality and reciprocity that are thought to be important components of naturally existing support.

Finally, the Internet is a recent development that is changing conceptions of social support and social networks. Physical proximity is no longer necessary, and individuals today may communicate frequently with persons who live in other towns or countries and whom they have never met. Research is beginning to study the role of Web-based health information services and online support groups for persons with various illnesses (e.g., cancer, diabetes) and has obtained preliminary evidence that these may enhance adjustment to illness. At the same time, research by Robert Kraut and others has indicated that extensive involvement in use of the Internet, at the expense of ordinary social interaction, may have adverse consequences for at least some persons. At present, research is needed to determine how Internet usage interfaces with actual social interaction and participation, and how these different types of communication are ultimately related to health status.

SOCIAL SUPPORT INTERVENTIONS

Social support refers to the exchange of a variety of helping behaviors that arise from people's interactions and relationships with members of their social network who have not received any formal mental health training. Natural support usually arises spontaneously when close network members such as family members and friends provide comfort, companionship, practical assistance, advice, and feedback about an individual's performance or worth. Moreover, a voluminous literature has amply documented the health-protective functions of perceived natural support under conditions of stress. What this means is that the belief that support is forthcoming—its anticipated delivery alone—seems to cushion the impact of stressors, perhaps by rendering them less daunting or by instilling greater confidence in the individual's own resources for resisting stress. High levels of perceived support are, at least in part, a consequence of past episodes when natural network members provided assistance. This entry reviews

different types of interventions designed to increase, improve, or specialize social support and then concentrates on the design and processes occurring in support groups.

Recognizing the stress-buffering and health-protective effects of social support, and with an emphasis on actual rather than perceived support, a number of investigators and practitioners have formulated ideas about ways of harnessing this resource in programs for people exposed to a variety of adversities. Whole network initiatives teach people how to identify and capitalize on the support of their field of close associates, whereas dyadic interventions concentrate on ways of mobilizing, specializing, and optimizing the quality and durability of the support rendered by a single valued social tie or confidant. A complementary set of support interventions differs from these natural network strategies by introducing new social ties deemed capable of meeting people's supportive needs. Confidence in their capability as relevant sources of support stemmed from a growing literature on the benefits of mutual aid, self-help (MASH) groups, longstanding community programs such as Big Brothers/Sisters, and, not least of all, the legacy of Stanley Schachter's work on affiliation and Leon Festinger's theory of social comparison, which documented the need for affiliation and comparison under conditions of threat that evoke fear.

The resulting armamentarium of support interventions can be summarized in a 2×2 matrix that takes into account the level of intervention (namely, the dyad or the group) and the relationship status of the support provider (namely, a member of the natural network or a stranger who is grafted onto the network on a temporary or permanent basis). Of these four types, the most widely implemented and studied is the support group, the main focus of this entry. The other three types include: (1) grafted interventions at the dyadic level, such as a program that links volunteers who have recovered from cardiac surgery with patients about to undergo similar surgery; (2) natural network interventions at the group level, such as programs that assemble key network members to support an associate who is affected by a mental or physical disability; and (3) natural network interventions at the dyadic level, such as efforts to improve the frequency and quality of support that a romantic partner provides to a woman affected by breast cancer.

Support Groups

The term *support group* is a generic label for a variety of small groups that generally range in size from 8 to 12 members and are facilitated by an expert who manages the group process, provides education, and, in some instances, provides behavioral training. Initially, the group participants are strangers who share a common disease, noxious habit, affliction, or stressful life experience, and who meet together on a fixed schedule for several weeks or months. Each session is divided into a portion when the facilitator or designated expert offers instruction and education, and another portion when the members swap experiences and anecdotes. Unlike most MASH groups, the membership is closed, the facilitator is not necessarily a “veteran sufferer,” and the group does not engage in advocacy activities. Examples of the most widely implemented support groups are face-to-face or online groups for cancer patients and their close associates, and groups for the family caregivers of persons affected by Alzheimer’s disease.

How can support materialize in a group composed of strangers? Numerous explicit and implicit interpersonal processes are implicated, the former consisting of increasingly penetrating and emotional disclosures about the members’ common predicament and their individual ways of handling it, verbal and nonverbal expressions of mutual empathy and concern that lead over time to valuing and trusting the group as an entity, and perhaps most important, diverse expressions of mutual aid and the reduction of uncertainty that lies at the core of stress. These processes mirror processes active in the development of close relationships, with group cohesion and feelings of belonging arising over time, along with the psychological sense of support that sustains the members in the intervals between group sessions. The implicit processes that unfold in support groups are equally impactful and include the private social comparisons that are vital sources of feedback and self-stabilization, the new attributions that permit the members to view the causes and control of their predicament in ways that are less self-incriminating, and the normalization and acceptance of the members’ feelings and experiences.

Support groups offer many opportunities to examine the conduct and course of both natural

and engineered human relationships that are mobilized during difficult times. Focusing on intragroup dynamics, investigators can use interviews, diaries, and observation (with permission of the group) to capture the support process that arises over time, both in terms of its behavioral expressions and its subjective perception. Shifting the focus to intergroup dynamics, researchers can examine support group outcomes in relation to the quantity and quality of the support that resides in the natural network. They can also study whether and how selected group members are transplanted from the group into one another’s natural network and take stock of any spillover that the knowledge, skills, and emotional expression gained in the group has on relationships with network members.

Although there is evidence that support groups are not universally appealing, those who choose to participate view this temporary social milieu as a way of supplementing, specializing, and, in some cases, compensating for deficiencies in the natural support rendered by their social network. With more research, a better appreciation of the ways that social ties can be structured as systems of support can be gained.

SOCIOECONOMIC STATUS

Socioeconomic status (SES) is one of the central concepts in the social sciences. Scholars use it to understand human relationships—for example, who individuals will marry, who will have children and how many, and who will eventually divorce and the consequences of divorce. Yet as Robert

Bradley and Robert Corwyn note, how scholars conceptualize SES varies greatly. Thus, as a basis for understanding the concept of SES, this entry discusses the notion of social stratification. Then it presents two theoretical perspectives that are foundational to the current interpretations of SES, some primary challenges of applying SES to real-world situations, and examples of research that has successfully linked SES with human relationships.

Social Stratification

The concept of SES comes from a broad area of research in sociology called social stratification. Scholars who conduct research in this area typically think of society as being made up of a series of layers. Stadium seating at a baseball game that situates individuals by the price of the ticket may offer an intuitive picture of how a layer in society may be constructed. Some people who cannot afford to pay a lot of money for a ballgame may purchase a lower priced ticket and sit far away from the ground, whereas others who can afford to pay for an expensive ticket may sit close to the ground, where they have a level view of the game. As in this hypothetical baseball stadium, social scientists argue that in the real world, individuals are situated in one of ordered areas depending on what they already have or can do. For example, people are unequal—positioned differently—in terms of how much money they make, the level of education they have attained, the power they can exert over others, and the prestige of their jobs.

An individual's location in this layered society may alter his or her human relationships. Belonging to the upper layer of society, for instance, can provide privileges and power to individuals compared with belonging to a lower layer of society. The location also gives or denies a person access to desirable relationships (e.g., wealthy individuals can afford to attend expensive parties where they are likely to meet other wealthy individuals). At the same time, establishing certain relationships, such as marrying into a wealthy family, affords a person entrance into particular layers of society that may be socially and economically advantageous.

However, unless placed in situations such as the seating arrangement of a baseball stadium organized by ticket price, people in everyday lives are

not visibly ordered in hierarchical layers. If observing layers is difficult for individuals in most situations, how do researchers know that these layers exist in the first place and know what they look like? Their typical approach is to come up with a theory of what these layers look like, often referred to as ideal types, and see how well they fit the physical world. Sometimes ideal types apply well in some societies, but not in others. At the same time, some scholars, such as Donald Treiman and David Featherman, argue that certain aspects of the layers are common to all societies.

Researchers use these ideal types to understand how resources (e.g., money, education, power) are allocated to individuals, how the allocation process affects human relationships, and how human relationships affect the allocation process. Social scientists, for example, find that higher status persons often use their political power to keep lower status persons from accumulating a share of the limited resources they enjoy, such as residential location, occupational opportunities, and entertainment venues. The result is that the different status groups experience intergroup competition and conflict.

Examples of Ideal Types

Two important social theorists who lived during the mid-1800s and early 1900s offer contrasting ideal types to understand the structure of the layers. The first one is Karl Marx. Although there are many ways of reading Marx's work, one way is to consider his argument that the only dimension that is truly foundational is economic class. In his day, he thought about economic class as having two levels. Either a person was an owner or a worker. Because the workers had to work for the owners, the owners had more money (and prestige and power as a result) to do what they wanted in society. Consequently, other dimensions, such as culture capital, which reflects knowledge of the arts and does not necessarily distinguish owners from workers, were only important if the owners thought they were important, making the one dimension of economic class foundational to everything else. From this perspective, a person's economic class would represent his or her SES.

Max Weber offers a contrasting view of the structure of the layers to this interpretation of

Marx by suggesting that many other social dimensions are important. In particular, he said that status (e.g., how cultured individuals are) and party (e.g., the organizations to which people belong) were equally consequential in a person's life as economic class (e.g., how much their income is). First, economic class for Weber was a position in the economic market, rather than a matter of being an owner or worker. For example, a CEO and an entry-level employee may work for the same company—neither is the “owner.” Yet they enjoy different amounts of power, money, and prestige due to the difference in their economic positions. Second, a person's status may not always be determined by his or her economic class. An individual may achieve academic success, for instance, despite coming from a poor household, and this academic success gives him or her a measure of status in the eyes of others. In fact, this academic success may improve the person's economic class by helping him or her obtain a high-paying job. Third, the parties or social organizations to which a person belongs, such as political parties, trade unions, and religious organizations, may place him or her in the upper layers of society because the parties or organizations seek to systematically gain power for their members. In this case, a number of dimensions may constitute a person's SES.

Challenges of Applying Simple Ideal Types

Although these ideal types are valuable models for understanding an individual's position and available resources (e.g., money, education, and power) in society, there are challenges when applying any ideal type in a dynamic social world. The following are several examples of the challenges that scholars face when using the ideal types in their research on human relationships.

Multidimensionality

Ideal types, unless they are complex ones, are typically unidimensional and do not take into account the fact that, in reality, individuals participate in multidimensions in society. For example, college professors often enjoy high status among the general public—people consider their work

prestigious. Yet many college professors also earn less money than people who work in less prestigious occupations, such as a plumber or an auto mechanic.

One way in which scholars have dealt with this human complexity is to determine which of the multiple dimensions is most salient. For example, Greg J. Duncan and his colleagues find that parents' level of income during their offsprings' pre-adolescent years has the greatest impact on the eventual academic achievement of their children. Therefore, parental income is arguably more important than other dimensions, such as the education level of the parents, when studying the causal factors of school success.

A second way is to separate out the dimensions. If individuals are multidimensional, then SES needs to be multidimensional. For instance, evidence indicates that women with high SES are attractive romantic partners for several reasons. One, a woman's income attributes needed financial resources to the family; two, her occupational status, such as being a doctor, may bring prestige to the family; and, three, her education may offer family members access to important people who could help family members find jobs.

A third way to maintain the multidimensionality of the layers to which individuals belong is to develop a scale that takes averages of each of the several dimensions and weighs them according to how important they are in a particular society. For example, in some societies, earning more money may be valued more than being better educated, but in other societies, the value system may be the opposite. This strategy is used in scales, such as Otis Dudley Duncan's Socioeconomic Index and Treiman's Occupational Prestige Scale.

Multilevel Structure

Another problem that scholars face in applying ideal types to the real world is that the layers are nested and multileveled. That is, although each individual has his or her own status position consisting of several dimensions, the status of units larger than the person, such as the family, the school, and the country to which the individual belongs, also influences his or her personal status. For example, although a husband may have his own earnings, years of schooling, occupation, and

so on, which define his personal status, the members of his family each have their own statuses too, which contribute to the family's overall status. This overall status may reflect positively or negatively on him in the eyes of other people. If the husband goes to school, his status is further defined by the prestige of the school that he attends. The prestige of the school may be defined by how wealthy the country is and how much it is able to pour into the quality of education it provides. This multilevel definition of status contributes to the context-specific causes and effects of SES, which are discussed further next.

Changing Structure of the Layers

A final problem of applying the concept of SES in real-life situations concerns the structure (e.g., the stadium at a baseball game). Certain structures shift over time; as a result, individuals' positions in the layers also change. For example, a person's economic class may change in his or her lifetime when the economic conditions of society change. Earning \$40,000 may place a person in the working class during a period of economic boom and in the middle class during a period of economic depression. Researchers apply certain techniques, such as the real income conversion based on the Consumer Price Index, to achieve research consistency and comparability over time despite shifting economic structures.

SES and Human Relationships

Notwithstanding the challenges, scholars have successfully shown that SES affects human relationships and is also affected by human relationships in a highly context-specific manner. Consequently, the association between SES and human relationships often varies by a country's cultural, historical, political, and institutional conditions.

SES Affects Human Relationships

One can take examples from a group of studies examining the effect of SES on marriage and divorce. Scholars who study marriages in the United States typically find that men and women

in higher SES positions are more likely to marry and are less likely to divorce. In other industrialized countries, however, this is not the link that is found. For example, in Japan, where expectations are that wives do housework rather than labor market work, women with a high level of income are less likely to marry than women with a low level of income.

Human Relationships Affect SES

Several studies find that the teacher–student relationship influences the eventual SES of the students. This occurs because teachers often unconsciously hold negative stereotypes about certain groups of people, such as females or minorities. Teachers may act differently toward these groups of students, directing them toward vocational training rather than 4-year colleges and beyond, for example. Thereby, they affect the students' abilities to attain a certain level of SES as adults. The impact of the negative stereotypes, however, may be more or less powerful depending on the context of the students' families. For instance, students who come from families that provide emotional support and empowering guidance may be less vulnerable to the detrimental effects of these negative stereotypes than students who come from families that provide no such support and guidance.

SOCIOEMOTIONAL SELECTIVITY THEORY

This entry describes a life-span theory of motivation that offers an explanatory framework and testable hypotheses about the ways in which perceived endings affect goals, preferences, and even cognitive processing. Because aging is associated with time left in life, the theory predicts reliable age differences in these domains. Socioemotional Selectivity Theory maintains, however, that such age differences reflect differences in perceived time horizons more than chronological age. Studies testing the theory have found similar patterns in younger people who face endings through terminal illness, wars, or even geographical relocations.

According to the theory, temporal horizons direct two overarching sets of goals that govern much of human social behavior. One set of goals concerns the acquisition of knowledge, whereas another concerns the regulation of emotional states. Both sets of goals activate behavior across the life span, but the relative importance and priority placed on them varies as a function of time horizons.

The theory posits that when time is perceived as expansive, informational goals assume dominance. Under these temporal conditions, people are motivated to plan for seemingly unlimited futures. Potential social partners are selected based on the potential for new information and future opportunities. Cognitive resources are allocated to these goals. People who prioritize information-related goals attend to all sorts of information in their environments because even information that is not immediately relevant could become important in

the future. Banking information takes precedence over emotional satisfaction. For example, learning one's place in the social hierarchy may be useful for social interaction even if it is relatively bad news. Similarly, when the future is perceived as long, people may invest in even taxing efforts if they may pay off in the future. As temporal horizons diminish, the relative importance of information-related goals decreases. When future time is constrained, emotion-related goals grow in importance. Emotional well-being takes priority over gaining new information. People engage in strategies aimed at optimizing well-being, especially decreasing the experience of negative emotions. Just as people select emotionally meaningful social partners over others because of the emotional satisfaction they derive from them, they direct their attention toward positive stimuli and away from negative stimuli in an effort to ensure well-being.

Temporal Horizons and Social Relationships

Socioemotional Selectivity Theory was first developed to explain a paradox observed in studies examining age differences in social and emotional functioning. Social relationships are critical for physical and mental health across the life span, with higher levels of perceived social support related to less depression and higher levels of life satisfaction. Social network size and level of social activity, however, decrease with age. Given these declines, older adults should presumably fair worse on studies of mental health, yet older adults in general are not more depressed or anxious, nor do they report more loneliness than younger adults. Moreover, in normal populations, older adults regulate their emotions more effectively than younger adults. At advanced ages, marriages often return to earlier levels of happiness, and relationships with adult children grow more satisfying.

The apparent contradiction between age-related reductions in social activity and stability, if not increases in affective well-being, is reconciled by socioemotional selectivity. According to the theory, older adults are motivated to optimize their interactions with emotionally meaningful social partners. As a result, they proactively cull peripheral acquaintances from their networks while continuing to interact with friends and family members

who offer emotional meaning and satisfaction. Over the years, people report spending less time with casual acquaintances and more time with close friends and family members. Older adults also report relatively higher percentages of emotionally close social partners in their networks than do younger people. Moreover, emotional satisfaction derived from close social partners increases with age.

Temporal Horizons Beyond Chronological Age

When asked directly about how they would like to spend an hour of free time, older adults choose close social partners, whereas younger adults are just as likely to opt for spending time with a new neighbor or the author of a book just read than with a close social partner. When evaluating lists of potential social partners, older adults are also more likely to weigh the potential emotional meaningfulness of these social partners more strongly than younger adults, who more likely weigh social partners by the potential for knowledge and future possibilities. Additional research shows that these findings are not limited to age per se, but are better explained by time perspective. When asked to imagine that their healthy active life span has been increased by 20 years, older adults no longer elect to spend time with close social partners and instead mirror the partner selection choices observed among younger adults. Similarly, when younger adults are asked to imagine that they are moving across the country without friends or family, they too focus on shorter time horizons and choose social partners in the service of emotional gratification. Thus, age per se does not guide these social choices. Rather, the perception of time availability accounts for social choices. Focusing on the present tends to be good for well-being.

Time perspective is intrinsically linked to chronological age, but social, political, and health-related conditions can also alter these perceptions and consequent social and emotional motivations. For example, prior to the return of Hong Kong to the People's Republic of China, the future for citizens was uncertain. Three months prior to the handover and in the midst of this uncertainty, people of all ages were asked about their social

partner preferences. Both younger and older adults reported a preference for emotionally close social partners. Three months after the handover, when dire predictions were not realized, people were asked again about their social preferences. Older adults' preferences were unchanged, whereas younger adults reported preferring to interact with novel social partners, just as they had before the handover was imminent. This pattern of findings was later replicated during and after the unrest created by a severe acute respiratory syndrome epidemic in Asia and the attacks of September 11th, 2001, in the United States. For men suffering from AIDS prior to the development of effective drug treatments, social partner preferences and the importance placed on emotional value derived from social interactions varied from same-age healthy peers in ways similar to older adults. Studies have ruled out emotional neediness as an alternative. When people were asked why they choose the partners they choose, people say that they are seeking emotional meaning more often than social support.

Temporal Horizons and Emotional Experience

Socioemotional Selectivity Theory maintains that poignant emotional states, defined as the co-occurrence of negative and positive emotions, usually occur in contexts that denote the end of one life chapter and the beginning of another, such as college graduations, weddings, and births. Theoretically, this is because the close of each life chapter marks progression through life. Even in young people, mixed emotional experiences are observed when endings are primed. In one study, participants were asked to imagine themselves in a place that was emotionally meaningful to them and to rate the emotions they were experiencing. Other participants were asked to rate their emotions after imagining that they were visiting this location for the last time. People in the anticipated endings conditions described a more bittersweet experience, characterized by both happiness and sadness. In another study, younger adults who were reminded that this was the last day of their college career reported higher levels of poignancy than participants who were not primed to focus on the temporal aspects of the condition.

Temporal Horizons, Cognitive Processing, and the Positivity Effect

The theory predicts that, because goals direct cognitive processing, age will be associated with preferences for difference types of information. In one study, older and younger adults were shown advertisements that appealed to either emotionally meaningful experiences or the desire for information gain. Older adults preferred the messages framed with the emotionally meaningful appeal more than younger adults did. Older adults were also more likely to remember advertisements that framed the product in terms of emotional meaning as opposed to information gain. The memories of younger adults did not differ as a function of message framing. Manipulating time perspective substantiated the influence of temporal horizons for explaining these age differences: The greater preference for emotional meaning by age was eliminated when people were asked to imagine that their time left to live had been expanded another 20 years.

Tests of Socioemotional Selectivity Theory led to the identification of the so-called positivity effect. Researchers hypothesized that when emotional satisfaction is a high priority, emotions—particularly positive emotions—will be more salient in cognitive processing. In direct tests of these hypotheses, researchers have observed preferences for positive information in attention and memory in older adults. When presented with pairs of faces featuring neutral and positive expressions, older people look more at positive faces. When neutral and negative faces were paired, older people looked more at neutral ones and away from negative ones. Studies of memory reveal that younger, middle-age, and older adults differ in the types of images they best remember. Successively older age groups remember proportionately more of the positive images. Patterns of brain activation are consistent with a preference for positive information among older adults, suggesting that the patterns described earlier are not simply reporting differences. When viewing negative images, regions of the brain associated with storing emotion memories show less activation in older adults. Compelling evidence that such differences are motivated also has been found. Mara Mather and her colleagues found that age-related patterns are most robust in older people

with well-preserved executive functioning and that the positivity effect disappears in dual attention tasks when cognitive resources are drained by demands of multiple tasks.

Preferences for positive material explain age differences in memories for decisions. When asked to remember the positive and negative characteristics of a chosen option and the nonselected alternative, older adults engage in more choice-supportive recall, whereby they remember the positive characteristics of their selected option as opposed to potential drawbacks. When choosing a health care plan from a range of alternatives, older people focus more on the positive aspects of the plans than negative aspects while they review the plans. They also later recall a greater proportion of positive information than younger adults recall. Consistent with Socioemotional Selectivity Theory, these differences disappear when controlling for time perspective.

Conclusion

For many years, social scientists presumed that old age was a time of loneliness and despair. As evidence accrued that older people suffer lower rates of mental disorders than younger people and report greater satisfaction with life despite reductions in their social spheres, the phrase “paradox of aging” was coined: Older people experience fewer negative emotions in everyday life and report even more satisfying relationships than younger adults. According to Socioemotional Selectivity Theory, as temporal horizons shrink, people live in the present. They shift attention away from the long-term future and prioritize the most important aspects of life. For most people, this prioritizes close relationships.

SOCIOMETER THEORY

Sociometer Theory proposes that self-esteem is an internal, subjective gauge of the degree to which people perceive that they are relationally valued and socially accepted by other people. The sociometer approach to self-esteem differs from most traditional explanations in suggesting that self-esteem has no value in its own right and that people neither need self-esteem nor are motivated to pursue it for its own sake. Rather, self-esteem is viewed as the output of a psychological system that monitors and responds to events vis-à-vis interpersonal acceptance and rejection. State self-esteem—people's current feelings about themselves that fluctuate in response to interpersonal events—is viewed as a reaction to people's perceptions of the degree to which they are, or are likely to be, valued and accepted by other people in the immediate context or near future. Trait self-esteem—people's average or typical level of self-esteem across situations and time—is conceptualized as a reflection of their general sense of the degree to which they are socially valued and accepted. This entry describes Sociometer Theory's perspective on the function of self-esteem, the nature of the self-esteem motive, and the relationship between self-esteem and dysfunctional behavior.

Function of Self-Esteem

Human beings and their hominid ancestors survived and prospered as species because they lived in

cooperative groups. Given the importance of group living, natural selection favored individuals who sought the company of others and behaved in ways that led others to value, accept, and support them. Because social acceptance was vital, a psychological system evolved that monitored and responded to cues indicating that the person may be devalued and rejected by other people. Prior to the appearance of self-awareness in evolutionary history, this system presumably operated on the basis of affective responses to nonverbal cues. However, after human beings developed the mental capacity for self-awareness, detection of a threat to social acceptance also triggered a conscious analysis of the situation, including an assessment of one's own characteristics and behavior. Thus, state self-esteem—the valenced feelings that people have about themselves—rises and falls with changes in perceived relational value, alerting people to real and potential rejection and motivating actions that maintain relational value and social acceptance. The sociometer system monitors relational value in all of people's interpersonal encounters, including those with friends, romantic partners, group members, acquaintances, family members, and even strangers, although the question has been raised whether people possess a single sociometer that monitors acceptance in all relationships or a set of relationship-specific sociometers that operate in different interpersonal contexts.

From the standpoint of Sociometer Theory, events that lower self-esteem—such as failure, rejection, embarrassing situations, negative evaluations, and being outperformed by others—do so because they potentially lower people's relational value to other people. Many laboratory experiments show that participants who learn that other people have excluded them from groups or interactions, do not want to get to know them, or hold negative impressions of them report lower state self-esteem than those who believe that others accept them. Similarly, studies of people's reactions to real-world instances of rejection and ostracism show that people consistently report decreased self-esteem following rejection. In general, rejection has a greater effect on state self-esteem than does acceptance. Because people are usually accepted at some minimal level by most people with whom they interact, being included is the default situation.

Self-esteem is closely linked to people's beliefs about whether other people are likely to accept or reject them, as Sociometer Theory predicts. Not only does explicit rejection lower state self-esteem, but people's feelings about themselves when they perform certain behaviors mirror the degree to which they think their actions will lead others to accept or reject them. The more that people think that their behavior will lead others to reject them, the worse they feel about themselves. Furthermore, research shows that people's own self-evaluations on particular dimensions predict their self-esteem primarily to the degree to which they believe that those dimensions are relevant to their social acceptance and rejection by other people. For example, people who believe that their relational value to others depends greatly on their physical appearance experience larger decrements in self-esteem when they believe they are regarded as more unattractive than people who do think that appearance is less important for social acceptance. Although some people maintain that their feelings about themselves are unaffected by acceptance and rejection, the effects of rejection on self-esteem are nearly universal. Research shows that rejecting feedback significantly affects state self-esteem even among people who insist that their feelings about themselves are not affected by others' evaluations or acceptance.

Although social and behavioral scientists agree that people's feelings about themselves are affected by others' evaluations, few theorists have addressed the question of why self-esteem is based so strongly on social evaluations and interpersonal acceptance. In fact, some have insisted that genuine self-esteem is not affected by other people's judgments. In contrast, Sociometer Theory maintains that people's views of themselves *should* be affected by how they think other people evaluate them, at least to a degree, because self-esteem monitors others' evaluations, which are important to personal well-being.

Self-Esteem Motive

People often behave in ways that seem intended to protect or increase their self-esteem. They make self-serving attributions that absolve themselves of responsibility for failure, compare themselves to those who are worse off than they are, misremember

information about themselves in flattering ways, choose friends and romantic partners who do not outperform them on important dimensions, and do many other things that make them feel good about themselves. According to Sociometer Theory, when people do things that appear intended to maintain or raise self-esteem, their goal is usually to protect and enhance their relational value to increase their likelihood of interpersonal acceptance. Self-serving attributions, self-handicapping behaviors, social judgments, prejudices, and ego-defensive reactions may reflect efforts to promote acceptance rather than to raise self-esteem per se. The theory acknowledges that people sometimes try to feel good about themselves in their own minds, but this fact does not contradict Sociometer Theory's claim that the fundamental function of the self-esteem system is to monitor and respond to threats to relational value and social acceptance.

Research investigating cultural differences in self-esteem enhancement has led some researchers to conclude that people in certain cultures, particularly those in east Asia, are either indifferent to self-esteem or do not experience self-esteem at all. For example, studies have shown that Japanese respondents do not engage in the self-enhancing biases that have been shown among American and European samples. From the perspective of Sociometer Theory, these data suggest that the criteria for being relationally valued differ by culture. Because self-enhancement does not promote acceptance in Japan as it does in the West, the Japanese are not only reluctant to self-enhance, but also feel badly about themselves when they do. Research suggests that behaviors that promote relational value in Japan—deference, self-effacement, and being other-oriented, for example—result in high self-esteem.

Self-Esteem, Emotion, and Dysfunctional Behavior

Many cognitive, emotional, and behavioral variables correlate with self-esteem. According to Sociometer Theory, some variables that correlate with self-esteem do so because they are associated with the perception that one is (or is not) valued as a relational partner by other individuals. For example, because people are more likely to value

those who are competent, physically attractive, norm-abiding, and likable, people who believe that they possess these acceptance-promoting characteristics tend to perceive that their relational value is high and, thus, possess higher self-esteem than people who do not believe that they have these attributes.

Other variables may correlate with self-esteem because they reflect ways of dealing with low relational value. For example, conformity may be related to low self-esteem because people who believe they have low relational value (and who, thus, have lower self-esteem) conform to increase their chances for social acceptance. Some variables that correlate with self-esteem may be both a cause and a consequence of feeling accepted or rejected. For example, feeling unaccepted may lead people to pursue social acceptance through deviant behaviors such as drug use (because certain antisocial groups often require little more than a willingness to participate in deviant behaviors), but then such behaviors may result in disapproval and rejection by others, thereby lowering self-esteem.

Virtually every negative emotion is more common among people who have low versus high self-esteem. In conceptualizing self-esteem as a gauge of relational value, Sociometer Theory suggests that low self-esteem is associated with these emotions because they are related to real, potential, or imagined rejection. Feeling inadequately accepted not only lowers self-esteem, but also makes people prone to emotions such as hurt feelings, sadness, jealousy, and anger, all of which often reflect the current or future state of one's interpersonal relationships.

Much of psychology's interest in self-esteem stems from the fact that low self-esteem tends to be associated with an array of emotional and behavioral problems. The relationship between low self-esteem and dysfunctional behavior is not as strong as many suppose, but the general pattern is for people with low trait self-esteem to be troubled by behavioral and emotional problems, such as depression, anxiety, alcohol and drug abuse, and conflicted relationships, more frequently than people with high trait self-esteem. From the standpoint of Sociometer Theory, low self-esteem may be related to maladaptive emotions and behaviors for three general reasons. First, feeling inadequately accepted by other people promotes a number of

aversive emotions (such as sadness, anxiety, and anger), as well as dysfunctional interpersonal behaviors such as derogating other people and interpersonal aggression. Such reactions have been demonstrated in response to short-term rejections in laboratory experiments and also are more common among people with histories of rejection, who tend to be depressed, anxious, hostile, and aggressive. As a monitor of relational value, self-esteem changes with perceived acceptance and rejection and, thus, correlates with other reactions to rejection.

Second, feeling inadequately valued typically increases people's desire to be accepted. Although people presumably prefer to gain acceptance through socially desirable means (such as through achievement, being a likable person, or treating others well), those who feel inadequately valued may resort to extreme, and sometimes deviant or antisocial, means when the prospect of gaining acceptance via socially desirable avenues looks unlikely. As a result, people with low self-esteem, who feel inadequately valued at the moment or inherently unacceptable over time, may join deviant groups—such as gangs, religious cults, or drug subcultures—in which the standards for acceptance by other people are lower than in mainstream, socially acceptable groups.

Third, some emotional and behavioral problems are related to self-esteem because they precipitate rejection. For example, nearly every psychological disorder leads other people to devalue and distance themselves from the individual, thereby lowering his or her self-esteem. Thus, people with psychological difficulties, whatever their cause, tend to have lower self-esteem. Similarly, although rejection may promote drug and alcohol use—either as an escape from the aversiveness of rejection or as a way to promote acceptance by deviant groups—substance abuse may lead to lowered acceptance and, thus, lower self-esteem.

Thus, the psychological difficulties that have previously been attributed to low self-esteem seem to be the causes or consequences of interpersonal rejection rather than effects of self-esteem *per se*. Furthermore, clinical treatments that focus on raising self-esteem to ameliorate these problems may have their effects by increasing people's real or perceived acceptability to other people. Virtually

all treatment programs designed to raise self-esteem involve interventions that would be expected to increase clients' perceptions of their social desirability and relational value.

SOCIOMETRIC METHODS

Sociometric methods include a large class of methods that assess the positive and negative links

between persons in a group. The basic principle of the sociometric method is that every group member has the capacity to evaluate every other group member on one or more criteria. The term *sociometry* often has a narrower meaning—that is, the assessment of sociometric status in peer groups of children or adolescents. Sociometric methods have been used extensively in research with children and adolescents to assess their social relationships in the peer group. The origins of sociometric methods are attributed to Jacob Moreno (1934). Moreno's work was embedded in a broader movement in the social sciences at the beginning of the 20th century aimed at understanding interactions and relationships in groups. This entry reviews the basic elements of a sociometric procedure and the information it provides.

The results of a sociometric test can be presented graphically in a sociogram, a picture of the associations and connections between the members of a social network. Quantitatively, information can be derived at three levels of analysis: individual, dyad, and group. At the individual level, the results from the sociometric test can determine the degree of popularity, network centrality, connectedness, isolation, or rejection of every member of the group. At the dyadic level, the procedure can identify different types of dyads, such as friendships, but also antipathies, mutually aggressive dyads, bully–victim pairs, or romantic relationships. At the level of the group, the procedure can identify cliques of well-connected individuals with a certain identity who form cohesive subgroups in the larger social network.

The most common application of the sociometric method in research with children and adolescents focuses on individual-level sociometric status, in particular peer rejection and popularity. What does it mean that a child or adolescent is “rejected” or “popular?” These sociometric status types are sometimes seen as absolute characteristics of the individual that are caused by stable traits or behaviors (e.g., the popular child is cooperative and helpful, whereas the rejected child is aggressive or withdrawn). However, peer status is not independent of the group in which it is assessed. A person who is accepted in one group may not be accepted in another group with different norms.

Throughout the history of sociometric measurement, various methods have been used. John Coie,

Kenneth Dodge, and Heide Coppotelli presented a sociometric method that has served as the standard in the child and adolescent literature since the 1980s. In this procedure, children are asked to name three classroom peers they like most (*acceptance*) and three they like least (*rejection*). Nominations received for both questions are counted for each child and standardized within classrooms to control for differences in classroom size. A continuous score for *social preference* is created by taking the difference between the standardized acceptance and rejection scores and again standardizing the resulting scores within classrooms. A continuous score for *social impact* is created by summing the standardized acceptance and rejection scores and restandardizing the results. Finally, each child is assigned to one of five sociometric status types: popular (liked by many, disliked by few), rejected (disliked by many, liked by few), neglected (neither liked nor disliked), controversial (liked by some and disliked by others), and average (around the means of acceptance and rejection). The continuous scores and categorical status types tend to be stable over time. This suggests that peer status is difficult to change.

In a sociometric procedure, the *reference group* is the larger social network within which status is determined. For children and adolescents, the reference group is often the classroom or grade, but other possibilities are sports teams, hobby clubs, the peers in an afterschool program, or all peers in the neighborhood. Because peer status is relative to the group, it matters which reference group is chosen. In North America, the reference group for kindergarten and elementary school children is typically the classroom, for early adolescents in middle school all peers in their grade, and for adolescents in high school further extended across grade levels. This may vary in other cultures with differently structured school systems.

The *voter population* is the children or adolescents who participate as evaluators in a sociometric test. The *votee population* is the children or adolescents who are being evaluated. Ideally, all members of the reference group (e.g., classroom or grade) participate as both voters and votees. The questions on a sociometric test are called *sociometric criteria*. Moreno distinguished two types: emotional and reputational. Emotional criteria are subjective evaluations that are personal to the

voter. Items measuring acceptance and rejection (liked most, liked least, best friends) are in this category. Reputational criteria measure perceived behaviors or reputations, rather than personal evaluations. Nominations of peers who start fights, cooperate and share, or stay by themselves are reputational items of social behaviors. Nominations of popularity, attractiveness, and being good in school or at sports are also reputational. Because reputational items measure shared perceptions, rather than personal perceptions, there is a higher consensus in the peer group for reputational items than for emotional items.

Today, there are many variations of the basic sociometric method that increasingly include technology, such as in computerized assessments. What started as a simple test has grown into a sophisticated method for relationship assessment that is widely used in research and applications. Although the procedure is relatively simple, the information obtained is powerful. Sociometric status in childhood and adolescence correlates with behavioral, social-cognitive, and emotional skills in important ways and predicts social adjustment or maladjustment later in life. Sociometric methods have also been used with adults in work settings to understand the interactions among the members of an organization and to create effective work teams.

SOCIOSEXUAL ORIENTATION

The construct of sociosexuality was developed to explain variation in the degree to which individuals need to feel emotionally close and connected to romantic partners before having sex with them. In his pioneering study of human sexuality, Alfred Kinsey documented that, although men on average report being more comfortable engaging in different forms of sociosexual behaviors than do most women, considerably more variability existed *within* each gender than between women and men. Early models developed to explain this variation posited that individuals who are willing to engage in sex without closeness or emotional intimacy have stronger sex drives. The sociosexuality construct, which was first introduced in 1990, shifted the causal focus away from a sex drive interpretation and toward a more psychological one.

Jeff Simpson and Steve Gangestad developed and validated the Sociosexual Orientation Inventory (SOI) in 1991 to measure the degree to which individuals need or require closeness and emotional intimacy before engaging in sexual intercourse with romantic partners. The SOI has five self-reported components: (1) the number of different sex partners (where *sex* connotes sexual intercourse) the respondent has had in the past year; (2) the number of lifetime one-night-stand partners; (3) the number of different sex partners realistically anticipated within the next 5 years; (4) the frequency of having sexual fantasies involving persons other than the current (or most recent) romantic partner; and (5) attitudes toward engaging in casual, uncommitted sex (e.g., "I can imagine myself being comfortable and enjoying casual sex with different partners"). The five components of the SOI are weighted and then summed to form a single sociosexual orientation score.

Individuals who score higher on the SOI have a more *unrestricted* sociosexual orientation in that they report having more sex partners in the past year, they have had more one-night stands, they foresee having a greater number of sex partners in the near future, they fantasize more about having sex with people other than their current or most recent romantic partner, and they express more positive attitudes about engaging in casual sex in the absence of love, commitment, or intimacy.

Individuals who have lower scores on the SOI have a more *restricted* sociosexual orientation given that their behavior and attitudes indicate that they require some level of love, commitment, or intimacy prior to having sex with someone. The SOI has recently been used to gauge the general mating strategies/orientations that individuals tend to adopt. People who score higher on the SOI (more unrestricted individuals) typically pursue short-term mating strategies devoid of emotional intimacy and commitment, whereas those who score lower (more restricted individuals) tend to enact long-term mating strategies defined by greater emotional intimacy and commitment.

Several studies have confirmed that scores on the SOI are systematically related to two constellations of variables: (1) other individual difference constructs and measures (e.g., measures of sexuality, personality traits, attachment styles, and gender-based measures) and (2) mating orientations and preferences (e.g., motives for mating, preferred mate attributes, and relationship initiation and interaction styles). As a rule, more unrestricted people tend to be more extraverted, less agreeable, more erotophilic, more disinhibited and impulsive, more likely to take risks, and more avoidantly attached. More restricted people, in contrast, are more introverted, more agreeable, more erotophobic, more socially constrained, less impulsive, less likely to take risks, and more securely attached. Although some evidence suggests that highly unrestricted individuals might also have more masculine characteristics than more restricted persons, this association is less conclusive.

A larger body of research has investigated how restricted and unrestricted sociosexual orientations are associated with different mating strategies, motives, preferences, and behavioral tactics. This work has confirmed that more restricted people have stronger intrinsic motives for entering romantic relationships; once relationships are established, they tend to be more committed to sustaining them. More restricted persons also prefer mates who, like themselves, value intimacy and commitment and are relatively more affectionate, trustworthy, and faithful. When attempting to attract such partners, more restricted men accentuate their best personal attributes, particularly those likely to be valued by persons seeking long-term mates (e.g., kindness, honesty, and loyalty).

More unrestricted individuals, in contrast, typically become involved in temporary, short-term relationships characterized by lower levels of commitment and emotional intimacy. Unrestricted individuals also gravitate toward more physically attractive and higher status partners, and they place more weight on sexual attraction and the potential for sex when choosing opposite-sex friends (who at some point might become romantic partners). Highly unrestricted individuals are also more likely to cheat—or claim they would cheat—on their current romantic partners, especially if a highly desirable alternative partner became available. In addition, more unrestricted women tend to perceive sexual rewards, resource acquisition, and the refinement of their seductive skills as positive outcomes of pursuing a short-term mating strategy. When trying to attract mates, highly unrestricted men tend to use direct, competitive tactics such as showing off, bragging about past accomplishments, or belittling other men. They also are more likely to display nonverbal behaviors that convey contact-readiness, such as coy smiles, flirtatious glances, and head cants, which are likely to facilitate sexual intimacy without accompanying love, closeness, or commitment. Some recent evidence suggests that more unrestricted women may at times use short-term mating tactics to evaluate, attract, and possibly retain certain men as long-term mates, which is not true of more unrestricted men. In addition, more unrestricted men and women report being more likely to “poach” and be poached by individuals who had been involved in other established relationships.

In conclusion, the sociosexuality construct and measure have spawned a surprising amount of empirical research since the construct was introduced in 1990. From a theoretical standpoint, the most fruitful lines of inquiry have used the sociosexuality construct and measure to test evolutionary-based models of human mating, including important life-span models of social, emotional, and physical development. The sociosexuality construct and measure have also helped to move the study of human mating away from simple sex difference accounts of how and why men and women mate and toward more complex, complete, and accurate models that incorporate the social and environmental conditions

under which *both* genders enact short- and/or long-term mating strategies.

SPEED DATING

Speed dating is an activity designed for individuals who are interested in meeting potential romantic partners. At speed-dating events, participants have the opportunity to meet other attendees on a series of brief, one-on-one, 3- to 8-minute “dates.” Heterosexual speed-dating events, for example, typically include 10 to 20 members of each sex, with members of one sex (usually the men) rotating to the next partner after each speed date until everybody has met all of the opposite-sex speed daters. After the event, participants report whether they would (“yes”) or would not (“no”) be interested in corresponding again with each of their speed-dating partners in the future. If two speed daters say “yes” to each other, they are a *match*, and the host of the speed-dating event gives them the opportunity to contact each other subsequently, perhaps to arrange a more traditional date.

Speed dating more closely resembles a party than a series of blind dates. Compared with parties, however, speed dating offers several advantages, including the assurance that the people who attendees meet are also interested in meeting romantic partners and the security of knowing that awkward or unpleasant dates require only minimal endurance.

History

Rabbi Yaacov Deyo invented speed dating in the late 1990s to help Jewish singles in Los Angeles meet each other. Since then, speed dating has become an international phenomenon serving diverse populations across dozens of countries. It has become a mainstay of popular culture, appearing in television programs, movies, and mainstream news outlets. It has also become big business, with millions of people paying tens of millions of dollars to attend events.

Although mechanisms for meeting romantic partners have existed for time immemorial, the rapid growth and widespread availability of the Internet in the mid-1990s spawned a variety of new avenues for individuals to find and meet partners. For example, today's singles frequently meet each other via online dating (e.g., eHarmony.com, match.com) and social networking Web sites (e.g., facebook.com, myspace.com). Speed dating also emerged with this burst of modern dating innovations, but it does not involve Internet use to the same extent as these other methods. Instead, speed dating is distinctive in featuring face-to-face interaction at the first step of the romantic initiation process. Speed-dating companies (e.g., Cupid.com, HurryDate.com) do allow users to register for events and contact their matches over the Internet, but this online communication does not substitute for the live interactions that lie at the heart of speed dating.

Speed Dating and Romantic Attraction Research

Soon after speed dating became a pop culture phenomenon, scholars recognized it as an efficient means of studying romantic attraction. A stream of articles began appearing in the scientific literature in 2005, with some reporting findings from

commercial speed-dating events and others reporting findings from events hosted by romantic attraction scholars for graduate or undergraduate students.

Scholars are enthusiastic about the scientific potential of speed dating because its procedures possess many features that make it an ideal method for studying romantic attraction. For example, speed-dating procedures allow scholars to: (a) study real relationships with a potential future, (b) study both partners from each speed date simultaneously, (c) maintain tight control over the circumstances in which individuals meet potential partners, and (d) examine how individuals select among a series of available romantic partners. Speed-dating procedures also allow scholars to assess background characteristics about individuals before they attend the event and to follow matched pairs into the future to study early relationship development.

A skeptic might question whether these benefits of speed-dating procedures might be offset by the disadvantage of each speed date's brevity. After all, perhaps individuals are not able to learn anything substantive about each other in only a few minutes. Although this concern is reasonable, it is contradicted by decades of research demonstrating that individuals can make impressive and nuanced social evaluations quickly—sometimes in a matter of seconds. Because the social psyche is so sophisticated, people can make speedy social judgments that go well beyond physical attractiveness evaluations. Indeed, one study revealed that speed daters tend to be especially attracted to others who selectively like them: When a speed dater encounters partners who experience romantic desire for everybody they meet, she tends not to reciprocate this desire, but when she encounters partners who experience romantic desire uniquely for her, she tends to reciprocate this selective desire.

Other speed-dating research has explored the roles that race and sex play in predicting romantic attraction. For example, evidence now suggests that (a) men are less selective in their “yessing” decisions than women are (especially as the number of attendees at the event gets larger) and (b) women show stronger preferences for partners of their own race than men do. Additional research has demonstrated that both men and women show strikingly poor ability to predict in advance which

characteristics of their speed-dating partners will inspire their romantic desire at the events. In other words, people may not know what they initially desire in a romantic partner.

Conclusion

Although speed dating is only a decade old, it has already substantially influenced the relationship initiation process for millions of singles and the scientific methodology employed by scholars of romantic attraction. It will be interesting to see whether speed dating's popularity continues to expand over the next decade and whether speed dating proves more or less effective than other methods at spawning meaningful, long-term romantic relationships.

STAGE THEORIES OF RELATIONSHIP DEVELOPMENT

Theories of relationship development try to explain how partnerships change over time. Such theories highlight the dynamic process of evolution across

the life span of relationships. *Stage models* are one class of theories of relationship development. Stage models propose that relationship development occurs as a succession of discrete phases. This entry identifies core assumptions of stage theories, describes examples, and evaluates their strengths and weaknesses.

Assumptions of Stage Theories

One assumption of stage theories is that relationship progression is marked by a series of delineated phases that partners must negotiate over time. A *stage* is an idiosyncratic period in the life span of a relationship that is noticeably different from adjacent periods. According to stage theories, partners experience a unique constellation of thoughts, feelings, and behaviors in each phase. Stage theories seek to (a) identify the phases that occur across the trajectory of relationship development and (b) describe the defining attributes of each phase.

A related assumption is that relationship development is punctuated at irregular intervals by events that transform the nature of the partnership. Stage theories portray relationship progression as sporadic, abrupt, and revolutionary. They argue that relationship-transforming changes occur at irregular intervals. Although stage theories recognize that later phases are linked to previous ones, they do not require adjacent stages to resemble one another.

Major Stage Theories

Many stage theories exist in the literature. Although they are united by common assumptions, the theories differ in the number and nature of stages they identify. The following subsections summarize prominent stage theories in approximate chronological order of their origin.

Wheel Model of Love

The wheel model of love, advanced by Ira Reiss, describes four stages in romantic relationship formation. During the *rapprochement stage*, individuals establish understanding and common ground. Next, in the *self-revelation stage*, partners engage

in self-disclosure to convey private information about themselves. This self-disclosure prompts the *mutual dependency stage*, during which partners provide important rewards for one another. The model asserts that couples who successfully negotiate the rapport, self-revelation, and mutual dependency phases enter the *intimacy need fulfillment stage*. This stage is when partners feel romantic love for each other. Thus, the wheel model uses a four-stage structure to depict how relationships progress from acquaintance to romantic love.

Filter Theory of Relationship Development

The filter theory of relationship development, constructed by Alan Kerckhoff and Keith Davis, argues that romantic couples must satisfy three filters en route to marriage. First, individuals appraise the extent to which potential partners possess *desirable social characteristics*, such as ethnic background, religious beliefs, and socioeconomic status. The filter theory contends that people will form a relationship with a partner who meets or exceeds their standards. Couples encounter a second filter when they begin to embark on a relationship. People assess their *similarity of attitudes and values* at this stage. If partners conclude that their perspectives are enough alike, the *need complementarity* filter becomes salient. Individuals evaluate whether their partner is capable of fulfilling their long-term needs. Accordingly, the filter theory identifies social characteristics, attitude similarity, and complementary needs as filters that determine relationship progression.

Stimulus-Value-Role Model

Bernard Murstein's stimulus-value-role model expands the filter theory by incorporating principles of social exchange. During the *stimulus stage*, people form romantic relationships with partners who possess rewarding characteristics, such as physical attractiveness, intelligence, and agreeableness. Once individuals have selected a romantic partner, they progress to the *value comparison stage*, where they examine the degree of compatibility between their values. Self-disclosure increases as partners exchange information to assess their similarity. During the *role compatibility stage*, people evaluate their mate's potential to fulfill

their role expectations into the future. Although individuals probably conduct stimulus, value, and role assessments throughout the life cycle of romantic relationships, the model argues that one reward filter is most relevant to each stage.

Premarital Dyadic Formation Framework

The premarital dyadic formation framework, proposed by Robert Lewis, identifies six processes that partners must fulfill as romantic relationships develop. First, individuals perceive *similarities* in their backgrounds, interests, and preferences. Next, people establish *rapport* within the relationship. During the third stage, partners engage in *self-disclosure* to reveal intimate information about themselves. Fourth, individuals empathize with each other's views in the *perspective-taking* stage. The fifth stage, *interpersonal role fit*, requires partners to evaluate how well they will complement each other over the long term. During the final stage, *dyadic crystallization*, people build commitment and integrate their routines. The premarital dyadic formation framework argues that partners must successfully complete each process before proceeding to the next one.

ABCDE Model of Relationship Development

According to George Levinger's ABCDE model, relationships develop and decay in five stages. During the *acquaintance stage*, people evaluate the attractiveness, availability, and desirability of potential partners. The *building stage* occurs when individuals assess their compatibility, increase their involvement, and discover their similarities. The *continuance phase* involves mutual commitment, expanded investments, increased love, and heightened predictability. As couples grow apart during the *deterioration phase*, they place more emphasis on independence, focus on individual outcomes more than joint outcomes, and have difficulty communicating effectively. During the *ending stage*, people cultivate alternative identities and begin new partnerships. The ending stage encompasses relationship termination.

Staircase Model of Relationship Development

Mark Knapp posited a staircase metaphor to describe the process of coming together and

coming apart. Five stages depict relationship formation. During the *initiating stage*, individuals seek to make a good impression and reduce uncertainty about each other. Their communication is cautious and conventionally scripted. During the *experimenting stage*, partners exchange demographic information, engage in small talk, and search for common experiences. This stage is marked by casual, relaxed, and pleasant communication. The *intensifying stage* involves a heightened awareness of the relationship. People engage in personal self-disclosures, employ informal forms of address, coordinate their behavior, and express their affection. During the *integrating stage*, individuals become a single unit often by sharing their responsibilities and integrating their social networks. Their communication accentuates togetherness and promotes understanding. The *bonding stage* occurs when partners complete a public ritual that formalizes their commitment (e.g., engagement, marriage, civil union). The bonding stage is the highest point of relationship development.

Five stages of Knapp's model portray relationship decline. The *differentiating stage* happens when people start to focus on their differences rather than their similarities. They assert their independence, perhaps through complaining or arguing. During the *circumscribing stage*, the relationship may appear healthy to outsiders, but partners limit the amount and depth of communication. They avoid topics that will spark conflict and instead discuss superficial issues. During the *stagnating stage* individuals are pessimistic about their ability to engage in pleasant interaction. They evade talking about the relationship because they do not believe that change is possible. The *avoiding stage* is marked by physical and emotional separation between partners. Individuals try to disentangle each other from their lives. During the *terminating stage*, one or both partners decide to stop communicating altogether. The end of the relationship may occur as a slow drifting apart or an abrupt termination.

According to the staircase model, relationship progression can involve forward movement, backward movement, and within-stage movement. Movement is always to a new location because people experience repeated stages differently. Although stages can be skipped, movement is typically orderly

and sequential. Fuzzy boundaries surround the stages because some behaviors overlap.

Family Development Theory

Family Development Theory contends that families experience predictable shifts in composition over the life cycle. The theory defines stages as family structures comprised of unique roles and behaviors. Initial versions of the theory concentrated on the trajectory of the traditional family form, but more contemporary renditions accommodate both nontraditional family forms and heterogeneous trajectories.

Family Development Theory argues that families progress from a qualitatively distinct stage to a transformative event to another qualitatively distinct stage. Transformative events include marriages, births, job changes, geographic moves, divorces, and deaths. When transformative events occur, family members shift their roles in response to the changes. Family development theory suggests that progression is predictable by the nature of the previous stage and the length of time the family spent in it.

Structural Helix Model

The structural helix model was created by Richard Conville. The model proposes that relationships cycle through stages by repeating similar, but not identical, experiences. It argues that relationships undergo four phases defined by two competing tensions: (1) the tension between security and alienation and (2) the tension between disintegration and resynthesis. The *security stage* involves pleasant and satisfying interaction between partners. During the *disintegration stage*, people notice, observe, and question their involvement in the relationship. The *alienation stage* occurs when one or both partners reject their roles within the partnership. During the *resynthesis stage*, individuals renegotiate and redefine their relationship. The structural helix model assumes that relationships continually cycle through these phases over their life span.

Strengths, Weaknesses, and Directions for Future Theorizing

Like all theories, stage models possess strengths and weaknesses. One strength is that stage

theories are richly descriptive. They provide detailed information about what people typically think, feel, and do across the trajectory of relationships. A second strength is that stage theories highlight the transformations that relationships undergo over time. Indeed, they offer considerable insight into how critical events permanently change the complexion of relationships.

Stage theories also have limitations. One weakness is that they do not pinpoint exactly *when* relationships will progress from one stage to another. Another limitation is that they are vague about *what* sparks movement between phases. Indeed, they are relatively silent about the circumstances that mark the end of one phase and the beginning of another. A related criticism is that stage theories do not identify *why* progression occurs. In fact, stage theories are more descriptive than explanatory. Other theories try to avoid these limitations by focusing on how variables like intimacy, commitment, self-disclosure, and uncertainty shift incrementally over time.

A direction for future research is to clarify whether relationship development is linear or cyclical. For example, the wheel model of love and the filter theory of relationship development suggest that relationships progress linearly through a fixed sequence of stages. In contrast, the staircase model and the structural helix model argue that relationships progress through stages in a cyclical fashion. This issue is the subject of considerable debate and remains unresolved.

STALKING

Stalking, also referred to as criminal harassment, is a pattern of unwanted pursuit, intrusion, or harassment that causes a reasonable person fear or sense of threat regarding self or family. Given that a significant portion of stalking emerges from prior relationships, and that many stalkers seek reestablishment or enhancement of intimacy, it is closely related to issues of courtship, relationship breakup, and disjunctive or asymmetric types of relationships. When unwanted stalking and stalking-like activities are explicitly intended to reestablish intimacy with the former partner, it is referred to as obsessive relational intrusion, unwanted relationship pursuit, or obsessive relationship pursuit. The history, nature and prevalence, processes, effects, and forms of coping with stalking are examined in this entry.

History

Different jurisdictions and statutes specify different features, but there are several common conditions of stalking. There must be a course of conduct or pattern of behavior that typically requires that more than one behavior is involved

across more than one time and place. The behavior must be unwanted. The characterization of harassing, pursuing, intrusive, or violent behaviors indicates that the behaviors are not forms of protected speech and serve no other legitimate purpose such as sales or picketing. In some laws, this means that the pattern of behavior must be intended to cause fear. Some statutes clarify the requirement that the threat is credible, indicating that even if the threat is not imminent, it is intended to cause fear.

The process of stalking has been identified in ancient narratives, but its modern representation has been closely tied to Hollywood characterizations of the stalker in violent dramas (e.g., *Play Misty for Me*, *Cape Fear*, and *The Fan*). Stalking first became a crime in 1990 in the state of California. Within a relatively short time after the 1990 law, dozens of state and national jurisdictions passed legislation criminalizing this conduct. Stalking laws recognize the possibility that a course of conduct may not involve actual communicated threats, but as a collective pattern of behavior may amount to a threatening experience. Stalking often involves a campaign of writing letters; making telephone calls; showing up at work, at school, or at a place of worship; waiting on a doorstep; leaving odd gifts; leaving tokens on a car windshield; and other such intrusive attempts at contact. If these last for months, or even years, it is the collective impact of such behavior that becomes threatening in its relentless persistence and deviance in the face of clear messages to cease and desist.

Nature and Prevalence

Research across many studies and countries indicates that 75 to 80 percent of stalking emerges from some type of preexisting relationship, and approximately half of stalking cases represent the vestiges of a previously romantic relationship. Studies vary considerably in their methodologies and populations and, thus, their estimates of prevalence. Conservatively designed studies indicate that less than 5 percent of men and 6 to 12 percent of women will be stalked in their lifetime, whereas many other studies indicate that approximately 17 percent of men and 25 percent of women have been stalked, and higher percentages

of both have experienced unwanted relationship pursuit. Research indicates that approximately 75 percent of stalking victims are females, and approximately 75 percent of stalkers are male, with the vast majority of stalking being both heterosexual and within ethnic group. In contrast, studies of unwanted relationship pursuit, especially studies of college samples, tend to find little evidence of sex differences.

Stalking and unwanted relationship pursuit display considerable behavioral variety, but descriptive meta-analytic research identifies the following general strategies. Hyperintimacy behaviors are forms of excessive or deviant courtship and flirtation. Contact behaviors represent attempts at mediated (e.g., e-mail, instant messaging, telephone) or face-to-face interaction. Surveillance behaviors involve synchronizing schedules, monitoring, and following and keeping track of a person. Invasion behaviors reflect attempts to enter the property or personal space of a person or illegitimately obtain that person's possessions or information. Given the rapid evolution of technologies for contact and surveillance, the term *cyberstalking* has emerged to describe the use of GPS, hidden cameras, the Internet, and other media for unwanted pursuit. Harassment and intimidation behaviors are patterns of activity that corrupt or threaten a person's self-concept, reputation, or economic health. Coercion behaviors are messages that communicate a threat, whether to self or others, pets, family or friends, property, job, sexual security, or life. Violence is any action that attempts to or actually causes physical harm to a person, property, or associates. Across studies, approximately a third of stalking cases involve violence, and over half when the prior relationship was sexual in nature. Finally, proxy stalking is the use of intermediary parties for any of these other forms of pursuit and harassment.

Stalkers are considered a relatively heterogeneous population. Theories tend to conceptualize stalking as an individual pathology, such as borderline personality disorder or erotomania (i.e., the delusional belief that another person is in love with self), as a product of personality traits such as preoccupied or insecure attachment, or as a product of disordered cognitive information processing. Other theoretical approaches are more cultural in nature, proposing that stalking is an extension

of distorted gendered societal expectations for the process of courtship. To the extent that societies create socializing and media images promoting courtship persistence in the face of rejection and idealize romantic visions of the perfect partner, people may pursue prospective partners beyond the pale of appropriate courtship.

Effects and Coping

Research indicates that being the victim of stalking is significantly associated with a variety of deleterious states, including impaired physical health, physiological health, psychological health, emotional health, social health, spiritual health, and economic health. A few studies indicate that small percentages of people who have experienced unwanted relationship pursuit also attribute ambivalent feelings to the experience, such as feeling attractive or more resilient and self-sufficient.

Victims attempt to avoid or deter such harassment in a variety of ways. Victims may move away from the harassment by attempting to relocate, alter schedules, and become more anonymous. Victims may move with the harasser by attempting to negotiate a mutually acceptable definition of the relationship or acceptable boundaries of interaction. Victims may move against the harasser by deterring, threatening, or attempting to harm the pursuer. Victims may move within themselves by focusing on self, meditating, seeking spirituality, redefining the experience, seeking distraction, or seeking self-actualizing activities. Victims may move outward to sources of social support, consultation, or expert or professional intervention, including victims groups or law enforcement. The fact that the average case of stalking lasts for more than 1 1/2 years suggests, however, that many of these coping strategies are attempted, and few are generally effective. There appears to be no typical way in which stalking eventually ends. The most common reasons reported for why stalking ends include asking or telling the pursuer to stop, contacting police, moving away, entering a new relationship, the stalker being arrested, a restraining order, and taking a variety of security measures. No particular sequence of these coping responses has yet been demonstrated consistently to provide the best protection, although expert advice

consistently advises tactics in the moving away and moving outward categories.

STEPFAMILIES

Stepfamilies are a prevalent family form in the United States, with one in three American children living in a stepfamily during their childhood. Stepfamilies represent a broad and complex set of members and circumstances, growing from combinations of first, second, or third (or more) adult cohabitations and/or marriages. The children that adults bring to stepfamilies may come from one or more of their previous relationships or may result from the union of the current parent and stepparent. Children may be living in the stepfamily full time or part time, ranging from regular to no contact with their nonresidential parent. Due to the increasing number of stepfamilies, research on this family form has multiplied, springing from clinicians working with stepfamilies to include scholars from a variety of disciplines, including communication studies, family studies, psychology, sociology, and social work. To follow, this entry describes how stepfamilies are often viewed from a deficit model. The remainder of this entry focuses on stepfamily development and types, stepfamily relationships, and stepfamily boundaries.

Deficit Model

Because of the many complexities of stepfamilies, they are a challenging type of family to understand

and study. Lawrence Ganong and Marilyn Coleman pointed out that many clinicians and researchers use what they called a deficit comparison model when studying stepfamilies. This means that stepfamilies are often compared to traditional, intact families and found lacking or problematic.

Cultural and societal stereotypes, especially those related to biological sex and gender, also include how stepfamilies are viewed and understood. For example, the stigma of the wicked stepmother continues to permeate both classical children's tales such as *Cinderella*, *Hansel and Gretel*, and *Snow White* and more modern, contemporary media images of stepfamily life. Not surprisingly, researchers have found that this stigma negatively influences stepmothers' attempts to relate to their stepchildren despite their attempts to challenge the wicked stepmother myth. Stepchildren who identify a stepmother as their primary stepparent often view their stepfamilies as functioning less well than stepchildren who identify a stepfather as their primary stepparent. The effects of stepfamily living on children also depend on the biological sex of the child, although these findings are somewhat less clear. Some researchers have found that boys in stepfamilies have more internalizing and externalizing behavior problems than girls, whereas others have reported that girls have more adjustment problems than boys, but only when living with stepfathers. Clearly, societal, cultural, and gendered beliefs about stepfamilies are likely to influence not only more general attitudes toward stepfamilies as a social unit, but also beliefs about the role of the stepparent and the communication dynamics that emerge among same-sex and cross-sex dyadic partners in the stepfamily system. Again, the deficit model may be in place when stepfamilies are compared to intact families, rather than on their own terms. Many scholars have called for viewing stepfamilies as a unique family form on their own terms and trying to understand their strengths as well as their challenges.

Stepfamily Development and Types

In an effort to understand stepfamily dynamics, researchers and clinicians have advanced a number of developmental models and taxonomies to classify stepfamilies and to examine differences in

family functioning and communication among different stepfamily types. For example, Patricia Papernow proposed a seven-stage model of stepfamily development highly regarded in clinical circles. Stepfamily development includes the (a) fantasy stage characterized by unrealistic and idealized expectations, (b) immersion stage in which challenges of stepfamily life confront expectations, (c) awareness stage in which members attempt to make sense of their confusion, (d) mobilization stage in which members attempt to manage difficulties, (e) action stage where new agreements create a foundation on which to build, (f) contact stage in which positive emotional bonds form, and (g) resolution stage where a more solid stepfamily unit emerges. Papernow argues that seriously troubled stepfamilies typically do not advance beyond the mobilization stage.

Taking a different approach, communication scholars have investigated the relational turning points and communication processes and messages that differentiate strong stepfamilies from those struggling to develop. Leslie Baxter, Dawn Braithwaite, and John Nicholson identified five stepfamily trajectories, or developmental pathways, using key turning points that transpired during the first 4 years of the stepfamily as members charted how much they "felt like a family." Five pathways emerged: (1) accelerated pathways where stepfamilies moved quickly toward 100 percent feeling like a family; (2) prolonged pathways where stepfamilies progressed to higher levels of feeling like a family, with some up-and-down experiences; (3) stagnant pathways where stepfamilies "never took off" and failed to feel like a family; (4) declining pathways where stepfamilies began with a high level of feeling like a family and then declined to zero usually due to overly high expectations for stepfamily living; and (5) high-amplitude turbulent pathways where stepfamilies experienced dramatic up-and-down shifts in feeling like a family. These findings can help stepfamilies understand that there are multiple ways to become a stepfamily, as well as pathways to avoid. Even for more positive trajectories, there is no one right path that will fit all stepfamily experiences.

Other researchers have examined differences in stepfamily functioning based on communication strategies, activities, and patterns that facilitate stepfamily development and healthy

stepparent–stepchild relationships. Tamara Golish examined stepfamily development using systems theory to identify communication strengths and weaknesses that differentiate strong from struggling stepfamilies. Strong stepfamilies were more likely to spend quality time together, establish unity through enacting family rituals, engage in everyday talk, and manage conflicts through family meetings, open communication, and compromise.

More recently, Paul Schrodts identified five different stepfamily types based on stepchildren's reports of stepfamily functioning and the stepparent relationship. Low levels of family dissension and avoidance and relatively high levels of family involvement, flexibility, and expressiveness characterized bonded and functional stepfamilies. In bonded stepfamilies, stepchildren were more likely to refer to their primary stepparent as "Mom" or "Dad," whereas in functional stepfamilies, stepchildren were more likely to view the stepparent as a friend. The third type, ambivalent stepfamilies, was characterized by stepchildren's general ambivalence toward the stepfamily, with above-average levels of stepfamily dissension and avoidance and slightly below-average levels of stepfamily involvement, flexibility, and expressiveness. The final two types, evasive and conflictual stepfamilies, were both struggling with stepfamily life, although for different reasons. Evasive stepfamilies experienced a lack of open communication between stepparent and stepchild and in the stepfamily as a whole, and conflictual stepfamilies had higher levels of expressiveness and dissension and the lowest levels of stepfamily involvement and flexibility. Using this approach, Schrodts found that meaningful differences emerged in perceptions of communication competence and mental health symptoms among stepchildren in all five stepfamily types.

Stepfamily Relationships

Most researchers have focused on the subsystems and dyads within the stepfamily home, starting with the marital couple. Stepfamilies often form quickly as couples cohabit or remarry relatively soon after they start dating. Marilyn Coleman, Lawrence Ganong, and Mark Fine examined studies of the quality of remarried relationships, finding mixed results, with some couples more satisfied

and others less satisfied than first marriages. More conflict and disagreement tends to exist in remarriages, especially over stepchildren. Overall, marital quality is lower when the adults both bring children to the relationship. Kenneth Cissna and colleagues stressed that remarried couples must establish the credibility of the stepparent in the eyes of the children by communicating a unified front. All this is complicated by the relationship with the nonresidential parent, which may help or hinder development of the stepparent role.

Researchers have studied the triangulation of relationships that may occur among the parent, stepparent, and stepchild(ren). Stepparents who work at creating and maintaining close relationships with their stepchildren are more likely to see a positive response to their efforts. Most stepchildren report that they want a close relationship and to be open with their stepparent; at the same time, they often feel disloyal to their nonresidential parent if a close relationship forms. Parental authority and discipline are often challenging for a stepparent. Stepchildren reveal that they desire guidance and discipline from stepparents, yet they often remain resistant to these efforts. Studies on stepchildren's psychological and social adjustment have produced mixed results. Overall, researchers have discovered that stepchildren are more at risk for problems (e.g., depression, lower school achievement, and drug abuse) than children in first-marriage homes, although the differences tend to be relatively small and about on par with children from single-parent families.

Of all the relationships in the stepfamily, stepsiblings have been studied the least. Although parents and stepparents are coming together out of love, stepsibling relationships are most often involuntary. Stepsiblings are dealing with the loss of their original family and are more likely to be disengaged emotionally. Researchers are studying ways that parents can help stepchildren reduce conflict and feel more positive about their stepsiblings and the stepfamily as a whole.

Stepfamily Boundaries

Although researchers have examined the various relationships within the stepfamily household, they are also studying boundaries and relationships

with those outside of the household. One important relationship is the postdivorce couple coparenting the children. Some coparents are able to negotiate healthy working relationships for the sake of the children, whereas others are continually acrimonious. One concern for children is being “caught in the middle” between their parents. Although children want to know what is happening with their parents and be included in decisions that affect them, often parents tell them more than they want to know, especially when criticizing the other parent. Many parents avoid contact with each other and obtain information about their coparent or pass along information (e.g., about finances, schedules, or a new romantic relationship) through children. Whereas parents often report this to be an efficient and less conflict-prone way to communicate, children often find being in the middle difficult. On the positive side, scholars are looking at how to help children to feel centered in the family without feeling caught between their parents.

Researchers are also studying the complexities of the relationship of children and their nonresidential parent. Children’s contact with their nonresidential parent is greatly influenced by the relationship between this parent and their former spouse. Although most children desire a close relationship with their nonresidential parent, they often find it challenging due to distance, the time it takes to interact enough to remain close, and the loyalty conflicts they experience while trying to have a relationship with both parents.

The relationship with extended family members is also important to stepfamily members. This includes members of the “old” extended family (e.g., grandparents, aunts, uncles, and cousins), as well as stepchildren and stepsiblings from previous marriages. It can be difficult to figure out who is part of the family and who should be included in family rituals such as graduations, weddings, and holidays. While adjusting to the new stepfamily, members must adjust to new relationships with extended family and friends who are now part of their lives. To date, the research on the “old” and “new” external family has been limited.

Recently, scholars have also begun to consider the various ways in which stepfamily functioning differs when the stepfamily is formed after the death of a parent. Although our understanding of

stepfamilies formed postbereavement is partial at best, there is preliminary evidence to suggest that a deceased parent fundamentally alters the experience of stepfamily life for remarried adults and stepchildren in these stepfamilies.

STORYTELLING

Storytelling is the act of constructing an account of a set of events that communicates who was involved,

what happened, where and when it occurred, why the events happened, and their significance. Although storytelling may occur about fictional events, this entry focuses on storytelling about autobiographical experiences. Researchers across a wide variety of disciplines and subdisciplines examine storytelling and its role in relationships.

Building and Maintaining Relationships Through Stories

Storytelling helps to build and maintain social relationships over time. For example, people exchange stories in the beginning of a relationship because doing so is a way to get to know one another by sharing important information about the past. As relationships become well established, two different features of storytelling activities have been examined.

First, people develop stories that characterize their relationships. In this work, the relationship is the context within which stories develop and change. For example, couples often share stories about “how we met” or about important relationship experiences with others, which can restore or enhance feelings of warmth and intimacy with the partner even when the partner is not present. Such stories develop over time within relationships as partners practice telling them over and over again and incorporating new events into their story. As pairs and families interact and engage in storytelling, one person may take on the primary role for telling a particular story, with others in the family providing helpful commentary. Research shows that narrating a family story allows a person to make sure that other family members share his or her memory and perspective on an important family event. As relationships become truly well established, as in long-term marriages, the way people share responsibility for telling relationship stories can evolve. Stories are also implicated in the dissolution of relationships, as people build an account of their relationship that justifies and explains why the relationship ended.

Second, some relationship stories are more adaptive than others. There is good evidence that telling stories that emphasize closeness and positivity, and perhaps even idealize the relationship partner benefit the longevity and quality of a relationship over time.

Idealizing one’s partner may help people to get through imperfect periods in a relationship, give partners the benefit of the doubt, and facilitate working together in stressful transitions, such as becoming parents. Creating stories that idealize one’s partner is one way that idealized images can be created and maintained, and thus provide these benefits. Telling a more complete story about the ending of a relationship also is associated with a greater sense of control and recovery from a breakup.

Storytelling as a Context for Fulfilling Relationship Functions

People in relationships also exchange their individual stories. This kind of storytelling has many functions and is seen in nearly all relationships—parent–child, friend, romantic, and family. This type of storytelling provides the partner with information about the person’s experiences, thus maintaining intimacy and connections. Because one of the most common patterns in the exchange of stories is to relate series of common experiences, this type of storytelling creates intimacy via both sharing and building a sense of a similar history. People also use this type of storytelling to seek validation of their beliefs about themselves and the world, to seek emotional support and reassurance, and sometimes to resolve problems in other parts of their lives. For example, spouses sometimes argue with each other about the stories they tell. Such disputes are less likely to concern what happened than to concern what the experience meant—or its larger significance. Similarly, parents and children don’t always concur about how the child felt during a particular experience—with the child telling the story about sadness, for example, and the parent telling it with an emphasis on anger. In both cases, the process of storytelling allows the pair to reach a common understanding of experiences that, under ideal circumstances, includes and validates multiple perspectives on a single event.

Storytelling and Socialization

Broadly, storytelling is a way of passing on culturally shared beliefs and ideas all over the world, and psychological studies have examined how this

process looks in parent–child relationships. Parents help structure the telling of stories and personal experiences for young children, effectively teaching them how to think about and tell personal events. This process varies across individual families, as well as by culture and gender. For example, American mothers vary in how they help children tell stories. When mothers help young children recall richness and detail in stories, children eventually produce more detailed, rich narratives of their own. Similarly, parents vary in whether they emphasize providing information about time and place in stories or help children create coherent and emotional stories. Over time, children whose parents were more likely to emphasize time and place in stories, or whose parents created more coherent and emotional stories, also come to tell better stories.

Cross-cultural comparisons also support the idea of storytelling as fulfilling socialization goals. American parents tell stories with their children more often and differently than do Asian parents. American parents' storytelling style tends to be more detailed and focused on the individual child when contrasted with Asian parents, whose reminiscing style tends to focus on moral behavior and the context of the larger community. As a result, American children produce longer, more detailed, self-focused narratives than their Asian counterparts. These differences may reflect the larger cultural emphasis on American individualism versus Asian collectivism.

Gender roles and expectations are also transmitted through storytelling. For example, parents tend to discuss emotions more with daughters than with sons. By the time they are school age, girls' stories contain more emotional content than do boys,' consistent with Western stereotypes of men as less emotional than women. Other work also suggests that peer storytelling, as well as parent–child storytelling, expresses and socializes conceptions of masculinity and femininity. Collectively, these variations (individual, cultural, and gendered) in storytelling have implications for variation in the way that individuals remember their past and conceive of themselves; this is the way in which storytelling creates a *self-in-relation*.

In summary, storytelling is a relatively new area of focus within the study of human relationships, but one that complements and extends many existing findings about the way relationships

develop and the way relationships influence individual development.

STRANGE SITUATION

The *Strange Situation* is a semistructured laboratory procedure for assessing individual differences in infant attachment security. It provides information about an infant's confidence in its caregiver's availability and responsiveness and about its skill at using the caregiver as a secure base from which to explore and as a haven of safety in naturalistic settings. Psychologist Mary Ainsworth (1913–1999) developed the Strange Situation procedure to illustrate the influence of context on infant attachment behavior and to measure individual differences in infants' attachment security. The procedure consists of eight brief episodes designed to simulate exploratory behavior and responses to separation and reunion that are part of an infant's everyday life. The Strange Situation is not a test of whether the infant or child is attached to the mother or of the "strength" of the

infant–caregiver bond. This entry discusses the background, procedure, scoring, and developmental significance of the Strange Situation.

Psychoanalysts were among the first to emphasize the importance of early experience on personality development. They tended to view the infant and young child as needy and dependent, seeking its mother as a means through which to reduce instinctual drives. Modern attachment theory (sometimes referred to as ethological attachment theory) stems from British psychoanalyst John Bowlby's important reformulation of this traditional view. He emphasized that infants and young children are both competent and inquisitive about their surroundings and that the hallmark of the child–parent bond is using the mother as a “secure base from which to explore.” Ainsworth worked closely with Bowlby in developing this perspective and grounding it in careful observations of infants and mothers in naturalistic settings. Reflecting this emphasis on naturalistic observation, they often described their work as an ethological attachment theory.

While a professor at Johns Hopkins University, Ainsworth, in 1962, undertook a detailed longitudinal study of 23 infant–mother dyads systematically observed in their homes from 3 weeks to 54 weeks of age. The Strange Situation procedure was developed as a semistandardized adjunct to the naturalistic observations made in this study. The goal was to confirm Bowlby's view that infants, instead of focusing primarily on internal drive states, are highly motivated to explore their environments and that confidence in the mother's availability and responsiveness makes her a valuable secure base from which to conduct such explorations, as well as a haven of safety to which the infant knows it can retreat when necessary.

The Strange Situation Procedure

The Strange Situation procedure consists of eight episodes: 1 minute to introduce mother and infant into the experimental room and then seven 3-minute test episodes. The entire procedure is recorded on videotape.

Episode 1 (Introduction to the room, 1 minute). Mother and baby enter the room. Mother sits on a chair. Baby plays with toys.

Episode 2 (Free play). Mother sits quietly. Mother responds to baby's bids for attention or interaction. This provides a baseline against which to compare baby's play in subsequent episodes.

Episode 3 (Stranger enters). Female research assistant enters and is seated on a chair. She sits quietly for 1 minute; she talks to mother for 1 minute and then begins to engage the baby. This episode provides a gentle introduction to the “stranger.” It provides an opportunity to observe the baby's interest in and style of approaching the new person. The stranger is not introduced in order to frighten the baby. Indeed, babies are less likely to cry when left with the stranger than when left alone.

Episode 4 (First separation). A knock on the wall signals mother to leave room. She is instructed to say “I'll be right back” and to leave in a manner familiar to the baby. Once she has left, she joins the experimenter observing the infant and stranger through a one-way window. Fewer than 50 percent of healthy home-reared infants cry in response to this separation. If the baby cries hard for a full minute, the episode is abbreviated.

Episode 5 (First reunion). Mother knocks on the door from outside, calls baby's name, and enters. She pauses just inside the door and extends her hands, offering the baby a chance to approach or be picked up. If the baby is crying, she can pick the baby up and comfort it as she would in other contexts. Many babies simply greet the mother across a distance, in which case she returns the greeting and returns to her chair. Once the reunion is established, the stranger leaves the room.

Episode 6 (Second separation). A knock on the wall signals mother to leave room as in the first separation. She exits and joins the experimenter observing the infant through the one-way window. Infant is alone. Approximately 50 percent of healthy home-reared infants cry in this episode. If the infant cries hard for a full minute, this episode is abbreviated. Importantly, crying is not an indicator of the infant's attachment behavior at home and is not the focus of Strange Situation scoring.

Episode 7 (Stranger enters). Stranger returns to the room. If the baby is playing, she sits quietly responding to bids for attention or interaction. If the baby is crying or seems distressed, she offers comfort in the form of holding, physical contact, soothing words,

or by offering toys. If the baby cannot be comforted, this episode is abbreviated. This episode provides an opportunity to observe the baby's preference for the mother as a source of comfort.

Episode 8 (Second reunion). Mother knocks on the door from outside, calls baby's name, and enters. She pauses just inside the door and extends her hands, offering the baby a chance to approach or be picked up. If the baby is crying, she can pick the baby up and comfort it as she would in ordinary contexts. Otherwise, she acknowledges any greeting and returns to her chair. She remains responsive to any bids for contact or interaction.

Normative and Individual Difference Results

Ainsworth examined both normative behavior averaged across the entire sample and individual differences in patterns of response. The normative results confirmed Bowlby's view that infant attachment behavior is characterized by a balance between exploration away from the mother and intermittent proximity and contact seeking. Instead of being controlled by the ebb and flow of internal drive states, infant behavior proved exquisitely sensitive to context. Exploration of the unfamiliar environment predominated when the mother was available. It declined dramatically in quantity and quality when she was absent. Although the stranger's presence often diminished distress, it rarely did so completely and rarely led to full recovery of active exploration. Mother's return elicited proximity and contact seeking, which in most cases promptly reduced distress and tipped the balance in favor of renewed exploration.

Patterns of Attachment

Overlaid on these normative patterns, Ainsworth noticed distinct patterns of individual differences. Infants who were most effective at using the mother as a secure base during Ainsworth's home observations (approximately 70 percent of the sample) actively explored the Strange Situation environment when mother was available, reduced play when she was absent, actively greeted or approached when she returned, and readily returned to active exploration. These infants were designated Group B (secure, confident in mother's

availability and responsiveness). The remaining infants, most of whom had been less effective in their secure base behavior at home, were designated insecure (less confident in mother's availability and responsiveness). They fell into two distinct patterns. Insecure-avoidant infants (Group A) may or may not have cried during the separation episodes, but were markedly avoidant of the mother during the first minute of the separation, ignoring her greeting, approaching her and then turning away, or playing distractedly with a toy while she tried to interact. Insecure-resistant/ambivalent infants (Group C) were in every case distressed by separation and yet responded with either anger or passivity, or both, when she returned, typically continuing to cry, falling limp when picked up, calming when held, and then struggling to be put down only to cry again without reaching for further contact. The validity of these classifications as indicators of the quality of the infant-mother bond is based on their links to secure base behavior at home. This link has been replicated in cross-cultural studies and is an important criterion when the Strange Situation is used in new populations.

Recent research on children at significant social or physiological risk for later developmental problems led to the discovery of a fourth, "disorganized" (Group D) pattern of Strange Situation behavior. Infants and young children in this group tend to behave inconsistently from episode to episode and often show "odd" behavior, such as freezing, odd postures, or other responses antithetical to secure base behavior during reunion episodes.

Validity

Infant attachment patterns are largely independent of infant temperament measures, and the fact that attachment classifications with mother and with father are not significantly correlated indicates that the Strange Situation assesses the child's relationship with the specific person who accompanied them in the Strange Situation, not a generalized personality trait or behavioral style of the infant. Numerous well-replicated studies have demonstrated that the ABCD patterns of attachment can be quite stable throughout childhood and are significantly related to analogous patterns

of insecure-dismissing, secure-coherent, insecure-preoccupied, and unresolved attachment assessed using the Adult Attachment Interview. Adult attachment classifications are, in turn, significantly related to secure base use and support in marriage, to important aspects of childrearing, and to care for elderly parents, as well as to personality structure and adjustment.

For observations in the Strange Situation to be useful, the infant must be at least 1 year old, an age at which most healthy home-reared infants have established a bond to one or a few primary caregivers, have good locomotor skills, and have achieved the level of object permanence necessary for mother's departure to be meaningful. The procedure can be conducted with toddlers up to 2 years of age and, with minor adaptations, with children as old as 5.

The Strange Situation is primarily a research tool. It provides useful information in research comparing one group of infants with another. Although proven useful for evaluating a variety of enrichment and intervention programs, it may not have the precision necessary for making clinical judgments or custody decisions about individual infants. In addition, both Bowlby and Ainsworth emphasized that expectations about a caregiver's availability and responsiveness are open to revision in light of experience throughout infancy and childhood. That early experience is often predictive of later development does not imply that early experience is destiny.

A 2002 survey of research child psychologists ranked Ainsworth's work with the Strange Situation third among the most revolutionary influences on modern child psychology.

STRESS AND RELATIONSHIPS

When considering the association between social relationships and health, scholars and lay people alike often think about the positive effects that close connections with others can have on psychological and physical well-being. However, relationships can be difficult to establish, conflict can arise, and dissolution can occur. Therefore, relationships come with potential costs; stressors can be ubiquitous in the context of interpersonal processes. For example, the lack of close personal bonds is a significant stressor for many individuals, leading to feelings of loneliness and social isolation. Not all close relationships are harmonious, and those characterized by conflict, criticism, or contempt can serve as a source of stress. Additionally, experiencing the dissolution of relationships through divorce or death is considered among the most stressful life events. Research in health psychology has demonstrated the wide range of negative effects that experiencing stressful situations can have on emotions, physiology, and mental and physical health. Therefore, understanding the role of stress in relationships can help elucidate not only the situations in which social ties can be beneficial, but also when they have negative health consequences. This entry describes the ways in which relationships can function as a source of stress, such as when social relationships are absent or deficient, when social relationships are conflictual, and when social relationships come to an end. These contexts can activate stress-related processes and lead to negative effects on psychological, physiological, and physical health.

Loneliness as a Stressor

Because the presence of social relationships confers a number of benefits, the lack of relationships may act as a stressor. *Loneliness* is a strong feeling of emptiness or social isolation. Lonely people often feel disconnected from others and may find it difficult to form social relationships.

Loneliness is associated with three factors that may influence disease: negative health behaviors (e.g., eating high-fat foods, smoking), insufficient bodily repair processes (e.g., sleep), and increased emotional and physiological reactivity to stressful events. However, the effects of these pathways on disease occur over a long period of time. For example, eating a single high-fat meal does not immediately increase one's risk for cardiovascular disease, but a consistent high-fat diet could have a cumulative negative impact over a prolonged period.

Social relationships may indirectly affect health by influencing lifestyle and health behaviors (e.g., exercising, cessation of smoking). Lonely individuals tend to engage in more health-compromising activities and behaviors than those who have more social relationships because they do not have as many people encouraging positive health behaviors (e.g., eating healthy foods, getting enough sleep) and discouraging the negative behaviors (e.g., restricting smoking and eating fatty foods). Loneliness may also influence normal restorative processes. For example, lonely individuals have poorer sleep efficiency, and during sleep, repair, restorative, and growth processes take place. Additionally, those who are deprived of sleep also experience more negative mood and impaired cognitive functioning. Finally, loneliness may also influence disease by affecting the ways in which people react to stressful situations. Repeated and frequent exposure to stressful situations may be beneficial to a point so that individuals can develop resistance to them, but excessive stress may leave individuals vulnerable to disease. For example, recurrent exposure to stress can create opportunities for people to develop coping strategies to deal with the stressors, but too much stress can be overwhelming and leave people susceptible to developing negative health behaviors or insufficient bodily repair processes, both of which can lead to disease. Having supportive social relationships may buffer individuals against this stress. For example, an

encouraging friend or partner when one is stressed may diminish physiological and emotional reactivity to the stressor.

Stressors Within Relationships

Although in some cases social relationships can provide invaluable resources that protect against stressors, close relationships can also be a source of stress; for example, disagreements and conflicts commonly arise among friends, family, and romantic partners, which can impair physiological functioning and health. A large body of laboratory research has shown that negative or non-supportive interactions with strangers, such as criticism or unhelpful support attempts, can lead to robust increases in stress hormones (e.g., cortisol) and cardiovascular indices (e.g., blood pressure, heart rate). Chronic experiences of conflict and/or consistent exposure to unsupportive others could therefore lead to repeated activation of these physiological systems, which can lead to negative health outcomes.

Other studies have examined physiological reactivity to conflict discussions within a close relationship, such as marriage. In these studies, couples are brought into the laboratory and asked to discuss an area of contention or a problem in their relationship. There is evidence that this type of conflict discussion affects couples physiologically. Couples that exhibited high levels of negative behavior had significantly greater elevations in stress hormones (e.g., cortisol) and decreases in immune system functioning (e.g., natural killer cell activity), compared with couples that had less negative behaviors during the discussion task. Other studies have found that couples that displayed more hostile behaviors took 60 percent longer to heal a wound compared with low-hostile couples; this suggests an association between relationships characterized by hostility and conflict and the *in vivo* functioning of the immune system, which could have profound implications for health. Interestingly, many studies have shown consistent gender differences: Women are more biologically reactive than men to negative marital interaction. The negative behaviors and biological changes exhibited by these couples contain important information

about the dynamics of the marital relationship. For example, research has shown that patterns of biological responses to conflict can predict couples' levels of marital satisfaction and even who gets divorced. Greater increases in adrenocorticotrophic hormone, which boosts the synthesis of cortisol in response to conflict, predicted more troubled relationships 10 years later, and larger elevations in epinephrine (a hormone reflecting sympathetic nervous system activity) during the conflict task predicted divorce 10 years later.

Marital conflict is not just a stressor for couples; it can also affect their children. Conflict in the home as well as harsh, cold parenting styles can lead to a variety of negative effects on children, which can alter their health trajectories. Early childhood environments can alter how one reacts to stressful situations and can predict mental and physical health outcomes over the life span. For example, adults who experienced cold, harsh, or neglectful parenting during childhood show altered physiological stress responses and are more likely to be diagnosed with depression and a wide range of physical health disorders.

Sometimes stressors may not stem from a relationship per se, but from situations faced by the couple, family, or social network. For example, dealing with a child's or spouse's chronic or terminal illness can be an extremely stressful and taxing activity and can have a profound effect on lives of the family, affecting health, economic, and social domains. Caregiving has been associated with higher rates of depression, declines in cognitive functioning, and greater incidence of disease. For example, caregivers reporting high levels of strain exhibit a 63 percent higher risk of mortality compared with noncaregiver controls. This could be due, in part, to changes in the immune system and stress-regulatory systems; a number of studies have shown that caregiving is associated with decreases in immune function and increases in stress-responsive markers.

End of Relationships

Relationship Dissolution

The end of a relationship is a stressor that may greatly affect individuals, both psychologically and physiologically. Few life events bring about

as much psychological distress as relationship dissolution. The process of marital dissolution cannot only increase the level of day-to-day conflict, but can simultaneously reduce the size of social support networks. Individuals may potentially lose the support of shared friends and family who are suddenly no longer part of their social circle. Indeed, compared with married individuals, those who are separated or divorced report experiencing greater levels of psychological stress symptoms such as anxiety, depression, and unhappiness. Separated and divorced individuals have an elevated risk for suicide, auto accidents, mental and physical illness, homicide, and mortality. Divorced individuals also experience significant changes in sleep patterns. One study found that people undergoing marital separation experienced less delta wave sleep (deep, slow wave sleep that is most restorative for the body) than those not experiencing this stressor. Additionally, people whose divorces remained unresolved at the study follow-up continued having lower delta wave sleep and shorter rapid eye movement sleep latency than participants whose divorces were finalized.

Certain resources may facilitate adjustment to divorce or buffer the effects of divorce. For example, people with strong social support networks (aside from their spouse) and high socioeconomic status (e.g., high levels of education and income) tend to adjust to divorce more easily than those lacking these resources. People with high levels of predivorce income are less likely to experience great economic adversities after divorce than their peers who have low levels of predivorce income. High levels of education may also buffer the effects of divorce on individuals, such that highly educated people may have developed successful coping skills through their educational opportunities or may utilize their education to find more lucrative employment opportunities after divorce. Thus, although relationship dissolution can bring about stress and negative feelings, personal resources may buffer against the harmful effects of relationship dissolution.

Bereavement

Experiencing the feelings of loss due to the death of a loved one, friend, or family member is

referred to as *bereavement*. Similar to those coping with relationship dissolution, bereaved individuals may experience other major life changes as well, including adapting to new roles in the family (e.g., becoming a primary caretaker), becoming the sole employed individual in the family, or relocating to a new city. These changes, coupled with bereavement, can make the grieving process stressful.

Bereavement has been shown to be associated with several biological changes. Widows and widowers show changes in sleep patterns and sleep efficiency, which can influence their mental and physical health. Bereavement from the sudden death of a healthy child has been associated with significant decreases in immune functioning. Likewise, some widows and widowers experience decreased immune functioning within the first 3 months following bereavement. Decreased immune functioning may leave bereaved individuals vulnerable to illness. As a result, the stress of losing a loved one can affect mental and physical health, resulting in, for example, increased rates of depression and greater susceptibility to illness.

Conclusion

Individuals can be negatively affected by feelings of loneliness and social isolation, disagreements within relationships, caregiving, and relationship dissolution. Despite the negative consequences that stressful relationships may have on the health of individuals, humans are resilient. For example, people may utilize different coping skills to handle daily and chronic stressors within the context of personal relationships. Much attention has been focused on the pathways in which positive relationships may confer health benefits. To fully understand how stress within relationships “gets under the skin” to affect physiological reactivity and health outcomes, the negative effects of stress must also be examined.

SUBSTANCE USE AND ABUSE IN RELATIONSHIPS

Substance use ranging from nicotine to alcohol to other drugs usually occurs in the context of interpersonal relationships. Even among those who abuse these substances, this activity is rarely solitary, but usually involves other people, including friends, intimate partners, and other family members. This entry discusses the selection of friends and intimate partners with similar substance use patterns and the influence by friends and partners on one's own substance use. The relationship between the use of these substances, particularly alcohol and illicit drugs, and the quality of and conflict within these relationships is also described.

In addressing these issues, the term *substance use* is used to describe use of tobacco, alcohol, or illicit

drugs. When any specific finding pertains primarily to one of these classes of substances, the specific classes are noted. The term *substance abuse* is used to denote the occurrence of social, interpersonal, and/or legal problems associated with the use of substances. Finally, the term *substance dependence* describes a pattern of substance use marked by excessive use, difficulties in quitting, perceived need for the substance, and physiological adaptations (tolerance, withdrawal symptoms).

It is useful to consider two broad issues: (1) the relationship between a person's substance use and the substance use of those in one's social network and (2) the relationship between substance use and the nature/quality of those relationships.

Substance Use and the Social Network

There is often substantial similarity between an individual's substance use and the use by his or her friends and intimate partners. There are two broad explanations for this similarity: influence and selection. Influence refers to substance-using friends and partners leading the individual to change his or her substance use. This may involve peer pressure, in which peers actively encourage substance use, although this is not as common as one might expect. However, influence may encompass other processes, such as associating with peers who use substances, which may lead to changes in norms or expectations about these substances. Influence may also occur because some adolescents view a substance user in a positive light and may use substances to be like that person or because they believe they will be more accepted by their peer group. It is important to recognize that influence may decrease use, rather than only increase use. The second broad explanation—selection—suggests that similarity exists because individuals choose to affiliate with similar types of individuals. Selection may not necessarily be based on substance use per se, but may be based on other risk factors associated with substance use, such as sensation-seeking or tolerance of deviance.

Peer and Own Use of Substances in Adolescence

Much of the early research demonstrating similarity in substance use with peers was interpreted as

peer influence. In the mid-1980s, researchers argued that the impact of peer selection had been underestimated. They noted that research was cross-sectional and could be interpreted as peer selection or peer influence. They also noted that research usually assessed the participant's perception of the peers' substance use, rather than a direct assessment of the peers. Consequently, it was argued that some of the similarity with peers' substance use may have been due to "assumed similarity," in which the adolescent's substance use influenced the perception that his or her peers were using substances.

Throughout the past 20 years, there have been numerous longitudinal studies of adolescent substance use addressing both of these issues. Although some studies have found evidence only for selection or only for influence, most studies have concluded that both processes are important. More recent research has attempted to identify the nature of these processes more precisely. One key point is whether there are factors that increase an individual's susceptibility to select or to be influenced by substance-using friends. In general, adolescents who do not value conventional behavior or who are tolerant of deviant behavior appear to be more likely to select deviant friends and more likely to be influenced by these friends to use substances. In addition, peer influence is strongest among close friends or best friends and is weaker among acquaintances or relationships with high levels of conflict. Adolescents can also be influenced by their sibling and their siblings' friends. Although romantic partners become important in adolescence, there is little research examining their impact on substance use. Finally, although peer substance use is an important influence on adolescent substance use, these effects can be minimized by warm parent-child relationships and parental monitoring of the adolescent's activities and friends.

Peer and Own Use in Adults

Although studies of college populations have examined peers and peer norms, only a few longitudinal studies have examined influence or selection, mostly focused on the transition to college. Similar to adolescence, there is evidence that heavy drinking college students select peers with similar levels of drinking. This occurs with respect to new

friends, but also with respect to becoming involved in the Greek system. For example, individuals who drink heavily before college are more likely to become involved with a college fraternity/sorority than light drinkers. Additionally, involvement with fraternities and sororities is associated with increased drinking and alcohol problems. Finally, particularly in the college years, individuals begin to develop “drinking buddies” (i.e., individuals who get together primarily for drinking and drinking-related activities), and these drinking buddies have an additional influence on drinking independent of the overall effect of the social network.

Studies of adults after college, although uncommon, have also found evidence for both influence and selection effects. However, one issue arising in adulthood that is not typically examined among adolescents is the role of an intimate partner. Considerable research documents that couples have similar patterns of substance use at the time of marriage. Although this is sometimes viewed as evidence that individuals select similar partners, a process called assortative mating, it may also reflect partner influence prior to marriage. However, there have been findings that married couples report similar histories of substance use in adolescence before they met or began dating, supporting an assortative mating explanation.

Research also supports an influence process among intimate partners. Studies of newlyweds have found that women, but not men, are influenced by their partners’ drinking over the transition to marriage, and that this effect is stronger among women with strong dependency needs. However, after the first year of marriage, both husbands and wives appear to influence each other. Partner influence has also been documented for tobacco and marijuana use. Finally, one may wonder who has the greater influence on substance use, intimate partners or peers. At this time, there is no clear answer to this question. The few available studies suggest that intimate partners and peers both have an influence, and it may be necessary to consider the quality of the relationships.

Partner and Peer Influence After Substance Abuse Treatment

Friends and family members who use substances can influence the outcomes of treatment for

individuals with substance dependence. Because substance use by individuals with substance dependence is typically viewed as biologically driven, the impact of social influence has often been overlooked. Findings across all substances indicate that the presence of individuals in the social network who utilize the specific substance facilitates relapse after treatment. Research has not addressed the reasons for this, but it is likely due, in part, to the availability of and exposure to substances that such individuals would provide. Conversely, the emotional support provided by nonusers in the network may help the individual with temptations to relapse. In addition, peer and partner use are associated with change in substance abuse for substance-dependent men and women, and even among dependent individuals who do not seek treatment. Support for abstinence in the social network is predictive of posttreatment sobriety and is one of the factors responsible for the effectiveness of self-help groups such as Alcoholics Anonymous.

Relationship Functioning and Substance Use/Abuse

The Impact of Relationship Quality on Substance Use

Excessive drinking declines among individuals as they become engaged to marry and transition into marriage, likely in response to changes in social/recreational activities and normative views about drinking after marriage. Similar findings have been reported with respect to illicit drug use, but not with respect to tobacco use. The transition to marriage is protective even for those with significant alcohol problems. In a parallel manner, divorce is associated with increased drinking and alcohol-related problems. The one exception may be among those who divorce a partner with an alcohol problem.

The quality of the intimate relationship may also influence substance use, although most of the research focuses on alcohol. Marital satisfaction is protective against alcohol problems in longitudinal studies of the early years of marriage. However, the strongest evidence is seen among alcoholics in treatment. Long-term prognosis after alcohol treatment is enhanced if the alcoholic reports high marital satisfaction. This has led to the coupling of

marital therapy with substance abuse treatment to improve therapy outcomes, and research has supported this coupling.

The Impact of Substance Use/Abuse on Relationship Functioning

Violence

Substantial evidence links substance use/abuse to violence within intimate relationships. This evidence is strongest for alcohol, having been observed in clinical samples, general population samples, and other community samples. Meta-analyses of this literature suggest that the risk of violence among moderate to heavy drinkers is twice that of nondrinkers and light drinkers, but there is also evidence that the risk for violence increases dramatically among frequent binge drinkers (having five or more drinks at one time at least once a week). Women's drinking and their experiences as victims or perpetrators of partner violence have also been linked in several studies, although some studies have failed to find a relationship after controlling for the partner's drinking. Moreover, there is some evidence that the configuration of a couple's drinking patterns is an important predictor of violence, with high rates occurring among couples in which one member is a heavy drinker and the other member is not.

The few studies of illicit drug use also indicate a relationship between drug use and partner violence. However, when other factors such as alcohol use and partner's use of drugs or alcohol are controlled, the relationship between an individual's illicit drug use and partner violence is not always significant.

Relationship Quality

Heavy drinking is often one of the reasons given for divorce, is a common source of disagreements among couples in marital therapy, and is often associated with marital unhappiness. The literature on the impact of illicit drug use on relationships is considerably smaller. There have been contradictory findings with respect to marijuana use, but there have been studies linking illicit drug use to separations and divorce. Although there is no doubt that heavy drinking and drug use have a causal influence on marital unhappiness and divorce, the

nature and strength of that causal influence is not clear for several reasons. For example, heavy drinkers and drug users often have other disorders such as antisocial personality and depression that correlate with marital satisfaction. Also, few longitudinal studies have examined this issue, and the results are not entirely consistent. Similar to partner violence research, some research suggests that discrepant drinking patterns and discrepant drug use are related to marital satisfaction and divorce.

SUICIDE AND RELATIONSHIPS

Suicide refers to deliberate self-harm eventuating in death. Historically, suicide, attempted suicide, and deliberate self-harm have been conflated in

the psychological literature, which has emphasized motives. Examples include Sigmund Freud's concept of the death instinct, Karl Menninger's search for the common motivational themes driving all health-damaging behaviors (e.g., alcoholism, attempted suicide), and, in more recent years, Roy Baumeister's assertion that the distinction between attempted suicide and suicide was "tangential" to the focus on motives. By conflating death by suicide with self-harm behavior, scholars may illuminate motivational issues, but at the risk of reaching inaccurate conclusions that could misdirect treatment and prevention efforts. This entry focuses on the epidemiology of suicide and on clinical considerations.

Epidemiology of Suicide

The World Health Organization (WHO) estimates that 1 million lives are lost to suicide worldwide on an annual basis. Once the province of religion and then the law, suicide has been recast as a public health problem. The U.S. Congress passed resolutions in 1997 and 1998 declaring suicide a national problem, and a U.S. National Suicide Prevention Strategy was released in 2001. These initiatives have resulted in an exponential increase in the quantity and quality of research worldwide.

Geographical Differences in Suicide Rates

Rates of suicide differ markedly across the globe. Ever since Émile Durkheim's 1891 seminal publication *Suicide: A Study in Sociology* established the field of Suicidology, Eastern Europe has shown the highest rates of suicide worldwide. Today, suicide rates remain relatively high in Eurasia (13 deaths per 100,000 population members), more moderate in North America and Oceania (6.5–13 deaths per 100,000), and low in Central and South America (less than 6.5 deaths per 100,000). The global quality of surveillance systems differs dramatically; little data are available for much of the African continent.

In the United States, the Mid-Atlantic and New England states have suicide rates nearly half those of the Mountain states. Regional differences may be partly due to religious practice and denomination, ethnicity, availability of firearms, geographic

isolation, degree of community cohesiveness or social capital, and access to mental health care.

Age, Sex, and Race Differences

Older adults have among the highest rates of suicide worldwide. The "gender paradox of suicide" describes the fact that, in most countries worldwide, women more commonly attempt suicide and yet men more commonly die by suicide. The exception is China; women have higher suicide rates than men in that country largely due to the high rates of suicide among young women in rural areas. Numerous explanations have been offered for the sex difference in suicide rates, including speculation about sex differences in socialization, social integration, attitudes toward receiving mental health care for emotional difficulties, and interactions with primary care physicians and other health care providers.

In the United States, suicide rates for men increase with age, but women's rates peak in midlife and remain stable or decline slightly thereafter. Middle-age men account for the majority of suicide deaths. Whites have higher rates than Blacks across the life span. White men more than 85 years of age have suicide rates nearly six times the nation's age-adjusted rate.

Marital Status and Living Arrangements

Durkheim reported higher suicide rates for single, divorced, or widowed people than for married people. More than a century later, this is still true in most countries worldwide. Widowhood may be a more potent suicide risk factor in younger versus older adults, given that it is off-time and thus an unexpected event in young adulthood. Little is known about the protective effects of remarriage following divorce or widowhood. Data suggest that living alone may confer increased risk for suicide perhaps due to social isolation, loneliness, and lack of encouragement to seek treatment for physical and emotional problems. Conversely, relationship conflict with spouses, children, and others may increase the risk for suicide.

Socioeconomic Status

Media accounts of suicides by writers (Ernest Hemingway, Sylvia Plath, Hunter S. Thompson),

artists (Vincent Van Gogh), musicians (Kurt Cobain), and business moguls (George Eastman) might lead some to believe that suicide is more prevalent among those with greater status. In reality, suicide knows no economic boundaries, and rates are higher among those with lower incomes and lower levels of education. The economically disadvantaged typically have poorer access to quality health care and less mental health literacy, and they are more likely to encounter stigma toward mental health care and chronic exposure to life stressors and strains.

Clinical Considerations

Clinical suicide prevention initiatives typically hinge on accurate risk identification and timely care provision. The statistical rarity of suicide precludes prediction of individual deaths by suicide.

Clinical Risk Markers

Recognizing that few studies have been conducted with sufficient rigor to conclude that any putative risk marker is a truly independent risk factor, a brief summary of the current state of knowledge is as follows.

Mental Illness. Most people who die by suicide have an active mental illness at the time of death. Mood disorders, even those that are relatively mild, have been shown to confer suicide risk, as do psychotic disorders, especially schizophrenia. Personality disorders, particularly borderline personality disorder, antisocial personality disorder, and avoidant personality disorder, also confer risk.

Substance Misuse. People who struggle with alcoholism are at greater risk. The same is true for people who abuse or are dependent on other substances, including cocaine and heroin. Interestingly, alcoholics who die by suicide are more likely than others who die by suicide to have been involved in a conflictual relationship prior to death. People with histories of alcoholism but who are currently sober might also be at elevated risk.

Life Events Stressors. Relationship issues lay at the heart of most events that drive suicide risk. Family discord, relationship conflict and disruption,

bereavement, and exposure to humiliating events are important risk markers. Financial stressors also drive risk, in part, because monetary concerns can cause family problems.

Physical Illness and Functional Limitations. Cancer, neurological disease, chronic lung disease, visual impairment, physical incapacity, and pain all elevate suicide risk. Relationships are often key to understanding suicide risk in physically ill people, as some patients may choose suicide because they fear they have become too much of a burden on family members or friends. This may be especially true among older adults.

Prior Suicidal Behavior. Prior suicide attempts, the extent to which prior attempts were planned or impulsive, lethality of prior suicide attempts, and chronic or acute suicide ideation and/or a wish to die are all important risk markers and warrant careful assessment.

Resiliency and Protective Factors

Degree of religious conviction mitigates suicide risk. Durkheim opined that the lower risk groups experienced greater social cohesion and greater religious commitment. Alternative explanations include religious proscriptions against both suicide and excessive alcohol consumption. Nonetheless, even individuals who regularly engage in religious practice might be at risk for suicide, particularly if their religious community involvement is minimal or if their faith community is relatively small or peripheral or discourages mental health treatment. Some individuals turn to religion when in emotional distress. Although religious practice can help inspire hope, it is rarely sufficient on its own to eliminate risk for suicide. Increasing social integration and belongingness may bolster resiliency, as might enhancing one's sense of hope, purpose, and meaning in life.

Clinical Interventions

Treatments for mood disorders, schizophrenia, or substance use disorders are now considered vital components of suicide prevention efforts. Suicide in alcoholism is known to be preceded by relationship

disruptions. Interventions focusing on alleviating or reconciling relationship conflict can help reduce suicide risk, as can those focusing on alleviating perceived burdensomeness on others due to physical, financial, and/or psychological impairment.

Service Delivery Parameters

Suicide risk among adults hospitalized for a mental disorder is high during initial hospital admission and transfer between hospital units or services and after discharge. Suicide risk may be increased by poor continuity of care; discharge stress; aborted or otherwise incomplete treatment; return to a dysfunctional, conflict-laden, or highly emotive family environment; and the tendency of some patients to conceal their suicide plans to care providers in order to facilitate prompt discharge. Poor communication among treatment providers has been shown to contribute to suicide in outpatients. Poorly integrated health care delivery systems, in valuing technical procedures over personal relationships, may unwittingly enhance mortality risk.

Survivor Issues

Suicide is often a solitary act, but family and friends are almost always left behind to grieve and try to make sense of the loss. Social support after any type of loss appears to be a crucial factor after loss, and this may be especially true of suicide. Grassroots networks of survivors have developed worldwide and are important support resources.

Need for Prevention and Treatment

Interventions have been developed that specifically target individuals with one or more risk factors and/or lacking in resiliency. However, this classic clinical research strategy, although potentially effective with patients engaged in the health care system, is not foolproof: It fails to reach individuals outside the system. Many at-risk individuals do not avail themselves of treatment, and few treatments are tailored to individual needs and preferences, threatening adherence to care. Public health prevention programs could indirectly reduce suicide rates by modifying attitudes about mental health treatment, shifting cultural norms concerning the acceptability of suicide, restricting access to

firearms and other lethal means, and increasing mental health literacy and health-promoting behavior. However, some so-called universal interventions, such as screening for suicide risk and firearm control, will not reach all at-risk individuals. Of course, the long-term goal is not to bring the suicide rate down to zero, an unrealistic goal in a free society, but rather to do whatever can be done to protect at-risk individuals from the belief that suicide is their only option. This will require better treatments *and* better prevention programs, targeting individuals, families, and communities.

SURVEY METHODS IN RELATIONSHIP RESEARCH

Survey methods are among the most popular approaches used by researchers to study human relationships. Survey methods refer to a type of research in which data are collected from a sample drawn from a population through the use of a questionnaire. Surveys entail asking questions of respondents directly, either orally or in writing. Beginning with a set of objectives, researchers using survey methods make decisions regarding the study design, the sample, the questions to be asked, and the survey mode to maximize their ability to answer research questions and minimize the cost of the study. In this entry, we review these

decisions and provide examples to show how relationship researchers use surveys effectively to address important relationship topics.

Survey Study Design

There are two standard survey designs that will be reviewed in this section: cross-sectional and panel. *Cross-sectional surveys* entail collecting data from a sample at a single point in time. Although researchers are not able to study change over time when using a cross-sectional design, they are able to examine the associations between variables at a given time. Cross-sectional surveys are often used by relationship researchers because they are a cost-effective way to fulfill research objectives. For example, sometimes relationship researchers are interested in knowing the association between two variables at a given time (e.g., how the current level of perceived need fulfillment is associated with the current level of satisfaction with a relationship). In such cases, cross-sectional designs are preferred because they provide data relevant to a researcher's hypotheses at minimal cost and effort.

However, there are many instances when researchers are interested in how a relationship changes over time. In such instances, panel surveys are used. *Panel surveys* are a type of longitudinal study in which the same respondents are asked questions at two or more time periods. Researchers using panel surveys are able to examine how changes in one variable over time are associated with changes in another variable (or variables). Thus, panel studies may provide researchers with some insight regarding the influence of one variable on another (although it must be noted that only an experiment, properly conducted, has the possibility of yielding definitive causal information). It is also possible to examine the stability versus change of variables over time with panel surveys. Panel surveys have the disadvantage of relying on respondents to answer questions at more than one time point. Although many people are willing to participate in one cross-sectional survey, fewer are willing to commit to participating in multiple surveys without some incentive (e.g., cash payment). In addition, it can be difficult to retain people in a study if they have moved away from the original site of the investigation or if their relationship has

ended or taken a negative turn. Moreover, panel survey respondents may become aware of what is being studied after participating in the initial survey, and this awareness may influence their responses to subsequent surveys.

Once a study design is selected, researchers must decide from whom they will attempt to collect data by selecting a sample.

Survey Sample Selection

There are two broad approaches to selecting a sample for a survey. First, one may collect data from a *probability sample*, in which each individual in the population of interest has an equal, nonzero chance of being selected. This sampling approach has many advantages. The most pronounced advantage is that findings can be generalized to the entire population from which the sample was drawn. However, a major disadvantage is that it requires full knowledge of and access to a population, which can be quite difficult and resource-intensive. Imagine a relationship researcher who was interested in studying conflict styles in married couples around the world. To have a true probability sample, the researcher would have to ensure that every married couple in the world had an equal, nonzero chance of being sampled. For some research objectives, attempting to survey the entire population may be necessary (e.g., a government agency seeking definitive information on marital divorce rates over time). However, there are many instances in which research objectives do not require such generalizability, especially when theory building is the primary goal of a study. There is a less resource-intensive option for those instances: the nonprobability sample.

A *nonprobability sample* is not randomly drawn from the population as a whole. Moreover, some members of the population have zero chance of being selected. For example, a researcher may choose to select students who are enrolled in an undergraduate course at his or her home institution as respondents. People who are not in that course have no chance of being selected to participate. This is often referred to as a convenience sample because it is selected out of convenience to the researcher. The major limitation of using a

nonprobability sample is that the results cannot be generalized to an entire population. Often researchers make the decision to use a nonprobability sample because the objective of their survey does not require a probability sample (e.g., hypothesis testing). For example, survey research by Christopher Agnew and colleagues involving a nonprobability sample of undergraduate college students found that those who reported that they were highly committed to their relationship partner also tended to think about their relationship in more pluralistic ways (e.g., they wrote sentences about their relationship featuring a greater use of plural as opposed to singular pronouns). This finding was consistent with the researchers' hypotheses concerning how people involved in committed relationships think about their partners. Although the finding cannot be generalized to the entire population, such hypothesis testing does not require a probability sample.

Survey Questions

After selecting the survey design and the sample, researchers must develop their questions. The questions may be combined to form a written questionnaire or an oral interview guide. Research objectives guide this stage of survey research in terms of which questions to ask and in which form to ask them. A major advantage to survey studies is that all respondents may be presented with identical instructions and questions, meaning that any differences observed among answers result from actual differences in respondents. Of course, this advantage is realized only when questions are worded unambiguously and all respondents understand them. For this reason, researchers should present questions to respondents in ways that are short and simple to ensure comprehension of the questions and to minimize any fatigue respondents may feel in answering the questions. Researchers also should try to avoid jargon specific to their field (unless required and explicitly defined), so that each respondent is not put in the position of having to interpret question meaning. Fortunately, many constructs of interest to relationship researchers (such as equity, love, and commitment) can be measured reliably with scales containing questions that have been

developed and validated by researchers in previous research.

In addition to selecting questions, researchers must also decide on the response options available to respondents. Some surveys feature open-ended responses, some feature closed-ended responses, and others feature both kinds. An *open-ended response* allows respondents to answer a question in their own words, whereas a *closed-ended response* requires respondents to choose from pre-selected options. When delving into a new area of research, researchers often start with open-ended questions to help them get a sense of the kinds of answers that respondents generate without prompting from the researcher. One example is a study of forgiveness conducted by Jill Kearns and Frank Fincham. Out of a desire to incorporate how "regular" (or lay) people think of forgiveness with how researchers conceptualize it, Kearns and Fincham asked respondents to list what attributes they thought of when they think of "forgiveness." From 208 respondents, 477 separate attributes of forgiveness were generated. This scenario points to one disadvantage of open-ended responses: Although they do provide a richness of information about a topic, they can be unwieldy to analyze. It is often preferred to offer closed-ended response options, particularly when a researcher is testing a specific hypothesized association between variables.

In developing closed-ended response options, researchers must decide, if using a response rating scale, which words to use as response scale anchors (e.g., *good-bad* or *strongly agree-strongly disagree*). Research indicates that respondents, when fatigued, not paying attention, or confused, are more likely to agree than disagree and to say something is good rather than bad. To ensure that this does not taint data, researchers typically ask more than one question about a given construct and average the responses across a given variable. In addition, including some questions that are worded as opposites of others (called item reversals) is standard procedure. One example of this is the commitment subscale of the Investment Model Scale (IMS), crafted by Caryl Rusbult, John Martz, and Christopher Agnew. Instead of asking one question to assess relationship commitment level, the IMS asks seven questions and averages the responses to create a measure of general commitment level.

Of the seven items, five are written as positive indicators of commitment (e.g., “I want our relationship to last a very long time”), and two are item reversals (e.g., “I would not feel very upset if our relationship were to end in the near future”).

An additional consideration that researchers make when constructing survey questions involves attempting to control for possible response bias. For example, it may be embarrassing for a person to admit that he or she is involved in a physically abusive relationship. Whether this is due to the fact that individuals may deceive themselves and others about negative aspects of their relationships or because people prefer to respond in socially desirable ways, it is important to assess because it poses a problem for the validity of survey data. Various survey instruments, such as Timothy Loving and Christopher Agnew’s Inventory of Desirable Responding in Relationships, can be administered so that those respondents prone to answering in socially desirable ways can be identified. However, as previously discussed, additional survey questions may increase respondent fatigue, which reduces the quality of responses, so additional measures should only be included if the researcher believes that the potential for socially desirable responding is high.

Survey Mode

Finally, a decision must be made concerning the mode in which the survey will be administered. The most common modes are interview and self-administered. Interviews are usually conducted on the telephone or face to face. Both afford the advantage of being able to probe incomplete or ambiguous answers to open-ended questions. Interviews also have the advantage of being used to collect data from populations that cannot read or write or may need additional explanation regarding survey questions. One disadvantage to interviews is that they can be expensive to conduct.

A less costly option is the self-administered mode, which includes paper-and-pencil and online surveys. Self-administered surveys are an excellent option if the questions being asked are sensitive in nature because respondents may be disinclined to share private information with an interviewer. Paper-and-pencil surveys can be mailed to potential

respondents, but the process of mailing surveys, waiting for responses, and sending follow-up mailings can take considerable time. A newer (and generally much faster) self-administered option is the Internet survey. Internet surveys can reduce the cost of sampling a large, diverse population, and they are more flexible than traditional paper-and-pencil surveys as they allow for question branching (i.e., certain questions can be asked only of some respondents depending on their previous responses). Internet surveys do not require human transcription unlike some other modes, making them potentially less error prone. However, the sample derived from an Internet survey is limited to those who have access to and use the Internet. Furthermore, Internet surveys typically have high rate of drop-outs (e.g., respondents who begin a survey but do not complete it), which potentially introduces self-selection biases to the data.

Conclusion

Survey methods are commonly used in human relationship research. Researchers make decisions regarding survey design, sample, questions, and mode to maximize their ability to meet the objectives of their study and to minimize associated costs. When properly designed and executed, a survey can yield information that answers a broad range of research questions. For that reason, they represent one of the most popular research methods used to study relationships.

SYMBOLIC INTERACTION THEORIES

Symbolic interactionism is a sociological perspective on social life based on the ideas of George H. Mead and other pragmatists in the early 20th century. It is a broad theoretical perspective that has spawned a number of important variations and some specific theories. This entry reviews the main features of symbolic interactionism, identifies the major variations and theories associated with this perspective, and briefly discusses some of the research on interpersonal relations generated by symbolic interaction theories.

The basic premise of symbolic interactionism is that human life is inherently social and symbolic. As the label *symbolic interactionism* suggests, the key elements of this theoretical perspective are the importance of social interaction and symbolic communication. Human language is comprised of symbols, culturally derived social objects having shared meanings that are created and maintained in social interaction. Symbol-based communication is a qualitative evolutionary leap from sign-based communication, characteristic of other social animals (e.g., bees, wolves). Much of what we consider essentially human—mind, self, society, culture—emerges from and is dependent on symbolic interaction for its existence.

Importance of Meanings

The label *symbolic interactionism* was coined by Herbert Blumer, one of Mead's students who did much to shape this perspective by developing one of its main variants, the "Chicago School" of

interactionism. Blumer's guiding premise is that humans act toward things and people on the basis of meanings. The focus here is on *meaning*, which is defined in terms of action and its consequences. The meanings of things and relationships are likely to vary from person to person and over time. However, the meanings we associate with the symbols we use in communication depend on some degree of consensus between two or more persons. The meaning of the word *wife*, for example, depends on the consensual responses of those who use it. If consensus is high, the meaning of a symbol is clear; if consensus is low, the meaning is ambiguous and communication is problematic. Within a culture, there is general consensus on the meanings associated with various words or symbols. However, in practice, the meanings of things are highly variable (especially for abstract terms such as *love*, *equality*, and *justice*) and depend on processes of interpretation and negotiation.

The interpretive process entails what Mead called *role taking*, which is the cognitive ability to take the perspective of another. It is a critical process in communication because it enables actors to interpret one another's responses, thereby facilitating greater consensus on the meanings of the symbols used. But the determination of meanings within a specific interaction also depends on negotiation—that is, on mutual adjustments and accommodations of actors. Role taking or perspective taking is the cognitive process that enables persons to take each other's perspectives into account in negotiating meaning. It is important to note that power relations are relevant to this process. In interactions between subordinate and superordinate (say, between a boss and an employee), the subordinate in a relationship tends to be better at role taking the superordinate than the reverse because the subordinate is under greater pressure to adjust and accommodate in this relationship than is the superordinate. However, for meaningful communication to take place, both (all) interactants must engage in role taking to some degree.

Definition of the Situation

The importance of meaning is reflected in W. I. Thomas' famous statement: "If situations are defined as real, they are real in their consequences."

The *definition of the situation* states that people act in situations on the basis of how they define the situation and its various components. For example, whether the situation is defined as “playful” or “dangerous” will matter for our actions. Definitions, even when at variance with “objective” reality, have real consequences for people’s actions and events. Whether dragons, angels, or witches actually exist is less important in a situation than people’s beliefs in their existence because our actions will be guided by our beliefs.

Defining a situation is not a static process. An initial definition based on past experiences or cultural expectations may be revised in the course of interaction. For example, an initially festive situation (such as a birthday party) may turn somber, a serious situation may become humorous, or a business relationship may become romantic. As the overall definition of the situation changes, so do the relevant identities of the people involved (*friend* may become *enemy*, *brother* may become *competitor*).

Much of the negotiation in social situations entails an attempt to present the self in a favorable light or to defend a valued identity. Erving Goffman’s insightful analyses of impression management, staging operations, use of deference and demeanor, as well as research by Terri Orbuch and other symbolic interactionists on the use of excuses, motives, justifications, and accounts, speak to the intricacies involved in situational definitions. Here as well, disparities in power and status affect whose definition of the situation is more likely to prevail.

The presentation of identities is an important aspect of defining situations. The determination of who we are (e.g., which identity to present) and who we think the other or others are in the situation is highly relevant to the interaction that will take place. In formal or highly structured situations, the determination of relevant identities may not be problematic or contested (e.g., “teacher” and “student” are typically considered highly relevant in classroom situations). But even in such formal situations, other identities come into play that might be more problematic (e.g., *strict teacher*, *unfair teacher*, *good student*, *lazy student*, *troublemaker*), and these may be further qualified by age, gender, and racial identities. In less formal situations, such as families and friendship groups, identity dynamics are even more

complex. For example, in a conflict situation between a husband and wife, it might not be clear as to which identities are being invoked, that of spouse, parent, or personal identities. Even if the situation starts with one set of identities, it could easily shift to other identities for one or the other person.

The identity presented in a situation is not necessarily the same as the identity assigned by others in the situation. For that matter, some situations generate skepticism about the identities presented (e.g., the *honest salesman* in a used car lot). Deviant identities are often products of this type of negative labeling (e.g., *bad kid*, *delinquent*, *pervert*). This process of imputation, in combination with interactionist ideas about self-concept formation, is the basis of the *labeling theory* of deviance (discussed next).

Self, Self-Concept, and Identity

Along with symbol, meaning, and interaction, the *self* is a foundational concept in symbolic interactionism. The essential feature of the self is that it is a reflexive phenomenon characterized by the interplay of the “I” and the “me,” the subjective and objective aspects of the self. Reflexivity enables humans to act toward themselves as objects (i.e., to reflect on themselves, argue with themselves, evaluate themselves, etc.). This human attribute (although gorillas, chimpanzees, and other social animals also show some indication of self-awareness) is based on the social character of human language and the ability to role take. Reflexivity and role taking enable persons to see themselves from the perspective of another and thereby to form a conception of themselves—a self-concept. The *self-concept* consists of the totality of our thoughts and feelings about ourselves and who we are, who we were, or who we aspire to be.

Much of the content of our self-concepts consists of identities. *Identity* refers to who one is, to the various meanings attached to oneself by self and others. For symbolic interactionists, there are several important types of identity: identities based on role relationships (e.g., professor, father), group memberships (American, Libertarian), values and character traits (environmentalist, honest person), physical characteristics (out of shape), and personal identity based on one’s name and biographical self.

Identities based on social roles and group memberships have received the most research attention. They are considered important because they situate persons in social space by virtue of the social relationships that they imply. These identities are not only important components of people's self-concepts, but they are also part of the public domain that structures social interaction.

Selves and self-concepts emerge from and are maintained in social interaction. The importance of others in the formation of self-concepts is captured in Charles Cooley's influential concept *the looking-glass self*. Using the metaphor of a mirror, Cooley proposed that individuals come to see themselves as they think others see them. For example, how a son thinks his father sees him affects how the son sees himself. This process is also called *reflected appraisals* and is the main process emphasized in the development of selves and identities. It is part of the more general process of *socialization*, which deals with the development of persons and the transmission of culture.

A major theme in the interactionist conception of self-concept is that the content of self-concepts reflects the content and organization of society. This is most apparent with regard to the roles that are internalized as role identities (e.g., *mother*, *student*). Roles, as behavioral expectations associated with a status within a set of relationships, constitute a major link between social and personal organization. Much of socialization, particularly during childhood, involves learning social roles and associated values, attitudes, and beliefs. Initially, this takes place in the family (e.g., parent-child relationships) and then later in larger arenas of the individual's social world (e.g., friendships and romantic relationships).

For symbolic interactionists, socialization is not a passive process of role learning and conformity to other's expectations. The self is highly active and selective, having a major influence on its environment and itself. Consequently, when people play roles, role making often is as evident as role learning. In role making, individuals actively construct, interpret, and uniquely express their roles. When they perceive an incongruity between a role imposed on them and some valued aspect of their self-conception, they may engage in role distance, the disassociation of self from role. The self is an active agent even in its own socialization.

Varieties and Theories of Symbolic Interactionism

Symbolic interactionism has several major varieties and a number of specific theories. Although symbolic interactionists share the belief that humans rely on shared symbols to construct their realities, and the methodological requirement that to understand human behavior the researcher must "get inside" the reality of the actor, there are substantial divisions within this perspective. The main division is between those who emphasize process and those who emphasize structure in studying human realities. The former, associated with Herbert Blumer and the "Chicago School," advocates the use of qualitative methods in studying the process of reality construction within natural social settings. The latter, the structural version, is associated with Manford Kuhn and the "Iowa School." Structural symbolic interactionism advocates the use of quantitative methods in studying the products of social interaction, especially self-concepts. The differences between these two "schools" of symbolic interactionism reflect the fundamental division in the social sciences between humanistic/interpretive orientations, which align with history and the humanities, and positivistic/nomothetic orientations, which align with the physical sciences.

A third important variation, somewhat closer to the Chicago School than the Iowa School, is Erving Goffman's dramaturgical perspective on social life. Goffman's guiding metaphor of social life is the theater, in which actors are performers on the stage of life. Social situations are viewed as analogous to theatrical productions. Goffman shows us how our attempts to construct realities are not much different from the reality construction efforts in a theater or play. Not surprisingly, the dramaturgical perspective has been frequently used in studies of dating, courtship, and other situations where making a "good impression" is important.

Symbolic interactionism (SI) has generated a number of more specific theories, some more closely aligned with one or another of the three major variations. These theories tend to be more limited in scope than the "schools" described earlier, and they tend to focus on a particular concept or process important to SI. The most prominent of these are role theory, labeling theory, and several types of self-theory.

Role theory emphasizes the importance of social roles in organizing and explaining social interaction, and it has generated considerable research on such topics as how persons are socialized into specific roles and how the meanings and content of roles such as *husband* and *wife* change over time and over different stages of the life course (e.g., parenthood). Much of this research is grounded in processual symbolic interactionism and emphasizes the processes of role making, role taking, and role negotiation, but some draws on structural symbolic interactionism and uses survey methods to study role relationships.

Labeling theory is an application of the process of reflected appraisals to the development of deviant identities. Developed mainly within the processual version of SI, labeling theory proposes that society's reaction (especially by persons in positions of authority, such as police, judges, and teachers) to a person's initial deviant behavior is the major factor in the development of deviants because it alters the self-concept and social identity of the person labeled. Research on child socialization, especially with regard to the development of juvenile delinquency and other deviant behaviors in families and in schools, provides some support for this theory. However, labeling theory has been criticized for overstating the influence of reflected appraisals and understating the effectiveness of resistance efforts on the part of those labeled with a negative identity.

The concept of self has generated the largest number of SI theories. Most of these self-theories derive from the structural version of SI, where identities are linked to social roles. Sheldon Stryker built on this foundation in developing his Identity Theory. In Stryker's Identity Theory, differential commitment to the various role identities that a person holds provides most of the structure and organization of the self-concept (i.e., a salience hierarchy of identities). To the extent that a person is committed to a particular role identity (which in turn depends on the degree to which the identity is enmeshed in social relationships), the more consequential the identity is for the person's conduct. Identity Theory has spawned several other self-theories: Peter Burke's *Identity Control Theory*, which focuses on the self's adjustment processes when receiving discrepant feedback regarding a particular identity; and *Affect Control*

Theory, developed by David Heise and colleagues, which incorporates affect and emotion into the role-identity model. All three of these self-theories were developed by structural symbolic interactionists at Indiana University—the “Iowa School” has evolved into the “Indiana School” of symbolic interactionism.

Considerable self-theorizing also has occurred beyond the Indiana School of SI, focusing on other aspects of the self-concept besides role identities. Important theorizing has focused on self-esteem, self-efficacy, self-motives and self-defenses, real selves and false selves, self-narratives and biographical selves, and the dynamics of self-presentation. The concept of self has provided fertile ground for symbolic interaction theories and for research on human relationships. How people see themselves and how they see each other is clearly important for individual well-being and for the nature of social relationships.

SYSTEMS THEORIES

Although human relationships scholars often refer to *systems theory*, as if there were only one, there

are, in fact, several systems theories that are relevant to understanding human relationships. Some systems theories examine large groups of people, such as societies, but this entry focuses on systems theories as they have been applied to intimate or close relationships. A general definition of a *system* is any entity together with relationships between the various parts of the entity and between their attributes.

The conceptual roots of systems theories may be found in a diverse array of disciplinary backgrounds. Although systems theory concepts are not new, predating modern times (e.g., one of the most well-known systems' propositions, "The whole is greater than the sum of its parts," may be attributed to Aristotle), the development of systems theories can be traced to the mid-20th century. Immediately before World War II and in the decade or so after the war, social and behavioral scientists from psychology (e.g., Kurt Lewin), sociology (e.g., Talcott Parsons, Walter Buckley), family therapy (e.g., Donald Jackson, Nathan Ackerman), communications (Jay Haley), and anthropology (e.g., Gregory Bateson) began borrowing systems concepts from biologists such as Ludwig von Bertalanffy, mathematicians such as Claude Shannon and Warren Weaver, and engineers such as Norbert Wiener and applying these concepts to developing theories about human social systems.

These social and behavioral scientists believed that the principles underlying nonhuman biological systems (e.g., wetlands, frog communities, and even organisms such as bacteria) could be applied to human social systems. Research conducted by Norbert Wiener and others during World War II that focused on the cybernetic, or self-correcting, capabilities of robots and weapon systems also stimulated new thinking about human systems. The definition of systems as any entity whose parts relate to each other and to elements outside of the entity reflect these multidisciplinary roots. Such definitions may indeed apply to frogs and other nonhuman organisms, to inanimate systems, and to intimate human relationships.

Systems theories share certain fundamental assumptions about interpersonal relationships, although they may differ in their focus (i.e., families, social organizations, friendships) and in the relative importance of selected concepts (i.e., power, communication patterns, and goals). The

following ideas typically are postulated as universal properties of human social systems by these theories.

Human Social Systems Are Open

Systems are open to *inputs* from outside of the system. Human systems are involved in continual exchanges of energy, matter, and information with the external environment. The open nature of systems means that elements outside of the social system continually influence the system's operation. At the same time, elements within the social system influence the environment; these are known as *outputs*. Because of the dynamic nature of systems that results from the continual exchange of inputs and outputs, systems theories are interested primarily in processes, such as how systems adapt to inputs and how they generate outputs. For instance, systems scholars might wonder how the unexpected firing of the major wage earner in a family (an input) affects family members' behaviors and relationships, including the socialization of children (a system output). Although some attention is paid by systems theorists to the structure of systems (e.g., how many members are there in a system), far more attention is focused on system processes.

The focus on system processes implies that systems theories are interested in change, which is hard to evaluate without observing system dynamics over time, either clock time (i.e., seconds, minutes, and hours) or calendar time (i.e., days, weeks, months, and years). For example, a photograph of a couple may suggest what is happening at the moment the picture was taken, but it would be difficult, or maybe impossible, to infer patterns of interactions and system inputs and outputs from the photo. A videotape of the couple would provide more information about their patterns of interacting than the photo would, and having several days of videotapes would yield even more information about the couple as a system.

Human Systems Are Self-Reflexive

Systems theories view human groups as goal-seeking and adaptive systems. Like all cybernetic systems that have feedback loops, human systems

are self-monitoring and self-aware of how they are behaving. Although systems theorists disagree about the extent to which human systems are capable of being aware of setting purposeful goals and planning actions to meet those goals, according to Carl Broderick, most systems theorists recognize that individuals are able to self-reflect, and such reflexivity distinguishes human systems from other systems.

Interdependence

All parts of human social systems are connected with all other parts. Any change that affects one person in a social system influences all other persons and relationships in the system. For example, in a family, a seriously ill child may mean that mother and father rearrange their work and leisure activities to devote time to caring for the sick child. Older siblings may not participate in caregiving, but may be affected nonetheless because the parents are not available to interact with them and the family routines change. Because of the interdependent nature of systems, changes in how parts of the system interact have indirect effects on all other parts of the system. Interdependence means that causal effects in systems are complex—individuals directly affect each other, they are indirectly affected by the interactions of others within the system, and they influence and are influenced by inputs from the external environment.

Wholeness Principle

Also known as *nonsummativity*, the well-known dictum that “The system is greater than the sum of its parts” means that relationship systems have unique characteristics that emerge from the interactions of individuals in those relationships. Human systems have properties that may be observed only at the level of the system; they cannot be inferred from knowing about the personalities or other individual characteristics of the system members. When individuals come together to form relationships, a social system is created that is more complex than the sum of the individuals in that relationship. System characteristics are called *emergent* properties because they are evident (emerge) only at the system level and

cannot be inferred from knowledge about the component parts of the system. For instance, knowing Susan and Brian well as individuals does not mean that one knows how they will relate to each other in a dating relationship; the entity of the couple is more than the sum of Susan’s and Brian’s characteristics as individuals.

Ongoing Systems Are Rule Governed

Human social systems that last for days, weeks, or longer, such as dating couples and families, exhibit regular, repeated patterns of interactions. Over time, these patterns may be observed, and the rules governing the system may be inferred from those observed patterns. Systems theorists assert that these patterned interactions are regulated by rules designed to organize the system. Some rules are explicit and known to people both within and outside of the system. For instance, a sorority may have explicit rules about when and where men are welcome in the sorority hours; these rules may be posted and may be part of the orientation of newcomers to the sorority. Of greater interest to systems theorists, however, are the implicit rules that govern behaviors. System members may not be aware of implicit rules; these rules develop over time in the course of interactions among system members and transactions with the environment. Some theorists have proposed that systems rules are organized in a hierarchical manner, with some rules applying more generally than others or applying only certain conditions. For example, in a college classroom, there are posted signs that say there will be no eating or drinking, an explicit system rule. An observer may notice that some students regularly bring food and beverages into the classroom (an implicit rule that eating and drinking are acceptable), but not every day. On days when the dean is likely to walk by the classroom, students are less likely to bring food or they bring only water; the observer may infer that, despite the explicit ban, clear fluids are always acceptable, and other beverages and food are okay when classroom outsiders aren’t around.

Subsystems

Social systems are often comprised of smaller units called *subsystems*. Usually, these subsystems

contain more than one person, although some theorists consider individuals to be the smallest possible subsystem of a larger system. Subsystems exist to perform specific functions for the system and for members of the subsystem. Subsystems operate under the same principles as systems do (e.g., wholeness, patterned interactions). Subsystems are differentiated from other parts of the system by rules known as boundaries.

Relationship systems are usually embedded within larger systems called *suprasystems*. For instance, family systems are often part of neighborhood suprasystems, and neighborhoods are systems within community suprasystems.

Boundaries

Rules that specify who is a member and who is not a member of a system or subsystem are called *boundaries*. Boundaries also regulate the transfer of inputs and outputs between a system and its environment, and boundaries control such transactions between subsystems. Boundaries vary in clarity (i.e., how clear is membership in a system) and rigidity (i.e., how easy or difficult is it to transfer inputs or outputs).

Equifinality

System goals may be met in multiple ways and from different starting points. There are many paths that lead to the same destination. For instance, couples that want to marry and want to be sure they are compatible partners could read books about marriage, participate in premarital counseling, date for several years to allow ample time to get to know each other, live together, separate for a time to date others to be sure the partner is “the one” for them, or do all of these things to prepare.

Feedback Mechanisms

Systems processes are complex combinations of interconnected positive and negative feedback loops. Positive feedback loops occur when a system member’s action has a consequence that increases the probability of those actions being

repeated or increasing in intensity. Positive feedback loops result in system changes over time (*morphogenesis*) as reinforced behaviors are amplified. Negative feedback loops occur when a system member’s new behaviors are met with consequences that reduce the probability that the behavior will happen again or, if it occurs, that it will have less intensity. Negative feedback loops discourage system change and result in system *homeostasis* or *system equilibrium*.

Positive and negative feedback do not refer to the nature of the responses to a behavior, but to the entire sequence of actions—if the feedback loop results in changes in system patterns, it is a positive feedback loop. If new behaviors decrease or intensity diminishes in response to the system’s reactions, it is a negative feedback loop because the system patterns will not change. For instance, as children enter adolescence, they seek greater autonomy from parents; when parents respond in ways that allow their children more freedom, they are engaging in positive feedback; when they resist, it is negative feedback. An adolescent who stays out past curfew is initiating system change, parents who punish the adolescent but make the curfew an hour later in the future are reinforcing the system change, and parents who punish the adolescent with no future curfew alterations are resisting change.

Criticisms of Systems Theories

Some scholars have criticized systems theories for being too general and ambiguous, not readily lending themselves to the development of testable hypotheses and propositions. Systems theories are seen by some critics as so abstract and broad that they are not theories as much as descriptive metaphors that describe close relationships. In the past, feminists and African-American scholars have charged systems theorists with ignoring gender-related power dynamics in social systems and of implicitly supporting conservative views of interpersonal systems that place women and ethnic minorities in submissive roles in social systems. These criticisms have been met with rejoinders by systems scholars, and to a large extent these complaints have diminished.

Application of Systems Theories

In the past several decades, systems theories have been heavily used by helping professionals (e.g., social work, nursing, counseling, and family therapy) and by relationship scholars in communications, family studies, and psychology. Systems theories have been applied in particular to the study of families and family relationships. There is a large body of literature on family functioning and interpersonal processes in family systems dating back to the 1960s. More recently, systems theories have been employed by researchers interested in other types of close relationships. Ecological systems theories, for instance, have been used to study relationships within families, schools, work settings, housing, health care organizations, criminal justice, social organizations, sports teams, small groups, and friendship networks. Statistical procedures such as hierarchical linear modeling and structural equation modeling have made possible quantitative analyses of propositions from systems theories, and these new procedures have greatly facilitated the application of systems theories to the study of relationship issues. The growth of qualitative research methods also has facilitated the use of systems theories

because such methods are well suited to examine systems processes.

T

TABOO TOPICS

U.S. residents tend to be inundated with messages that relational partners and family members should be completely open with one another. For instance, popular women's magazines are often filled with messages (i.e., "Ten ways to get your man to open up to you!") that suggest that partners should reveal everything to one another if they want to have healthy and satisfying relationships. Yet, people often avoid talking about certain topics and have good reasons for doing so. People are especially likely to refrain from talking about topics that they consider taboo or "off limits" in a relationship. This entry describes topics that tend to be taboo, identifies the reasons why people tend to refrain from talking about them, and discusses some of the implications of these choices for individuals' personal and relational health.

What Are Taboo Topics?

Researchers often refer to the research on topic avoidance, disclosure, and secrets as "information regulation." Typically, avoidance, disclosure, and secrets are analyzed as ways in which people regulate or manage the amount and type of private information they give to, and receive from, others. However, it is important to differentiate among these different types of information regulation. With topic avoidance, people refrain from talking

about a topic that the other person knows exists. For instance, if Jenny is dating someone her parents dislike and they simply choose not to talk about him, it would be considered avoidance. If, however, Jenny is engaged to her partner and she has not told her parents about it, it would be a secret. Because secret-keeping involves concealment, it usually takes more effort to keep the information private and has more negative ramifications than does topic avoidance if the information were to be revealed.

Taboo topics are often considered to be topics that are highly avoided, but they can also be secrets. As Leslie Baxter and Bill Wilmot note, topics that are taboo are considered "off limits" in relationships. These topics tend to be too sensitive or emotionally laden to discuss. Often these topics are declared taboo by the people in the relationship, but other times, they are implicitly taboo when norms and relationship rules make them inherently off limits for discussion. For instance, it might be known in your family that religion and politics are off limits for conversation because of conflicts that have occurred in the past as a result of discussions about them. In this example, the topics of religion and politics are not introduced in conversation and, thus, would be considered topic avoidance. In other instances, topics could be kept secret because they are condemned by one's family or society. For example, Anita Vangelisti identified three different categories of secrets in families: taboo secrets, rule violations, and conventional secrets. *Taboo topics* usually involve behaviors or activities that are stigmatized by society. Some

examples of taboo secrets include marital difficulties, substance abuse, mental health, or illegalities. Taboo secrets are often the most commonly reported type of family secrets. *Rule violations* involve breaking family rules, such as premarital pregnancy, drinking or partying, breaking curfews, and cohabitation. *Conventional family secrets* are secrets that are judged as inappropriate for discussion. These topics often include religion, politics, death, conflicts in the family, and dating partners.

Relationship Types and Motivations for Taboo Topics

The topics that are considered taboo may also depend on the type of relationship. For example, the current state of one's relationship is often taboo in cross-sex friendship because to talk about this topic might change the dynamics of the relationship. Likewise, children from divorced families and stepfamilies often avoid talking about the state of their family relationships. Stepchildren refrain from talking about their new family relationships for fear that it will alter the status quo of their family or that the new information that could be gleaned from discussing the topic would make things worse. However, children whose parents are divorced also tend to make the topic of their parents' relationship taboo because they are afraid of being caught in the middle of their parents' disputes. Finally, dating partners often avoid talking about issues such as their previous dating partners to prevent conflict and feelings of jealousy.

People declare certain topics taboo in their relationships for many reasons. Regardless of whether topic avoidance or secrets are the focus of investigation, people tend to refrain from introducing topics for protection reasons. More specifically, people avoid talking about certain topics with others to protect themselves, protect their relationships, or protect other people. For self-protection, people often refrain from talking about certain topics because they are afraid of being vulnerable—that they might be judged, ridiculed, looked down upon, and that the information might be used against them in some way. They also long to protect their relationships from changing, becoming stressed or conflict-ridden, or losing a close bond that they have developed. Individuals also desire to

protect the other person or other family members from becoming hurt, angry, or sad if they talk about the topic. In general, people are less likely to reveal secrets that are taboo because of the negativity and stigma associated with the topic.

Personal and Relational Implications

What type of an effect do taboo topics have on one's self and one's relationships? In general, concealment tends to hinder one's physical and mental health and revealment tends to benefit one's health. For instance, James Pennebaker has found that when people write down their secrets or tell them to someone else, it improves their immune functioning. Disclosure tends to be cathartic because it releases the pressure that can build up as a result of hiding or suppressing important information. Keeping secrets, especially if they are taboo, can drain a person emotionally because people often have a desire to rid themselves of the deception, guilt, and pressure that secrets can invoke.

Avoidance and secret-keeping also tend to be associated with dissatisfaction in relationships. When people feel as though they are avoiding or keeping secrets from others or that others are keeping information from them, it tends to be associated with dissatisfaction. Research has found that even if your partner says that he or she is not avoiding you, if you think that your partner is avoiding you, it is dissatisfying. Perception may matter more than actual avoidance tendencies. Topics that can be declared taboo more covertly or without a person realizing it are also less dissatisfying than are topics that are declared taboo more overtly.

Nevertheless, in some situations avoidance could help maintain or perhaps enhance one's health and relationships. For instance, research on the disclosure of HIV status suggests that patients' cell counts can improve or deteriorate depending on how the recipient of the information reacts to the revelation of the patient being HIV positive. Similarly, research suggests that avoiding trivial topics with one's marital or dating partner can prevent unnecessary strain and conflict. Some things may be better left unsaid—especially if they are unimportant and would only

hurt one's self or one's partner. Therefore, the impact of taboo topics on relationships and one's personal well-being depends on a host of factors and circumstances, including the importance of the topic.

TEACHER–STUDENT RELATIONSHIPS

There is growing consensus that the nature and quality of children's relationships with teachers play a critical and central role in motivating students to learn, and teaching them what they need to know to become knowledgeable and productive citizens. Effective teachers are typically described as those who create relationships with students that are emotionally close, safe, and trusting, that facilitate provisions of instrumental help and communication of positive and high expectations for performance, and that foster a more general ethos of community and caring in their classrooms. In general, theoretical perspectives and empirical research supports the notion that these relationship qualities support the development of students' emotional well-being and positive sense of self, positive motivational orientations for social and academic outcomes, and actual social and academic skills.

This entry describes the theoretical perspectives most often used to guide research on teacher–student relationships, a summary of findings relating teacher–student relationships to social and academic outcomes at school, and issues in need of further study.

Theoretical Perspectives

Researchers have adopted multiple theoretical perspectives to study the affective nature and qualities of teacher–student relationships including those of Attachment Theory, Self-Determination Theory, and social support and person–environment fit frameworks. Central to these perspectives is the notion that the affective quality of teacher–student relationships is a critical motivator of student adjustment, and that aspects of teacher–student relationships have a causal effect on children's school-related competence, primarily by promoting a positive sense of self and emotional well-being.

Attachment Theory has provided the strongest impetus for work on teachers' relationships with young children. According to this theory, the dyadic relationship between a child and caregiver (usually the mother) is a system in which children experience various levels of felt security, safety, and responsiveness to their basic needs, with predictable and sensitive responses being associated with secure attachments that foster curiosity and exploration of the environment, positive coping skills, and a mental representation of one's self as being worthy of love and of others as being trustworthy. Although teacher–student relationships are not typically viewed as primary attachment relationships, Attachment Theory principles would suggest that they would be fairly concordant with the quality of parent–child attachments and therefore, related to children's intellectual curiosity, positive sense of self, and emotional well-being. In turn, these intrapersonal outcomes are believed to contribute to the development of positive social and cognitive skills at school.

Self-Determination Theory posits that students will engage positively in the social and academic tasks of the classroom when their needs for relatedness, competence, and autonomy are met. Contextual supports in the form of interpersonal involvement, structure, and provisions of autonomy (e.g., opportunities for choice and self-direction) are believed to be essential to this process, with teacher involvement (e.g., demonstrating genuine interest in students' well-being and providing emotional support) and students' corresponding sense of relatedness being most frequently associated with the study of teacher–student

relationships. Feelings of relatedness are believed to facilitate students' adoption of goals and interests valued by teachers and desires to contribute in positive ways to the overall functioning of the social group. Feeling related to teachers has been studied most often in relation to academic motivation and engagement during the elementary and middle school years.

Social support perspectives on teacher–student relationships reflect the notion that students' subjective appraisals of teachers' support have implications for their subsequent adjustment to school. Similar to Attachment Theory, social support perspectives focus on students' mental representations of relationships, with perceived emotional support from teachers serving as a buffer from stress and anxiety. However, whereas Attachment Theory focuses on interpersonal relationships reflecting dyadic systems with fairly stable histories of interactions, social support perspectives typically consider relationships as personal resources that can range from highly familiar and stable (e.g., an elementary school teacher who teaches all subjects to the same students for an entire year) to relatively impersonal and fleeting (e.g., a semester-long instructor in one subject).

Person–environment fit perspectives are based on the notion that adaptive functioning occurs when there is a good match between the needs of the individual and what the environment can contribute to the fulfillment of those needs. Therefore, a distinguishing characteristic of this approach when applied to school settings is a focus on multiple provisions that are central to the educative process, such as a structured environment in which expectations are communicated clearly, resources contribute directly to learning, and a physically and emotionally safe classroom. Although the quality of dyadic relationships is not always the explicit focus of discussion, researchers assume that ongoing student–teacher interactions reflect a form of social reciprocity that provides students with opportunities to pursue their own goals but also to learn about and then actively pursue those social and academic goals that are valued by others at school.

This broader socialization perspective is supported by students' and teachers' qualitative descriptions of caring and supportive teachers. For example, middle school students describe caring

and supportive teachers as those who demonstrate democratic and egalitarian communication styles designed to elicit student participation and input, who develop expectations for student behavior and performance in light of individual differences and abilities, who model a “caring” attitude and interest in their instruction and interpersonal dealings with students, and who provide constructive rather than harsh and critical feedback.

Teacher–Student Relationships and Student Outcomes

The empirical literature supports a conclusion that the affective nature and qualities of teacher–student relationships are related significantly to a broad range of positive student outcomes. For example, preschool- and kindergarten-aged children who enjoy emotionally secure relationships with their teachers are more likely to demonstrate prosocial, gregarious, and complex play and less likely to show hostile aggression and withdrawn behavior toward their peers. Close, secure teacher–child relationships also have been related positively to school readiness scores, whereas teacher–child conflict has been related negatively to positive work habits and readiness scores. Researchers who have studied the same preschool-aged children over a number of years report that teacher–child closeness in preschool is associated positively with children's language skills, sociability, and attention in kindergarten and first grade, and negatively with forms of internalizing and problem behavior. Other longitudinal studies have documented that qualities of teacher–student relationships in kindergarten predict similar social-emotional outcomes as much as 8 years later.

In samples of adolescent students, the affective quality of relationships with teachers also has been related to classroom grades and dropping out of school, as well as to motivational outcomes such as academic goal orientations, values, interest, and self-efficacy. Some young adolescents report declines in the nurturant qualities of teacher–student relationships after the transition to middle school that correspond to declines in their academic motivation and achievement. Students' appraisals of supportive relationships with teachers also have been related to social outcomes

including pursuit of goals to engage in positive forms of social behavior, prosocial actions, and aggressive, delinquent behavior. Perceiving emotional support from teachers also has been related positively to adolescents' emotional well-being and negatively to internalizing problems such as depression and emotional distress.

Finally, researchers have examined teachers' relationships with students along multiple dimensions to include emotional support as well as communication of expectations, instrumental help, and safety. Empirical evidence indicates that multiple dimensions of support predict aspects of students' social and academic adjustment to school in Caucasian, African-American, and Latino samples. However, qualitative findings also suggest that specific dimensions of support are beneficial as a function of students' ability and race. For example, students from high-ability tracks tend to value teachers who challenge them, encourage class participation, and express educational goals similar to theirs. In contrast, students from low-ability tracks tend to value relationships with teachers marked by kindness, fair treatment, academic help, and effective classroom management. Racially mixed groups of middle school students highlight the importance of teachers who are responsive to individual differences and needs, provide students with autonomy and choice, show interest in students as individuals, help with academics, encourage students to work up to their potential, and teach well and make subject matter interesting.

Unresolved Issues

Despite consistent findings that teacher–student relationships play an important role in students' social and academic lives at school, several issues remain unresolved. First, research indicates that students' characteristics might enhance or detract from their ability to benefit from supportive relationships with teachers. In the elementary school years, positive teacher–student relationships tend to be more beneficial for ethnic minority and at-risk students than for Caucasian students. In addition, relations between perceived emotional support from teachers and student adjustment tend to be influenced by socioeconomic status (SES) and race such that students from lower SES

backgrounds and members of minority groups tend to benefit more from close relationships with teachers than do other students. School-level factors such as safety, racial homogeneity, SES of the student body, and composition of instructional teams also appear to moderate relations between perceived teacher support and student outcomes. Although speculative, school-related outcomes of students at risk because of special needs, SES, or ethnicity might reflect feelings of discrimination or alienation because of their minority status. If so, close and positive relationships with teachers might provide these students with a secure base for developing a more positive sense of self and corresponding social and academic skills.

An additional issue worthy of note is whether relationships with teachers have a meaningful impact on students when other sources of support are taken into account. For the most part, when children rate the importance of their relationships with mothers, fathers, siblings, teachers, and friends, they typically report being very satisfied with their relationships with their teachers, and rank teachers as most important for providing instrumental aid and informational support at levels comparable with instrumental help from mothers and fathers. However, on dimensions such as intimacy, companionship, nurturance, and admiration, teachers are routinely ranked by children as the least likely source of support when compared with parents and peers. Moreover, although these relative rankings remain stable from childhood into adolescence, the overall importance of teachers in students' lives appears to decline with age.

Most conclusions concerning the importance of teacher–student relationships and interactions are based on studies that have not considered the contribution of other relationships that might contribute to students' adjustment to school. However, research on the concordance of students' attachment relationships with parents and teachers indicates that continuity across contexts is not always evident, and aspects of teacher–student relationships often predict student outcomes beyond similar aspects of parent–child relationships. The effects of teacher–student relationships on student outcomes appear to be strongest when parent–child relationships are less positive than are teacher–student relationships. In this regard, teachers have the opportunity to provide social

and emotional supports to children when they are not available from parents and, therefore, have a greater impact on these children's school-related functioning.

Findings also suggest that the effects of perceived emotional support from teachers are likely to be domain specific, with teacher support being related most strongly to those outcomes to which teachers contribute most, such as academic interest and classroom behavior. Identifying specific ways in which these relationships can actively and directly promote the development of positive motivational orientations toward learning and academic competencies, independently of other relationship supports from parents and peers, remains a challenge for researchers in this area. Similarly, identification of ways in which students contribute to the formation and maintenance of relationships with their teachers also remains a significant challenge for the field.

TECHNOLOGY AND RELATIONSHIPS

This entry explores the ways in which information and communication technologies—such as e-mail, instant messaging, text messaging, and other Internet-based exchanges of information—hinder or facilitate relationships. Research examining the effect of information and communication technology on relationships began as the development and diffusion of computers and Internet technology was adopted by household members. In the late 20th century, personal computers began to be purchased for home use. The U.S. Department of Commerce reported that fewer than 10 percent of households had computers in 1984, compared with more than 60 percent of households in 2003, and Internet access increased from about 18 percent of households in 1997 to more than 55 percent in 2003. The Pew Internet and American Life Project found that about 70 percent of U.S. residents reported going online in 2007. Young adults, Whites, affluent, and better-educated adults were the most likely to be online. Among these groups, about 90 percent reported Internet use.

Some predicted that the introduction of Internet-based communication tools would have positive implications for relationships, arguing that people would develop and maintain stronger social ties. Others predicted that these technologies would lead to isolation and fracture social and family relationships by supplanting face-to-face interactions with computer-mediated communication. The research findings are much more

complex than either of these perspectives would suggest.

Family Relationships

With the advent of Internet communication, a central concern was whether online relationships would have negative implications for off-line family relationships. An early study by Robert Kraut and his colleagues in the late 1990s suggested that those adults who spent more time on the Internet were more socially isolated than were those who spent less time on the Internet. However, this appears to have been only a short-term effect associated with early adopters of the technology because most subsequent research has not replicated these initial findings. In general, researchers have found that Internet use has no relationship with the amount of time spent with family members or the quality of those relationships.

Barry Wellman and his colleagues have begun to take a more in-depth look at how communication technologies are being used by family members. They reported that Internet communications are becoming more common among household members when they are away from each other such as when parents are at work and children are at home. Most of the e-mail communication is between the adults in the household. Although parents mostly use the telephone to stay in contact with their children, parents do report e-mailing their children. Their findings indicate that women are more likely to contact children and use the Internet to maintain family ties, which suggests that women are now using the Internet to perform the social networking role that they have long held in families. Another finding by Wellman is that families tend to share time using a single household computer. Husbands and wives report spending 1 to 3 hours per week using the Internet together, and parents report spending from 2 to 4 hours per week using the Internet with their children. Wellman noted that in contrast to concerns about the computer isolating family members, it appears to bring them together. However, this may be a temporary phenomenon. Most households currently have one computer, but as households obtain multiple computers, these sharing activities may disappear.

Romantic Relationships

Dating and Intimacy

Online dating, which can be defined as using the Internet to meet new people with the intention of potentially developing a nonplatonic relationship, has become a popular medium for mate selection during the past decade. Once stigmatized as a dating outlet for the socially inept or desperate, a 2006 report of the Pew Internet and American Life Project found that 74 percent of single Internet users seeking romantic partners had used the Internet to advance their dating interests in some way, and 37 percent had visited an online dating Web site. Moreover, 31 percent of all U.S. residents reported knowing someone who had used a dating Web site, and 15 percent knew someone who had been in a long-term relationship or marriage with a partner he or she initially met online. Online dating has clearly matured beyond its early stigmatization to become a widely used and socially acceptable resource for those seeking intimate partners. In fact, the online dating industry now has more paying subscribers than any other online industry.

One particularly appealing aspect of online dating for many people is the ability to quickly filter through a vast number of potential partners based on demographic or related criteria, such as age, height, education, income, or appearance. Similarly, mate selection practices based on matchmakers and arranged marriages have also benefited from online services. For example, Indians commonly expect couples to share the same dialect and caste, and matchmakers have found that the Internet provides an efficient method of identifying acceptable matches based on these types of criteria.

The length of time that a promising online relationship remains exclusively computer-mediated varies. However, at some point, online relationships typically progress to a period of telephone communication followed by a face-to-face meeting. It remains unclear whether relationships initiated online differ from their off-line counterparts in long-term stability and satisfaction.

Extramarital Relationships

Cybersex has blurred the definition of sexual relations because highly sexualized interactions often take place through the Internet among people

who have never had, nor intend to have, a face-to-face meeting or physical contact with one another. Although definitions of computer-mediated infidelity vary from person to person, most therapists agree that secrecy coupled with sexual excitement forms the key ingredients for feelings of betrayal to emerge in partners following discovery of the behavior. Research has found that, among marital relationships destabilized by a partner's cybersex behavior, about 60 percent involved only computer-mediated interaction with no face-to-face meeting and many of these cases ended in divorce. Accordingly, the sex and relationship therapy literature on cybersex-related behaviors and treatment approaches for Internet infidelity has burgeoned in recent years.

Sexuality and the Internet

The ACE Model of Cybersexual Addiction (anonymity, convenience, escape) and the Triple "A" Engine (access, affordability, and anonymity) have been proposed to explain the appeal of cybersex. Some have also suggested that approximation be added as a fourth component of the latter model to capture the lure of risk-free experimentation associated with cybersex. That is, the sensations associated with sexual behaviors that arouse one's curiosity but would not be pursued off-line can be approximated safely through online fantasy sex. Interestingly, some research suggests that women are more likely to struggle with cybersex addiction than are men. One hypothesis is that the anonymity of computer-mediated communication is more liberating for women because of sociosexual norms that tend to suppress women's sexual expression.

Although Internet pornography and cybersex addiction garners a great deal of attention in both the popular media and scientific literature, positive aspects of sexuality are also associated with the Internet. For example, the Internet is a democratizing agent for the sexually marginalized. Homosexuals, transsexuals, older adults, HIV-positive individuals, and the disabled are among the sexually disenfranchised who have formed online communities to pursue shared interests, including those related to sexuality. Sex therapists have also reported successful experiences conducting therapy for issues such as erectile dysfunction

and premature ejaculation solely through the privacy and anonymity of the Internet.

Families and Social Networks

Scientists have also been interested in how computer-based communication technology helps or hinders children's and adults' ability to maintain social relationships outside of the family.

The primary question addressed regarding social relationships among adults has been whether the Internet results in better or worse relationships with friends. The research findings have been mixed, but more recent longitudinal studies indicate that online communication with friends strengthens these ties. Researchers have theorized that online communication provides a stimulus for adults to communicate more often both online and off-line with friends and suggest that it is easier to maintain these relationships through online communication, which requires less formality and less effort.

The primary issue that has been studied regarding children's Internet use has grown from concern about strangers contacting young people for dangerous or inappropriate activities. Studies in the United States and the Netherlands suggest that relatively few adolescents have contact with strangers online. These studies indicate that 84 to 88 percent of teenagers' online communication is with friends that they know from off-line settings such as school and the neighborhood. Little evidence suggests that online activities diminish young people's off-line social interactions because there is considerable overlap between online and off-line relationships. Janis Wolak and her colleagues conducted a nationally representative telephone survey of teens in 1999 to 2000 to obtain an overall assessment of the degree to which U.S. adolescents were at-risk because of online contact with strangers and found that although most adolescent Internet users occasionally communicated with strangers, those contacts rarely led to close relationships or face-to-face meetings. Rather than being a source of concern, researchers have found evidence that online communication among teenagers can lead to positive social ties. For example, in 2007, Patti Valkenburg and Jochen Peter tested a number of hypotheses regarding the impact of

online communication on relationships and found that online communication by teens with their peers generally led to greater feelings of closeness. Valkenburg and Peter also found that socially anxious teens may especially benefit from the opportunity to develop closer ties to friends through online communication.

Conclusion

Research on technology and relationships is preliminary. A challenge regarding our understanding of the links between relationships and Internet communication technologies is that the technology is rapidly evolving. Research on social phenomena requires many years to develop a clear understanding of an issue, yet new types of technology-based communication interactions are constantly emerging. Likewise, people have increasing experience with Internet tools and are more sophisticated in putting them to use for their own purposes, meaning that the context and consequences of the same communication behaviors change over time.

Regarding theory about technology and relationships, technology affords individuals opportunities, but people also shape how technologies get used. This is most obvious in the use of the Internet by adolescents. Of all the possible things that teenagers might do with a computer, they spend most of their time talking with friends and listening to music. In short, the Internet has mostly replaced the radio and telephone use of a previous generation. Perhaps little has really changed regarding the development and maintenance of social and family relationships; maybe only the tools have changed.

TEMPERAMENT

Temperament is the emotional and regulatory core of personality, incorporating traitlike individual differences in emotional, attentional, and motor reactivity and in self-regulation. Temperament is biologically based, present early in life, and develops through a person's interactions and experiences with the environment. As self-regulation develops across childhood, individuals gain more conscious control of their emotions and activity, influencing the expression of temperament. This entry describes dimensions of temperament, stability of temperament, links to personality, measurement, and the role of temperament in human relationships.

Definition and Basic Concepts

Mary Rothbart depicts temperament as having two major components: emotion reactivity and emotion regulation. Emotion reactivity involves individual differences in physiological and behavioral responses, such as exuberance when receiving a gift or fearfulness when meeting new people. Emotion regulation refers to higher-order attentional processes and cognitive control in response to emotion reactivity. Temperamental effortful

control, for example, is the ability to suppress a dominant response to perform a secondary response, such as counting to 10 when angry rather than striking another person. Temperament is rooted in the infant's neurophysiology and shaped by both genetic and environmental factors. With development, individuals gain more conscious control of their emotions and activity. By interacting with the environment over time, temperament evolves into a predictable pattern of behavior or personality style. Thus, temperament is conceptualized as constitutionally based individual differences in emotional and motor reactivity and self-regulation.

The study of temperament has a long history in the field of developmental psychology, and Rothbart's theory stems from the pioneering work of two psychiatrists, Alexander Thomas and Stella Chess. Based on parental descriptions of infant behavior and observations across a number of different contexts, Thomas and Chess identified nine dimensions to describe characteristic ways of responding emotionally and behaviorally to environmental events. These nine dimensions are activity level, rhythmicity or regularity of functioning, approach-withdrawal in novel situations, intensity of emotional expression, overall valence of mood, adaptability to changes in routine, persistence, distractibility or soothability, and threshold of sensory responsiveness.

Thomas and Chess formed three temperamental types from these dimensions: easy, slow-to-warm up, and difficult. Easy children are high in rhythmicity (high regularity in sleep, eating, defecating), high in adaptability (accept change readily), and not overly active, intense, or moody. Slow-to-warm-up children have slower adaptability and higher negative responsivity. Difficult children are characterized by low rhythmicity (irregularity in biological functions), low adaptability, and high negative moodiness. Children classified as difficult are more likely to experience later behavioral problems than are easy or slow-to-warm-up children; however, the prediction depends on the *goodness of fit* with their environment. Goodness of fit refers to the match between the child's temperament and the demands of the situation or expectations of others. A good fit predicts healthy development, whereas a poor fit generates stress and leads to problem behaviors and disorders. For

example, highly irritable children need predictable family routines to assist them in regulating these behaviors, whereas children low on irritability are less sensitive to unstructured environments.

Contemporary empirical studies have demonstrated that Thomas and Chess's nine dimensions of temperament are overlapping; thus, Rothbart's two components of temperament are more typically used in research today.

Stability of Temperament

Temperament is relatively consistent across situations and stable over time, developing through interactions with the environment. In general, temperament has modest stability during infancy and toddlerhood and then shows an increase in stability around age 3, when emotion regulation plays a larger role in behavior. Although attentional orienting is quite stable from infancy on, other dimensions are less stable. In infancy, approach-withdrawal, sociability, shyness, and behavioral inhibition (wariness of new people or situations) are moderately stable, with negative emotionality being less stable in infancy and childhood. Activity level is not stable in infancy, but becomes more so with age.

Twin studies have found genetic influences on temperament account for stability in behavioral inhibition, shyness, attentional orienting, sociability, and activity level. Changes in temperament across childhood appear to result from environmental influences, with shyness increasing when, for example, a child moves to a new school.

By the preschool years, temperament is stable enough to predict adult personality, but there is still some change across middle childhood and adolescence. Temperament is shaped in part by the ways individuals engage and evoke responses from their environments as well as how they interpret their experiences. For example, anxious and irritable children tend to perceive negative events in their lives as more threatening than do other children. Conversely, temperament affects responses from other people. For example, mothers of irritable, difficult-to-soothe infants experience lower confidence and greater depression than do mothers of easy infants, further shaping the development of temperament.

Temperament and Personality

Along with experience, temperament influences the development of personality. Personality is a broader concept, including habits, skills, goals, values, needs, the content of individual thought, and the perception of self in relation to others. Thus, personality is a characteristic pattern of thinking, feeling, and acting. The Big Five Personality factors, Extraversion, Agreeableness, Conscientiousness, Neuroticism, and Openness, can be predicted by early temperament. Specifically, childhood fearfulness and irritability predict adult neuroticism, whereas childhood positive approach behaviors predict openness, agreeableness, and extraversion, and childhood inhibitory control predicts adult conscientiousness. Although temperament and personality are not the same thing, temperament forms the affective core of later personality.

Assessment of Temperament

Temperament is most commonly assessed through parental report, examiner report, or behavioral observation techniques. Behavior observation paradigms include both structured, such as Hill Goldsmith and Mary Rothbart's Laboratory Temperament Assessment Battery, and unstructured paradigms, such as observations on the playground. Each method of assessment comes with advantages and disadvantages. Parental report is inexpensive and taps the extensive knowledge of parents who have observed their children's responses to a variety of stimuli in several different contexts. However, parental report is limited in that parents only observe their children's behavior when in their own presence and children may act differently when not with their parents. Although parents are high-quality informants of their own children's behavior, parents' responses might be influenced by their own personalities or psychopathology or they may adjust their responses to create a particular impression on the researcher. Structured observational assessments, although expensive, allow precise control, but are limited to behaviors that can be elicited in the laboratory setting.

Temperament is hierarchically organized and can be assessed on various levels. Temperament

researchers come from a variety of perspectives, from emphasizing the importance of mother's perceptions of her child's temperament to considering biological indicators or correlates such as heart rate and stress hormone levels. A complete assessment of temperament typically involves a combination of multiple approaches to maximize validity and minimize the weaknesses of any one approach.

Ties to Attachment Style and Relationships

Temperament has an impact on infant attachment to caregivers, and likewise, attachment can affect temperament. Securely attached infants are appropriately soothed and regulated by their caregivers, whereas insecurely attached infants have a less positive and more unstable bond with their caregivers. Although temperament is associated with behavior during the Strange Situation attachment assessment, it does not relate to the attachment classification of secure or insecure. The Strange Situation is a series of parental separations and reunions with their infant that predicts future relationships. With preschool children, negative temperamental reactivity is modestly associated with attachment assessed using Q-sort methods (raters sort descriptive statements into categories indicating how typical the descriptions are of a child). In addition, attachment classification is associated with later temperament, and an interaction of emotion reactivity and attachment classification influences later fear of novelty. Thus, temperament and attachment are different constructs, yet related to the extent that they both influence future relationships.

Temperament plays a key role in forming parental, sibling, peer, and romantic relationships. Children's temperament can elicit different responses from caregivers. An environment that might be a good fit for one child may provide a poor fit for a sibling with a different temperament. For example, difficult children are more negatively reactive to parental punishment. Also, parents who gently discourage shyness have children who are less shy later on. Temperament also influences the quality of the developing parent-child relationship. If the parent or child has higher levels of negative mood, the parent-child relationship can

be marked by increased conflict and decreased warmth and connectedness.

Sibling relationships are also influenced by temperament. Differences in sibling temperament (i.e., withdrawal, unadaptability, mood, persistence, and threshold) have been linked to more sibling conflict. Recent studies show that similarities in difficult temperament are related to more conflict, whereas similarities in easy temperament produce less conflict. When there is a temperament mismatch, regardless of the age and sex of siblings, siblings with strongly active and intense temperaments have more sibling conflict. The positive influence of an easy temperament is stronger if it belongs to the older sibling. Traditionally, the older sibling dominates throughout middle childhood, so an easy temperament in a younger sibling would not have the same effect on the relationship. Older siblings also change the overall family environment and affect the younger sibling's goodness of fit; the same temperament traits that suited the older sibling well may not be as adaptive for a younger sibling.

Temperament also affects the development and quality of peer relationships. High activity level, low regulation, and negative mood result in more negative peer experiences that lead to peer rejection, neglect, and bullying. Through direct modeling, peers play an integral part in social development.

Temperament is also associated with romantic relationships in adulthood. Higher levels of temperamental regularity and adaptability are related to more successful romantic relationships, whereas higher levels of negative moodiness and anger have been linked to dating violence and less successful relationships. Contrary to the popular belief that *opposites attract*, the evolutionary perspective of positive assortative mating holds that *like attracts like*. Individuals are naturally attracted to others who display similar characteristics because of the increased likelihood of successful mating and reproduction. For example, according to this perspective, a well-regulated individual would seek or prefer a partner who also exhibits good regulation. Temperament is a stable individual characteristic that influences all relationships.

TOUCH

Human beings cannot thrive without touching one another. This may seem an extreme statement, but ample evidence supports the notion that pleasing (i.e., hedonically positive) physical contact is vital for both mental and physical health, particularly during infancy and childhood. Touching is a powerful form of emotional communication in both romantic and platonic relationships and contributes a crucial dimension to intimacy.

Although the sense of touch provides important information about the texture and location of objects in the environment, this entry focuses primarily on its communicative and regulatory functions in social relationships.

Conceptualization and Measurement

As an aspect of communication, touch has meaning, and various characteristics of the “touch episode” and its participants may alter its meaning and effects. For example, when one person touches another, both experience the physical contact. However, the perceived mutuality of the contact can vary along a continuum from unidirectional (e.g., a hand massage) to completely reciprocated (e.g., a warm handshake). Unidirectional touch may or may not be expected or welcomed, depending in particular on the preexisting relationship between the giver and the receiver of the touch. Another critical factor is which parts of the body are involved in the touch—different areas of the body are considered more or less appropriate for touching by others (e.g., shoulders vs. thighs), depending on the relationship between those involved as well as their sociocultural background. Mechanical aspects of the touch itself (e.g., light stroking versus deep pressure) are likely important because individual differences in tactile sensitivity may lead to differing preferences for the quality of touch. The meaning and effects of touch may vary depending on its frequency of occurrence. For example, someone in a romantic relationship with a high level of physical affection between partners may benefit differently from a massage than would someone who has few avenues for positive physical contact. Last, but certainly not least, attitudes and beliefs about the appropriateness and desirability of touch in various contexts may influence how touch is perceived. For example, an affectionate pat from a spouse might be welcomed within one’s home, but not during a meeting at work. Although all these characteristics are important to fully understand the meaning and effects of touch, little research has been carried out in some of these areas.

Attitudes and beliefs about touch are most often measured using multi-item self-report scales, whereas touch behavior has been assessed with

both retrospective self-report and observation. However, several aspects of touch complicate its measurement. For example, because much interpersonal touch occurs in private, naturalistic observation of some of the domains of touch (e.g., intimate partner touch) is difficult. Sociocultural mores concerning touch limit the ability of researchers to manipulate it in the laboratory, both because of ethical concerns and because its meaning depends on the context. Diary studies, in which participants record information about their environments, behaviors, feelings, or thoughts one or more times per day, are a relatively recent addition to touch research and enable more ecologically valid assessment of the concurrent relations between touch and other behaviors or mental states. Another exciting trend in touch research involves measuring the physiological effects of interpersonal touch (e.g., its ability to reduce cardiovascular stress responses) and its potential health benefits, using both correlational and experimental designs.

Because the effects of touch depend on contextual factors, including sociocultural background, it is important to note that most of the research summarized in this entry was carried out in the United States, Canada, and Europe, with mostly White samples.

Research Findings

The sense of touch is one of several modalities that are typically grouped together as “somatosensation,” and include heat, pain, and itch along with touch. While a primary function of somatosensation is to convey environmental information to the central nervous system, it also has an affective function, endowing that information with hedonic value (e.g., pain is usually hedonically negative). Recent research suggests that the discriminative and affective aspects of touch are conveyed to the central nervous system by different classes of peripheral nerves, further supporting the central importance of this hedonic dimension.

Touch in Infancy

Touch is the most highly developed sense at birth, and extensive evidence indicates that positive

tactile stimulation is essential for human and other social mammals to grow and develop normally. Both animal and human research suggests that nurturant touch is an integral part of a neuroendocrine system specialized to facilitate both maternal caregiving and offspring attachment. Maintenance and reestablishment of physical contact between mother and offspring are highly characteristic of successful maternal care across many species of mammals, and more nurturant touch is associated with more secure attachment in human infants. Giving and receiving touch have beneficial effects and reduce stress responses in infants and their caregivers. Further, psychological and physical health outcomes are poor when human infants receive insufficient nurturant touch. These undesirable outcomes may include behavior problems, attachment disorders, failure to thrive, and even mortality in the severest cases of deprivation.

The ability of touch to regulate and communicate emotion begins early in life, as physical contact influences infants' emotions and their expression. For example, maternal touch can reduce an infant's arousal, particularly when it co-occurs with vestibular stimulation (e.g., rocking, riding in a moving vehicle), and can reduce expressions of distress during painful medical procedures. It also appears that infants are quite sensitive to the stimulus qualities of the physical contact they receive; touching an infant can generate contentment or distress based solely on the quality of the touch (e.g., forceful and abrupt versus gentle and prolonged).

Touch in Adulthood

The meaning of touch depends on a number of factors, including both individual characteristics and the context in which the touch occurs. Researchers have described these contexts and the interpretations of touch associated with them in five categories that range along a continuum from most distant to most intimate as follows: functional/professional, social/polite, friendship/warmth, love/intimacy, and sexual/arousal. Context constrains meaning, that is, a particular form of physical contact (e.g., a hug or a touch on the arm) may be interpreted differently depending on the type of situation in which it occurs.

Not surprisingly, the meaning ascribed to physical contact strongly influences its perceived

pleasantness and desirability. When a touch is perceived as incongruent within its context (e.g., when it violates sociocultural expectations), it is often perceived negatively. Other important moderators of the hedonic value of touch include gender (although same-sex touch is generally perceived as less pleasant than opposite-sex touch, this effect is stronger in men), the relationship between the giver and receiver of the touch (men tend to enjoy equally being touched by female acquaintances or strangers, but women like being touched by male acquaintances much more than by male strangers), and personality variables such as touch avoidance (touch avoidant individuals, in general, feel discomfort and anxiety when being touched) and attachment style (endorsement of positive physical contact is higher in individuals with secure attachment styles than in those with avoidant styles).

Physical contact is essential in both the development and maintenance of intimate romantic relationships. Research suggests that touching is arguably the most important avenue by which partners in intimate relationships cultivate and communicate that intimacy. Although it most often declines in frequency after the first year, the amount of touch reported by partners in a long-term relationship is strongly correlated with their reports of its intimacy and happiness. In addition, physical contact is a fundamental aspect of sexual relationships.

Physical contact promotes compliance in interpersonal interactions. In a number of experiments, different researchers have shown that participants who are touched are more likely to comply with requests to give money, sign a petition, help others in need, increase alcohol consumption, tend a stranger's dog for several minutes, and sample or purchase food. Few studies have investigated the mechanisms by which this effect occurs, but neither attraction to the toucher nor even awareness of being touched appears to account for it. Some have speculated that enhancement of compliance through physical contact occurs because higher-status individuals are more likely to initiate touch (and lower-status individuals are more likely to comply with those having higher status). However, although the belief that higher-status individuals initiate more touch than do lower-status individuals is pervasive, a recent meta analysis of nonverbal behaviors and verticality in social relations

revealed that there is no consensus in the literature about whether this is actually the case.

Physiological Effects of Touch

The immediate cardiovascular effects of social touch (usually a touch on the wrist or forearm) have been investigated in a number of laboratory experiments. The most consistent findings are that physical contact causes heart rate to decrease from baseline and reduces heart rate reactivity to stress tasks; a recent study suggests that this effect likely results from an increase in vagal activation of the heart.

With regard to more intimate or affectionate forms of physical contact, recent research has shown positive associations between “warm partner contact” (comprising both physical affection and positive, relationship-oriented conversation with one’s romantic partner) and reduced cardiovascular responses to stress. For example, both men and women who experienced 10 minutes of warm contact with their partners (including a 20-second hug) before a laboratory speech stressor had lower systolic and diastolic blood pressure and lower heart rate responses to the stressor than did those who did not. Another study revealed lower blood pressure before a stressor and lower heart rate during the stressor in women who reported more hugs with their partners on a daily basis. Another study tested neck and shoulder massage separately from social interaction and found that massage from a cohabiting romantic partner or spouse, but not verbal social support, reduced women’s heart rate and cortisol (a stress hormone) responses to a subsequent laboratory stressor.

Although relatively few studies have been done, most of the evidence suggests that physical contact tends to lower cardiovascular responses from baseline and reduces stress reactivity. However, this research was conducted in laboratory settings; almost nothing is known about the physiological effects of physical affection in daily life outside the laboratory. Recent advances in ambulatory monitoring of cardiovascular function, along with non-invasive methods of measuring cortisol, will improve future research in this area.

Massage Therapy

Massage therapy is a specialized form of touch. Typically, it is unidirectional; a trained practitioner

applies particular types of physical contact (e.g., rubbing, deep pressure) within an agreed-upon healing context, and is compensated for his or her efforts. Thus, it does not fall under the rubric of a friendship or other close relationship—in fact, it is explicitly professional. However, it is relatively well-studied, particularly with regard to physiological outcomes. Massage therapy has shown positive psychological and physiological effects in many studies of both normal and clinical samples. A recent summary of experimental studies in adults found conclusive evidence that (a) single applications of massage therapy reduced state anxiety, blood pressure, and heart rate; and (b) a course of multiple massage treatments significantly reduced chronic pain, anxiety, and depression. In addition, massage reduces crying, improves alertness, and increases weight gain in both pre- and full-term infants.

TRANSFERENCE

Do past relationships arise to haunt current ones? If so, when might this happen and how? The process of transference is known to arise when a mental representation of a significant other is triggered by the presence of someone who at least minimally resembles that significant other. The result is that this representation then serves as a lens through which the new person is viewed. Perceptions are colored by past experiences, expectations, and emotions. This is so whether the significant other is from one's family of origin (e.g., one's mother) or is from another domain (e.g., one's best friend). The content of the representation is a function of what is known and has previously been experienced in the particular relationship, yet the psychological process generally occurs in the same way across people in the context of everyday interpersonal relations, that is, relative to basic psychological processes. This entry addresses some ways in which prior relationships influence new ones, as well as current conceptions of the self, through the process of transference.

How Transference Works

The emotional and motivational relevance of close others is what renders them as broadly influential as they are. They are linked to the self in memory so that one experiences the self differently depending on the particular relationship. Cognitively, the frequency with which these representations have previously been activated and used leads them to have a special readiness to be used again. In short, they are chronically accessible. At the same time, triggering cues in the form of qualities of a new person will heighten the transient activation of a specific representation, making it more likely to be used at that time. Indeed, anything in the external context that maps onto what is known about the significant other can cue the representation, even if seemingly incidental, such as a style of responding or a first name. This cuing occurs even if the resemblance is outside of awareness.

Historical Background

Historically, transference was conceptualized as a clinical concept largely occurring in psychotherapy

and useful to therapeutic ends. Freud proposed the concept and conceived it as the patient re-experiencing with an analyst the infantile psychosexual conflicts felt with a parent. As reformulated by Harry Stack Sullivan, transference came to be called *parataxic distortion*. Notions of the self and significant other were at the forefront and bound together by the self-other relationship (termed *personifications* linked by *dynamisms*). Transference occurs, then, when material about the significant other is superimposed onto a new person and the learned interpersonal dynamics are experienced anew. The social-cognitive model of transference, formulated by Susan Andersen, is compatible with Sullivan's assumptions, though conceptualized in contemporary terms and in a way that can be examined scientifically. The scientific approach has allowed the first experimental demonstration of this century-old concept.

Procedures Used in Transference Research

In studies of transference, people typically learn about a new person by reading a series of statements about this person. In one condition, a minimal number of the features they learn are ones that they themselves had generated to describe their own significant other in an allegedly independent session several weeks earlier. For example, a feature listed to describe the significant other and then presented about the new person might be "drives a fast sports car" or "bites nails in public." This is how transference is triggered. In a control condition, participants learn the same information about the new person, but this information does not resemble their own significant other. Instead, it resembles someone else's significant other. Thus, there is no significant-other representation triggered in the latter case.

Findings in Transference Research

Inference and Memory

A central finding from this research is that people fill in the blanks about a new person using their significant-other representation when this new person at least minimally resembles this significant other. That is, their inferences about this

new person and their memory of what they actually learned about this person will be biased by what they know about the significant other rather than mainly reflecting the features actually learned. People in the significant-other resemblance condition infer that the new person has features that he or she does not in fact have simply because these features describe the significant other. For example, although the feature “is obsessed with politics,” may not have been presented as a feature of the new person, participants in the resemblance condition will be more likely to remember having learned that the new person “is obsessed with politics,” if it is a quality of their own significant other. That is, they are confident that they learned features about the new person that were not actually presented. This process is triggered implicitly—that is, with participants being unaware or only dimly aware of it—as has been shown using a variety of significant others. It even occurs when the triggering cues themselves are presented subliminally (i.e., so quickly that they cannot be consciously seen).

Evaluation

The literature also shows that people tend to evaluate a new person in line with how they evaluate a significant other if the new person at least minimally resembles that other. More unobtrusively, their facial expressions while learning about the new person also reveal this same overall evaluation. People show more positive facial affect in these initial moments of having a transference experience if the significant-other representation that the new person triggers is of a significant other who is well liked or loved, rather than disliked. No comparable effect is observed in control conditions.

Expectations and Behavioral Confirmation

Along similar lines, if the individual sees the significant other as having been accepting rather than rejecting, expectancies for acceptance will also be evoked in transference. That is, people will expect to be accepted rather than rejected by the new person, and nothing of the kind will occur in control conditions. Beyond this, expectancies influence interpersonal behavior and this occurs in

transference as well. In the transference context, people seem to act on their expectations about what the new person will be like and do so in a way that actually leads the new person to confirm their expectations. If one’s best friend tends to behave in a responsive, caring way, a stranger who shares a few qualities with one’s best friend will be expected to be responsive and caring as well, and this attitude will even tend to evoke a responsive and caring behavior from the new person. Expectations become reality in the behavior of the new person.

Motivation and Interpersonal Roles

Motivation, too, is influenced by transference. The goals pursued with a significant other are stored in memory along with the representation and, as a result, when the significant-other representation is activated, the corresponding goals will be also activated indirectly. For example, in close relationships, the motivation to remain close and connected is profound. Correspondingly, in positive transference (e.g., when a new person triggers the representation of a loved significant other), people are more highly motivated to be emotionally close with the new person than they otherwise would be. Moreover, the interpersonal role one typically occupies with a significant other (e.g., underling vs. authority figure), which is also infused with pertinent relationship goals, is also activated in the context of transference—with the result that a violation of that role is disturbing because goal pursuit would be hampered.

The Self

Even the way one experiences the self shifts in the context of transference. Representations of significant others are linked in memory with what is known about the self. Triggering such a representation will thus indirectly activate the self, and specifically, the version of self typically experienced with that significant other. For example, when a new person is even slightly reminiscent of one’s own mother, one is more likely to see oneself at that moment as one sees oneself while with one’s own mother. In such a transference, one comes to describe the self using the same kinds of terms used to describe the self as when with one’s mother, and the positivity or negativity of these self-descriptive

terms also shifts to reflect one's overall evaluation of the self in the significant-other relationship.

Self-Regulation

The self is involved in transference in the sense that self-regulatory processes are readily provoked once a significant other is activated. For example, if one experiences a threat to the self in transference, the result will often be compensatory self-inflation by bringing to mind self-features that are highly positive, presumably as a means of self-protection. Likewise, when negative information is encountered about a new person who resembles a positive significant other, the affective response to those exact negative features becomes positive. That is, just as people are known to treat the flaws of these loved ones as if they were virtues, people also show unusually positive affect in response to negative qualities of a new person who resembles a positive significant other.

Conversely, people do not always rally their self-regulatory resources when transference involves a conflicted relationship. For example, when transference concerns a parent who holds one to a standard of which one falls short, it activates an emotional vulnerability. According to Self-Discrepancy Theory, formulated by E. Tory Higgins, individuals may experience a discrepancy between a parent's ideals for them and the qualities their parent sees them as having (an actual-ideal discrepancy) or between a parent's sense of who they feel obliged to be and the qualities the parent believes they have (an actual-ought discrepancy). If so, when the mental representation of this parent is implicitly activated in transference, the particular discrepancy should be activated, which should lead the individual to feel dejected or depressed (if it is an actual-ideal self-discrepancy) or to be filled with hostility and have trouble calming down (if it is an actual-ought self-discrepancy). This is exactly what the evidence shows.

For individuals who were physically abused by a parent, activating this parental representation in transference has been shown to lead to profound mistrust of the new person as well as to the expectation of rejection by the new person and, at the same time, emotional indifference about how the new person might feel about them. Recent research has shown that under the circumstance of an

additional threat—for example, when the new person is said to be becoming increasingly irritated and annoyed while waiting for an upcoming interaction with the participant—abused individuals in transference show so little negative affect as compared with participants in other conditions that it may be akin to what is termed “emotional numbing.”

Such distancing may have been functional and adaptive when the individual needed to live and interact with the significant other, but it may be problematic to the degree that it might dampen a response of alarm to potential new threats with the new person. When the new person is in fact benign, the palpable disengagement might prevent a new and positive relationship from forming.

Intergroup Relations

Recent research has extended work on transference from the dyadic domain into the realm of intergroup relations. Activating a significant-other representation indirectly activates not only relational aspects of the self but also group identifications shared with this other. Specifically, when the new person resembles a significant other who shares one's own ethnic background, the new person is in fact assumed to be of this same ethnicity (in the absence of any relevant cues). Moreover, one's own ethnic identity is also activated, as shown by increased intergroup ethnic bias in judgments made about people outside the relationship—if the significant other also has an ethnically narrow social network rather than a diverse one. A diverse social network buffers the effect. This work is provocative both because it suggests a link between relational and social identity in transference and because it appears to be moderated by aspects of the significant other's own social network.

Conclusion

After a century of theorizing about the clinical concept of transference, advances in experimental social cognition have demonstrated that this process is both common and influential in shaping behavior toward others. Evidence suggests that transference is a normal aspect of basic cognitive processes and sets in motion both vulnerabilities

and opportunities deriving from our past personal relationships as they arise in the present.

TRANSFORMATION OF MOTIVATION

Transformation of motivation occurs while interacting with others when interaction behavior reflects a motivated shift away from one's immediate, self-interested behavioral impulse. The shift is motivated in that it is driven by a person's broader aims for the given interaction. Many interpersonal situations in the immediate moment elicit an urge to behave a certain way, such as in competitive situations. A shift in behavior occurs, however, because of broader interaction goals with a particular person or broader social considerations (for example, a business competitor versus a spouse). *Transformation of motivation* was coined by the authors of Interdependence Theory, Harold Kelley and John Thibaut, who developed this

theory to explain and predict thoughts and behaviors in interpersonal interactions.

Transformation of motivation is conceptualized as the mental process that, in many situations, shapes the nature of a person's interaction behavior, making it a central concept in understanding interactions in relationships. This entry discusses goals or “motives” people have in interactions, when and how such motives direct behavior in interpersonal situations, and the benefits of having this concept.

Interaction Motives

Before developing the concept of transformation of motivation, prevailing models predicting behavior were based on simple economic assumptions. These models suggested that in interactions with others, people are motivated to maximize their own gains—that is, their sole goal or motive is pursuing their own self-interest. The concept of transformation of motivation allows for the possibility that not all behavior is driven by immediate self-interest and, indeed, interaction motives may vary; a person is likely to have different goals when interacting with a potential relationship partner, a cooperative coworker, a friendly neighbor, or a competitive sibling.

The various motives people have in interacting with others can be understood in terms of different patterns of resources or “outcomes” each person obtains relative to the interaction partner. In studies where people make decisions about their own and another's outcomes (both the benefits and costs), people typically display one of four motives: maximizing one's own outcomes (self-interested motives), maximizing the partner's outcomes (altruistic motives), adopting the action that yields the highest own and partner outcomes (communal motives involving maximizing the pair's joint outcomes), or adopting the action that maximizes the difference favoring one's own outcomes *relative to* the partner outcomes (competitive motives).

Some interaction motives become more prevalent than others in specific types of relationships. Parents often act in ways to maximize what is best for their children, even when it means they themselves could have obtained better outcomes from alternative actions; friends often act in ways to

maximize their joint outcomes, unless they become involved in a friendly rivalry (e.g., in playing games or sports), in which the aim might become to do better than the other, even if an alternate action would have allowed both to do well. Individuals in well-functioning relationships typically do what is best for both of them or for the partner; those in distressed relationships may behave in more selfish ways (knowingly disregarding the partner's outcomes and instead acting to maximize their own outcomes).

When people face similar situations repeatedly, motive-consistent behavior may become relatively automatic. This is the case when one automatically enacts a social norm, rather than behaving in a purely self-interested manner. For example, when a man in an office setting is rushed and yet is greeted by a coworker ("Hey, how's it going?"), the man is likely to give little thought to greeting the coworker back ("Fine, thanks! How are you?") as he rushes by.

Before these responses became automatic, they would have required a more conscious transformation of motivation to override the temptation to respond to the given situation by ignoring the greeter. A person who is unfamiliar with office norms may indeed ignore the greeter on one occasion and find that this has unpleasant consequences—the greeter might scowl rather than smile in a future greeting opportunity. The greeter may then try another response, perhaps engaging the greeter in lengthy conversation, only to be avoided by the greeter in the future. Thoughtful acts that worked well (i.e., yielded satisfactory outcomes) in a specific type of situation—in this case, a situation in which the two people affect each other minimally and it is easy for each to invoke the greeting norm—become favored over those that result in unpleasant experiences, and repeating acts that work well give way to automatic tendencies.

When Are Interaction Motives Relevant?

When does behavior shift as a result of a transformation of motivation? Transformation of motivation is likely to occur when the given situation is such that the actions of each partner affect the other, and the initial, self-interested impulse to act

is one that will not serve broader interaction goals. Characteristics of a given situation will tend to elicit relatively uniform, short-sighted responses when one does not consider social norms, one's values about how to treat others, or concerns about how to treat a specific person. Once such considerations come into play, the uniform response is changed into a response tailored for those specific considerations. As such, the response of what would be a self-interested generic person—someone with no interest in or concern for another—is transformed into the response of someone with specific interaction motives.

To illustrate, imagine that Harry and Sally are a happily married couple. Sally had a long and trying day at work, but she takes refuge in knowing that she is almost home. Harry arrived earlier and had promised to cook and clean the kitchen, but he became sidetracked when a friend called on the phone. When Sally arrived, the situation she faced was that she was tired and hungry, no food was ready, the kitchen was a mess, and Harry was laughing on the phone.

Sally's initial urge, and that of most people faced with this situation, is to yell at Harry; in the immediate moment, most people would prefer—that is, attach a higher outcome to—yelling than to saying nothing. This is a situation, however, where a shift in motivation may occur, given that yelling undermines the interaction motives of happily married couples. As such, her preferred action—the one likely to yield the highest outcome for her—may shift from yelling toward whispering to him, "I'm a wreck; please get off the phone in the next minute or so." As for Harry, his initial impulse may be to say, firmly, "No way! I'm in the middle of a conversation!" Upon considering that she is a "wreck," however, he might shift toward ending his conversation quickly and turning his attention to Sally. Transformation of motivation conceptually accounts for the fact that each response moves beyond the "given" situation once Sally and Harry consider each other (and their relationship). Their underlying motive shifts from being self-interested to interaction motives that reflect broader interpersonal and social considerations.

What evidence is there that an actual shift occurs in how one is inclined to act? Is there any proof that people actually engage in a transformation of their motivation? Evidence indicates that in many

situations, actual behavior reflects a shift away from a generic response driven by self-interest. For instance, the many studies observing marital interaction have shown that the individual preferences that spouses describe before a problem-solving discussion are often compromised to promote cooperative solutions that are responsive to the needs of both partners. The cost of interdependence is that Sally may have to agree to attend *Harlequin Romance* with Harry when she would personally prefer to see *Terminator III*. The gain is that her more important motivation is to spend time with Harry and enjoy his company.

Similarly, when individuals in dating relationships are asked to recall a time when the partner behaved badly, the responses they report having considered enacting are more destructive than the responses they actually enacted. Also, when individuals consider hypothetical instances in which their dating partner behaves badly, having less time to respond or being distracted with other matters causes more destructive responses than having more time. This suggests that (a) actual behavior does not match initial behavioral inclinations, and (b) there really is an intermediary psychological process that involves transforming the situation by reflecting on broader social and interpersonal considerations.

To summarize, interaction motives become relevant when a given situation is likely to elicit behavior that would be socially inappropriate for the given interaction—it might violate social norms, go against the grain of one's personality or values, or undermine how one wants to be with a specific interaction partner. Evidence supports the idea that a process of transformation of motivation immediately precedes actual behavior.

Transformation of Motivation as a Useful Concept

The concept of transformation of motivation has been useful for understanding several aspects of human interactions, two of which are highlighted here. One is that it can be used to predict and account for interaction behavior. Provided with a precise account of an interaction situation—relevant physical, social, and personal characteristics, such as occupying a tight space with an acquaintance, or

interacting with demanding others when one is already exhausted—and provided with the broader considerations or goals one has for a given interaction, it becomes possible to better predict a person's behavior than from his or her individual characteristics. For example, a son-in-law who has had an exhausting day and feels ready to snap may react several different ways to the demands of an overbearing mother-in-law. If he is highly committed to his wife, one would predict that he will acquiesce to the mother-in-law's demands. The account for why a person engaged in a specific behavior would rest on the motive that was invoked.

Transformation of motivation is also a useful conceptual tool in understanding how people discern information about others—their norms, values, and desires for a specific relationship. Behavior is only partly attributable to features of a given situation, and largely attributable to what a specific person “makes” of the given situation. For example, office settings make for situations where coworkers typically greet one another. If one person greets another and stands very close, smiles a lot, and engages the other in flirtatious conversation, people would discern that the person is romantically interested in the other. The more a behavior departs from what might be expected given the situation, social norms, and the general type of interaction, the more that behavior provides rich, diagnostic information about specialized motives driving a person in that situation. As such, behavior that goes against what might be expected or predictable in a given situation conveys motives that are unique to a given person in a particular setting.

TRANSGRESSIONS

“All’s fair in love and war”—or so the saying goes. In real life, however, both love and war are bound by codes of proper conduct. When bad behavior violates the code of proper conduct in a close relationship, it is a relational transgression. When a stranger makes a rude or insulting comment, we feel annoyed and insulted, but there is no long-term cost because there is no emotional investment in the relationship. However, when a friend betrays or deceives us, the emotional response is much deeper and more troubling. Likewise, to learn that a romantic partner has been unfaithful is to experience waves of hurt, anger, fear, and jealousy. This entry more fully defines relational transgressions and explores the factors that influence their effect on relational quality and stability.

Defining Relational Transgressions

Although most people know intuitively what a relational transgression is, scholars use specific definitions to guide their research. The most widely used definition is that relational transgressions are *behaviors that violate implicit or explicit*

norms or rules that constitute the definitional terms of a relationship. Implicit norms and rules are not formally negotiated; they are simply the taken-for-granted assumptions that guide expectations for appropriate behaviors in most relationships (e.g., we will not say hurtful things, we will not display violent behavior, we will provide emotional support when needed). Explicit norms and rules are established as relationships develop or ambiguous definitions are negotiated (e.g., a dating couple makes an explicit commitment to be sexually and emotionally exclusive or cross-sex friends agree to have sex but not display jealousy if one partner begins dating). Explicit norms and rules are also established when some event requires a couple to clarify expectations (e.g., an ex-partner reappears and a rule is established that he or she is not to be included in the partner’s social network).

Importantly, these norms and rules are not simply regulatory guides for appropriate behavior. They are the defining features (or definitional terms) of close relationships. That is, whether explicitly acknowledged or not, the assumption that a certain set of expectations will be met, like a “moral code,” is the basis of trust in another person. When trust is established and maintained, we feel safe and become open with our thoughts and feelings. This openness contributes to the special feelings we call *relational closeness* or *intimacy*. Ironically, the emotional vulnerability that follows the development of trust also opens partners to the painful consequences of a transgression when trust is violated. Indeed, some scholars prefer to use the term *betrayal* rather than *transgression* to underscore the role of broken trust.

In sum, when scholars study relational transgressions, they are studying behaviors, actions, and messages that violate the norms and rules that underlie assumptions that a particular other person can be trusted—trusted to protect the relationship, show goodwill, keep private information private, and privilege the relationship as special. This perspective allows researchers to separate “bad behavior” from true transgressions. For example, some people are chronically late. This behavior may be annoying to network members, but would not be considered a relational transgression because it does not violate implicit or explicit norms or rules that are part of a relationship’s definition.

This entry now discusses the types of behaviors scholars have identified as relational transgressions and draws primarily from the research focused on close relationships such as friends, family, dating partners, or spouses. Although transgressions can occur in professional settings when a coworker violates a norm of appropriate conduct, these transgressions are not typically as personally devastating as is the transgression committed by a close relationship partner.

Types of Relational Transgressions

Scholars have delineated the types of actions and behaviors that are typically included within the broad category of relational transgression. Although not the most common in frequency of occurrence, the most serious transgression is generally considered to be relational infidelity, both sexual and emotional. *Sexual infidelity* is defined as engaging in sexual behaviors outside of a relationship when explicit or implicit rules prohibit it. Perceived severity depends on the context (e.g., a one-night stand with a stranger versus repeated occasions with the same person) and the extent of involvement (e.g., kissing, petting, or sexual intercourse). *Emotional infidelity* is defined as emotional involvement with and strong affection for another person that includes the investment of time and attention, either in face-to-face or mediated interactions (e.g., telephone or Internet) without the knowledge of one's partner.

When considering the question of which type of infidelity is perceived to be the most distressing, the answer depends partly on how researchers collect their data. One method of collecting data (called "forced choice") involves giving respondents three options (e.g., imagine that your partner has committed sexual infidelity, emotional infidelity, or both) and asking them to select the situation they would find the most upsetting. In these studies, respondents usually pick the situation with both types of infidelity as the most upsetting. When only two scenarios are provided, one with sexual infidelity and one with emotional infidelity, most men select the sexual infidelity as the most upsetting and most women select the emotional infidelity as the most upsetting. Some scholars explain this pattern as a function of the evolutionary differences

in the reproductive goals of men and women. Specifically, men want to be assured that any child born within a relationship is their own, whereas women want to be assured that the resources provided to them and their children by their partner will not be diverted to another woman. Other scholars explain the differences as the result of socialization for men and women. That is, because women are socialized to practice a restricted orientation toward sex and to link sex with emotional commitment, their partners may be threatened by their sexual infidelity because they assume that it also includes emotional attachment—a presumed double threat to the relationship. However, because men are socialized to practice an unrestricted orientation toward sex, their partners may be less threatened by their sexual involvement with another woman because they do not assume it suggests any emotional commitment.

A different method of collecting data, however, does not yield this pattern of gender differences in response to infidelity. When respondents are asked to rate the degree to which they would feel specific emotions such as anger or hurt rather than to pick the most upsetting type of infidelity, both men and women feel more total negative emotion over sexual than emotional infidelity. In addition, both men and women report feeling more anger over sexual infidelity, but feeling more hurt over emotional infidelity. Finally, even when using the forced-choice method, researchers find that women and men who have actually been the victims of a partner's sexual infidelity rate it equally distressing. In short, research continues to explore the nature and consequences of sexual and emotional infidelity, especially whether gender differences exist in responses.

A second type of transgression that is commonly reported by relational partners, and often associated with infidelity, is deception. *Deception* is communication intended to lead a partner to believe something that the deceiver knows is untrue. It is not misspeaking or accidentally forgetting—it is strategically designed to mislead a partner. Deception is accomplished in three general ways: omission, falsification, and equivocation. *Omission* is simply not informing a partner when that information is obviously relevant. *Falsification* is an explicit lie, usually forced by a partner's question. *Equivocation* is also forced by

a partner's question but contains some element of truth that allows the deceiver to sidestep the purpose of the question. For example, if a woman believes that her husband might be interested in a coworker and asks why he is working late so often, an equivocal response would be, "I told you I have year-end reports to finish." This response sidesteps the issue implied in the question but is somewhat true in that he does, in fact, have reports to finish up. If, however, she asks if he is spending time after work with another woman and he says absolutely not, when he is in fact doing so, he has lied to his wife. Deceptive communication, as a relational transgression, is damaging because it violates the expectations of a relationship to be honest and open.

Although infidelity and deception represent perhaps the prototypical relational transgression, many other types exist. For example, hurtful messages that devalue the relationship or the partner are commonly mentioned by research participants as a transgression they have experienced. Inappropriate or rude behaviors are often reported as a relational transgression, especially in sensitive contexts such as during conflict. Lack of sensitivity, such as thoughtless, disrespectful, or inconsiderate behavior, is also considered a relational transgression. Other transgressions include actions that show disregard for the relationship such as choosing other people or activities over the partner, breaking important promises, violating privacy such as looking at another's e-mail messages, being verbally or physically abusive, and abruptly terminating the relationship without warning or explanation.

Consequences of Relational Transgressions

A transgression's effect on relationship quality and stability depends on several factors. Two factors related to the transgression itself are severity and frequency or repetition of occurrence. For example, sexual infidelity is certainly a serious challenge for a romantic relationship, but it becomes even more severe when it has happened more than once and when it is embedded within a series of lies. And emotional infidelity is certainly more serious than a hurtful message or an act of disregard. However, if repeated over time, even

transgressions that appear to be less serious begin to erode the quality of a relationship because a partner feels more devalued, hurt, and resentful.

Two other factors that affect the quality and stability of a relationship are how the transgression is revealed and the explanation provided by the offender. When the transgressor voluntarily reveals the transgression, the consequences are less severe than when the offended person hears about it from others or discovers the transgression by him- or herself. In addition, the way the transgressor explains (or fails to explain) his or her actions is an important predictor of how the transgression will affect the relationship; it will either intensify the feelings of betrayal or will facilitate forgiveness. Specifically, if the transgressor offers a sincere apology, accepts responsibility for his or her action, and does not try to minimize the severity of the transgression or blame the victim in some way, the offended person is more likely to forgive the transgressor. To the extent that the transgressor's open acceptance of responsibility and expression of regret encourages forgiveness from the offended person, continued communication may reaffirm mutual commitment to the relationship and enhance qualities of trust, satisfaction, and openness.

Of course, forgiveness does not necessarily mean that the relationship will remain intact. Forgiveness is an emotional transformation—letting go of hurt, anger, and negative feelings toward the transgressor and actually transforming them into positive regard. Despite these positive feelings for the transgressor, however, an offended person may realize that the relationship has been damaged beyond repair and reconciliation is simply not possible.

Concluding Remarks

Relational transgressions play an important role in the quality and stability of a relationship. Maintaining the principles of honesty, fairness, and loyalty is essential for a satisfied and committed relationship. Relational transgressions test, and sometimes shatter, the trust that characterizes close relationships. Some relationships continue but trust is never fully restored. Some relationships terminate with rancor and lingering negative emotions. Fortunately, for relationships in which

productive communication facilitates forgiveness, reconciliation is possible. Even when the victim of a transgression does not choose to continue the relationship, forgiveness for the transgressor is a healthy emotion because it enables the offended person to move forward without lingering negative emotions.

TRUST

Imagine a hypothetical couple, Chris and Susan. Susan has just decided she wants to pursue her dream of going back to school to become a psychologist, and she is preparing to tell Chris about her plans. How will Chris react? Can she count on

him to support her decision, even if it entails costs for Chris? Should she worry that he may not be willing to make the sacrifices necessary for her to follow her dream?

This example illustrates principles of interpersonal trust, which is an important phenomenon in the daily lives of virtually all couples. Morton Deutsch, one of the founders of interpersonal trust research, defined *trust* as the confidence that one will find what is desired from a partner rather than what is feared. Trust reflects the juxtaposition of people’s loftiest hopes and aspirations in relation to their deepest worries and fears, and it might be the single most important ingredient for the development and maintenance of happy, well-functioning relationships. Several major theories, including John Bowlby’s Attachment Theory and Erik Erikson’s Theory of Psychosocial Development, are built on the premise that greater trust experienced early in life lays the psychological foundation for happier and better-functioning people and relationships in adulthood.

This entry describes some basic definitions of trust and trust-relevant social situations, reviews a new dyadic model of trust in relationships, discusses conditions under which greater trust could have negative effects on close relationships, and notes how trust is linked to other variables in relationships.

Conceptualizations of Trust

Interpersonal trust has been studied with two traditions in psychology. Earlier work adopted a dispositional view of trust in which trust was viewed as a property of individuals similar to personality traits such as shyness or extraversion. According to this approach, trust involves beliefs and attitudes about the degree to which other people in general can be depended on to be reliable, cooperative, and helpful. In the 1980s, conceptualizations and measures of trust became more partner-specific and relationship-specific. According to this dyadic or interpersonal view, trust is a psychological state or orientation of an individual (the truster) toward a specific partner (the trustee) with whom the individual is interdependent (that is, the truster needs the trustee’s cooperation to obtain valued outcomes or resources). According to this perspective, the

extent to which an individual trusts one person has no necessary association with how much she or he trusts another person. What makes interpersonal trust especially difficult to study is that it involves three components: “*I trust you to do X.*” In other words, trust depends on properties of the self (I), the specific partner (you), and the current situation (to do X).

Social psychologists Roderick Kramer and Peter Carnevale have further proposed that trust involves a set of beliefs, expectations, and attributions about the degree to which a partner’s actions are likely to support one’s long-term self-interests, particularly in situations in which one must count on the partner to provide unique benefits or critical outcomes. Such trust-relevant situations typically activate two cognitive processes: (1) feelings of vulnerability, and (2) expectations of how the partner is likely to behave across time. When a partner promotes an individual’s best interests instead of his or her own, *both* parties are likely to feel and report greater trust. Trust is also likely to be higher when (a) each partner’s self-interested outcomes match (are similar), (b) both partners have self-interested outcomes that match those that are best for the relationship, or (c) both individuals believe that their *partner* will act on what is best for the relationship, even when the partners’ personal self-interests are at odds.

Two types of trust-relevant situations have been described in the psychology literature. John Holmes and his colleagues have focused on “strain-test” situations. Strain-test situations occur when one individual wants a specific outcome that requires investment from his or her partner, but the needed actions differ from what would benefit the partner. For example, if Chris supports Susan’s desire to change her career even though he must make personal sacrifices to support her while she is in school, he most likely has “passed” a strain-test and, as a result, Susan should trust him more than before the test. Strain-test situations can be used intentionally or unintentionally to gauge the level of trust an individual should place in his or her partner. If, for example, Chris starts spending more time with his friends and less time with Susan, she may feel less confident about Chris and how he feels about the relationship. In this situation, Susan could gauge the level of trust she has in Chris by seeing how he reacts in this situation. She might ask him to go to a movie with her, knowing that

doing so would mean Chris would have to forgo a valued night out with his friends. If Chris gladly goes to the movie, Susan’s level of trust in Chris ought to increase. Deliberate or intentional attempts to create strain-test situations should be more likely when important, unexpected, or suspicious events lead individuals to question whether they can truly trust their partners. Though potentially diagnostic (an accurate gauge of trust), premeditated tests are probably conducted rather infrequently, and they could damage relationships.

Based in a game theory approach, Harold Kelley and his colleagues have investigated a second interpersonal trust situation. Similar to strain-tests, trust situations occur when partners are highly interdependent (that is, the actions of each partner strongly affect the other), partners have established rules for the coordination and exchange of behavior that maintain their interdependence, and partners have somewhat noncorresponding (dissimilar) outcomes. Whereas strain-test situations diagnose the level of trust that one can place in a partner at critical times in relationships (e.g., during important life transitions), trust situations may be used to determine the level of trust an individual should place in his or her partner during more mundane, everyday interactions so that trust situations may be the primary context in which trust gradually develops in relationships across time.

Consider another example. Suppose that Chris and Susan have a deck in their backyard that is a good place to spend quality time together. The deck, however, needs major repairs, and the upcoming weekend might be a good time to work on this project. There are four possible outcomes for this prototypic trust situation. In one outcome (outcome 1), Chris and Susan could both decide to work on the deck together, which would produce the maximum reward—the task gets done quickly and they also spend time together. In a second outcome (outcome 2), Chris decides not to work on the deck, whereas Susan does. In this case, Chris experiences some gains because progress is made on the deck, but Susan experiences some losses because she is saddled with all the work. Outcome 3 is the reverse of outcome 2, with Chris being saddled with all the work, yielding slightly more positive outcomes for Susan but slightly poorer ones for Chris. In outcome 4, neither Susan or Chris work on the deck, and no benefits are gained

or lost since no progress is made on the deck and they don't spend time together. According to Kelley and his colleagues, trust should increase when relationship partners repeatedly choose outcome 1 (mutually beneficial decisions) that yield the maximum rewards for *both* partners.

Trust situations have three unique properties. First, cooperative behavior by both partners always yields better outcomes compared with when partners do not cooperate. Second, the best outcome always occurs when both partners make the cooperative choice. Third, cooperative choices are risky because, if one's partner makes a noncooperative choice, the cooperative choice generates the *worst* possible outcomes for the individual. If this happens, the individual is likely to feel exploited, which should erode interpersonal trust.

Based on a recent review of the interpersonal trust literature, Jeff Simpson has identified four basic principles of interpersonal trust:

1. Individuals often gauge the degree to which they can trust their partners by observing whether their partners make sacrifices for the good of the individual or the good of the relationship in *trust-diagnostic* situations (that is, in trust or strain-test situations).
2. Trust-diagnostic situations (e.g., strain-test situations) often occur naturally and unintentionally during the ebb and flow of everyday life. Depending on circumstances, however, individuals may sometimes enter, transform, or occasionally create trust-diagnostic situations to test whether their current level of trust in a partner is warranted.
3. Individual differences in attachment style (secure versus insecure), self-esteem, or self-differentiation (the extent to which individuals have varying "selves" and roles with others) may affect the growth or decline of trust over time in relationships. People who are more securely attached, have higher self-esteem, or have more differentiated self-concepts should experience higher levels of trust and increases in trust in their relationships over time. In contrast, individuals who have lower self-esteem, have less differentiated self-concepts, or are less securely attached should be less likely to experience heightened trust and may experience decreases in trust as their relationships progresses.

4. Neither the level nor the trajectory of trust in relationships can be fully understood without considering the dispositions and actions of *both* relationship partners, especially in trust-diagnostic situations. Trust, therefore, is a truly interpersonal phenomenon.

Dyadic Model of Trust

Research on interpersonal trust has been guided by dispositional *or* interpersonal perspectives, rarely both. Dispositionally oriented work has documented that individuals who are more insecurely attached, have lower self-esteem, or have more poorly differentiated self-concepts (self-concepts that are less diversified, more imbalanced, and poorly tied together) usually trust their romantic partners less. Research has confirmed that trust tends to be higher when individuals believe their partners are more committed to the relationship and harbor more benevolent relationship intentions and motivations. It is also higher when partners regularly display "prorelationship transformations of motivation," that is, turning initial gut-level negative reactions to a partner's bad behaviors into constructive responses that ultimately benefit the relationship.

Transformations of motivation occur within the truster in relation to the trustee. Susan, for example, may refuse to work on the deck. Chris, in turn, may initially feel annoyed or frustrated that Susan is "letting him down," but he may quickly transform this initial negative reaction and protect the high regard that he has for her by giving her the benefit of the doubt. This transformation should also alter how Chris behaves toward Susan, which should result in more accommodative behavior by Susan in response to Chris's accommodative actions.

A model depicting how these core principles may be linked in social interactions is shown in Figure 1. The Dyadic Model of Trust in Relationships includes features of the relationship as well as individual difference (personality) components of both relationship partners. The relationship components of the model are depicted in the five boxes in the middle of the figure. The individual difference components, represented by circles for each partner, reflect the relevant dispositions of each relationship partner (e.g., each partner's attachment

Figure 1 Dyadic Model of Trust in Relationships (Simpson, 2007)

orientation, self-esteem, and self-differentiation) plus their connections to each relationship component in the model. Feedback loops between the individual components and the relationship components are not depicted, but are presumed to exist. According to the model, each individual's perceptions of his or her own *and* the partner's standing on each construct are necessary to explain and understand what happens in the downstream portions of the model.

The model assumes that information about the dispositions of *both* partners is essential to understanding and explaining the growth of trust—or lack thereof—in a relationship over time. The dispositional tendencies discussed should motivate certain people to enter, transform, or sometimes create social interactions that increase trust over time. Dispositional factors also may influence an individual's motivation to gauge the level of trust that can be placed in his or her partner as revealed in trust or strain-test situations. Before these situations can occur, however, one or both partners must have enough confidence to take the interpersonal risks necessary to confirm or reaffirm that their partner *can* be trusted to some degree. Individuals who have more positive working models, namely those who hold themselves and their partners in high regard and value the

current relationship, should be more likely to take these risks.

Once they are in trust-diagnostic situations, individuals who display the transformation of motivation needed to make decisions that benefit the partner or relationship at some cost to the self ought to experience more trust and felt security (see the second relationship component in the figure). Partners who have more positive working models should display benevolent partner or relationship-based transformations more often and more strongly. As a result, they should be more motivated and perhaps more capable of steering trust-relevant social interactions toward mutually beneficial decisions. Such decisions, in turn, should be interpreted positively by both partners. Individuals who have more positive working models may also grant themselves and their partners “fuller credit” for their joint willingness to maximize partner or relationship outcomes over self-centered interests, whereas the reverse should be true of individuals who have more negative models.

This series of events should then generate benevolent attributions of both one's own and the partner's relationship motives. If, for example, Chris makes major personal sacrifices to help Susan fulfill her goal of becoming a psychologist,

Susan should be more likely to infer that she needs and values Chris and the relationship. These attributions should result in more constructive problem-solving by Susan, more adaptive emotion regulation, and more optimistic expectations about future trust-diagnostic interactions. These positive outcomes, in turn, ought to increase perceptions of trust, at least temporarily. Each of these positive effects may be slightly stronger in individuals who have greater dispositional security (more positive working models), and they may be even stronger in relationships in which both partners are highly secure. Perceptions of greater trust should in turn engender perceptions of enhanced security, which may then determine whether or when the next trust or strain-test situation occurs.

Over time, individuals who repeatedly experience mutually beneficial outcomes in the presence of their partners may perceive greater “added value” (heightened rewards simply by engaging in pleasant activities with their partner in particular), especially in trust-diagnostic situations. Such repeated outcomes may encourage individuals and their partners to engage in additional relationship-sustaining or relationship-building acts, such as disparaging attractive alternative partners or perceiving the partner in an especially desirable light. These cognitive processes, in turn, might increase the likelihood of more mutually beneficial decisions and outcomes in the future. Positive effects ought to diminish, however, if one or both partners have dispositional characteristics that are not conducive to trust, repeatedly decide *not* to enter mutually beneficial agreements, or harbor negative attributions regarding their partner’s relationship motives.

This raises a paradox. Early in relationships, greater preresolution transformation of motivation by both partners should be a good barometer of the level of trust that is warranted in the partner, especially when partners are equally dependent on each other for unique or important outcomes or have similar levels of vulnerability or commitment. As relationships progress, however, most individuals blend their partners and relationships with their own self-concepts as their individual plans and goals gradually merge. This means that transformation of motivation should be *less* likely in well-established relationships. Couples in long-term relationships may, therefore, need to identify new

trust-diagnostic situations in which each individual’s self-interests start out being discrepant from what might be best for his or her partner or the relationship. If partners jointly reaffirm their willingness to make large transformations when new trust-diagnostic situations arise, this should sustain or increase trust even in long-standing pairs.

Potential Downfalls of Trust

High levels of trust can, of course, have downsides. For example, trusting one’s partner should be good for individuals and their relationships when an individual is willing to discount, ignore, or forgive isolated or one-time partner transgressions. But what happens when a person gives his or her partner the benefit of the doubt *despite* repeated evidence that the partner isn’t worthy of trust? Individuals who experience a series of failed strain-tests and continue to trust their partners “blindly” may become vulnerable to exploitation or abuse. In these more extreme cases, *dispositional* trust—trusting versus not trusting others regardless of who one’s current partner is or what the current relationship is like—may generate negative outcomes.

Interpersonal trust, which is rooted partly in features of the self, the partner, and the current relationship, emerges from the ebb and flow of daily interactions. When an individual has a disposition that is not conducive to the development and maintenance of healthy forms of trust, interpersonal trust building and gauging mechanisms are likely to be ineffective, derailing the normal process of trust development and maintenance.

TURNING POINTS IN RELATIONSHIPS

Turning points are events or relational incidents that are associated with change or transformation in a relationship. For example, participants in romantic relationships commonly report that their first kiss or first date was a significant turning point in their relationship affecting the degree of commitment between partners. Relational turning points were first conceptualized by Charles Bolton in a study examining marital dyads in which he wanted to focus on interpersonal processes that occur over time. Life-history scholars also work with the turning point concept, where it is generally understood as a transformative event in the life of an individual, in contrast to the relational focus provided by Bolton and subsequent relationship scholars. One of the key assets of focusing on turning points is that researchers are able to examine relationships and experiences from a process point of view. This entry discusses how turning points are measured through the Retrospective Interview Technique and findings from the research on turning points.

The Retrospective Interview Technique (RIT) is the most common methodological approach used to gather turning point data. The RIT allows researchers to assess both the magnitude and

valence of significant turning points. For example, the first study to use this method was interested in finding out how premarital relationships change with respect to commitment to marry. The RIT was also useful in developing a relational typology indicating different pathways or trajectories that lead to marriage. Essentially, what was learned was that couples experience different turning points at different times in their relationship, which puts them on a somewhat unique path to getting married.

Using the RIT, turning points are gathered and analyzed in a two-step process that includes a participant graphing exercise accompanied by an interview. Typically, participants are asked to indicate when significant events in a given relationship have occurred since the relationship began by placing them along the x-axis of a graph that is typically marked off in monthly increments. The y-axis of the graph has traditionally been used to position turning points according to varying levels of commitment to the relationship. In past research, participants have been asked to indicate turning points along the y-axis based on how events affected their chance to marry relational partners, influenced their commitment to the relationship, or affected their degree of emotional closeness. More recent research studies have altered the y-axis to assess different kinds of relationship impact, including extent of identification with a work organization for new employees, extent of feeling like a family for stepfamily members, and the degree of commitment to, or chance of, a post-divorce relationship for ex-spouses. Overall, the graphs offer a visual representation of significant events as they have occurred over time and the impact that those events have on various relational outcomes. The open-ended companion interview asks participants to describe the turning points in their own words.

Traditionally, the RIT and turning point analysis were used in studies that evaluated developing romantic relationships. Other studies have since used the technique or modified versions of the RIT to evaluate turning points that occur in other kinds of relationships. Relationships among divorcees, blended families, grandmothers–granddaughters, mentors–mentees, academic department chairs–faculty, parents–children, friendships, and relationships involving intimate partner violence have been evaluated for significant turning points.

Much has been learned from research that has gathered and examined turning points among various types of relationships. As an alternative understanding to stage models of relationships, which frame relational growth and development as a linear process of movement from one developmental stage to another, turning point analysis allows us to see how relationships grow and change in ways that are not so clean and tidy. For example, research conducted on mate selection has identified different pathways or trajectories to marriage such as accelerated, accelerated-arrested, intermediate, and prolonged paths. These pathways capture variations in the rate and turbidity of relationship change, with accelerated pathways representing relatively rapid and smooth progression toward 100 percent commitment, closeness, and so forth, in contrast to the prolonged pathway that represents a roller-coaster-like progression that is slower with turning points that both propel the relationship forward and move it backward.

Furthermore, related research complemented these findings in illustrating that romantic relational turning points occur for various reasons including individual (e.g., a change in how one partner feels about the other), dyadic (e.g., having a fight), social network (e.g., the presence of a rival), and circumstantial influence (e.g., a job transfer). Dyadic and social-network reasons—those grounded in the interaction between relationship partners or in the web of others that surrounds the relationship—often involve occasions when parties grapple with basic underlying contradictions that animate relating. For example, significant junctures in the negotiation of partner independence and autonomy versus partner interdependence or connection often are identified by relational partners as turning points. Turning

points vary in their valence—whether they propel a relationship positively toward a higher y-axis outcome or affect a relationship negatively with regression along the y-axis outcome. Turning points also vary in their intensity, with some resulting in small increments of y-axis change and others characterized by greater degrees of positive or negative change. Turning points often are remembered by relationship parties because they serve as the focus of subsequent storytelling and commemorative rituals. Relationship partners appear to agree in the identification of some turning points, but they also provide unique retrospective understanding of how their relationship changed over time.

U

UNCERTAINTY REDUCTION THEORY

Human relationships are fraught with uncertainty. From initial encounters between complete strangers to enduring close relationships, individuals experience uncertainties about their relationship partners as individuals and uncertainties about their relationships. Uncertainty Reduction Theory (URT) assumes that increasing levels of uncertainty makes communication between relational partners more difficult. Because people in relationships communicate to satisfy individual and relationship goals, high uncertainty levels undermine individuals' ability to attain goals, thus increasing the potential for frustration and reduced relationship satisfaction. Communicators must reduce uncertainty in order to tailor their messages to attain their goals.

URT was initially developed to explain why interacting strangers employ relatively ritualistic ways of getting to know each other. In American society, strangers meeting for the first time usually exchange factually oriented biographical information and reserve more private information, for example, attitudes and opinions on controversial issues, for later conversations. During an initial interaction, it probably would be somewhat odd for an individual to utter "I am an ex-convict" within the first minute or two of the conversation. Although people sometimes label background information such as "I grew up in Philadelphia" or "I attended Michigan State University" to be superficial, from URT's perspective, such information is

vital; for individuals experience uncertainty because they are unable to predict and sometimes explain others' attitudes, beliefs, and actions. Uncertainty is reduced when individuals can make accurate predictions about other's attitudes, beliefs, and future actions and when necessary, explain them. Communication rituals have emerged in encounters between strangers precisely because complete strangers are difficult to predict and explain. People persist in using such rituals even as they demean them as being superficial.

Acquiring seemingly superficial background information about individuals aids in the development of predictions and explanations. For example, consider the inferences a hearer would most likely make upon hearing different responses to the superficial question, "What is your occupation?"—the very kind of question typically asked during initial encounters. Suppose one stranger answers, "I am a neurosurgeon," while another answers, "I clean beer vats in a brewery." It would be reasonable to infer that the neurosurgeon has substantially more education than does the beer vat cleaner, although of course the beer vat cleaner could be an ex-neurosurgeon. Relatively confident inferences also could be made about their income levels. Exchanges of background information make it possible to formulate predictions about each other's attitudes, opinions, and actions that are yet to be revealed, thus enhancing the ability to create messages to reach desired goals. Inferences about such attributes as income could be based on the clothes another person is wearing, as well as on other nonverbal information. Thus, the process of

uncertainty reduction can begin well before words are exchanged in encounters between strangers.

It would be a mistake to conclude that high levels of uncertainty occur only in initial encounters between strangers. Uncertainty can arise in relationships when individuals say or do things that violate relationship partners' expectations. In many cases these violations are negative, for example, finding that a heretofore faithful spouse has been cheating or that a close friend has been saying negative things to others behind one's back. Such revelations dramatically increase uncertainty and, not surprisingly, are associated with increases in negative affect, as noted in 1985 by Sally Planalp and James Honeycutt. Positive expectation violations can occur, as when a normally inattentive husband showers his wife with expensive gifts. Of course, such behavior might fuel the wife's suspicions concerning the reasons for the sudden outpouring of positive attention, including the possibility that the husband might be cheating on her. In any case, even when individuals are encouraged to think of positive events that increased their uncertainties about others, they overwhelmingly recall negative events.

Individuals can use a number of strategies to reduce uncertainty. Merely observing others, using passive strategies, is one possibility. Unobtrusively observing a person engaged in interaction with others might reveal important information about the person. Active strategies might involve gathering information indirectly from third parties. Finally, interactive strategies, such as question asking and disclosing information about one's self with the hope that the disclosure will be reciprocated, can be deployed to gather information in social encounters. Of course, information seekers may encounter an array of strategies others use to avoid revealing information.

As noted by communications scholar William Gudykunst, research has found similarities and differences in the ways uncertainty is reduced by people from different cultures. Some have suggested that when potential outcomes are negative, people may avoid reducing uncertainty. For example, spouses who suspect that their mates are cheating on them may prefer not to obtain evidence that this is so. Although ignorance may sometimes be bliss in the short run, it may prove to be relatively nonadaptive over time. Individuals,

relationships, and society are in a constant state of change and flux; consequently, uncertainty can never be fully reduced. Those involved in close relationships at one point in time may become strangers later. Uncertainty reduction is a ceaseless process, even when individuals leave the world. Indeed, the considerable interest people have in tracing family lineages and finding their roots is a testament to the continuing nature of the uncertainty reduction process.

UNCONDITIONAL POSITIVE REGARD

This entry focuses on the concepts of conditional and unconditional positive regard and their implications for healthy psychological functioning. The concept of unconditional positive regard was introduced in the 1950s by Carl Rogers in the context of therapist–client relationships. It refers to the therapist communicating unqualified love and acceptance of the client, regardless of whether or not the therapist approves of the

client's specific actions. Unconditional positive regard is one of three therapist qualities (the other two are genuineness and empathic understanding) that foster positive growth and change on the part of the client. Considerable research substantiates the importance of these general therapist qualities to positive therapeutic outcomes.

In addition to its demonstrated importance in therapeutic settings, unconditional positive regard has been implicated in healthy outcomes associated with parenting, socialization practices, and romantic relationships. According to Rogers, all people have the capacities for healthy personal growth and development, and environments can either support or undermine these natural tendencies toward growth. Rogers asserted that environments that provide people with unconditional positive regard support natural tendencies toward growth and development. Conversely, environments thwart these tendencies by establishing conditions of worth (i.e., conditional positive regard), where love and acceptance are given only when individuals live up to standards established by significant others (e.g., parents and other adult relatives, teachers, friends, spouses). Given that people are extremely motivated to receive the love of important others, they typically become very good at satisfying the others' criteria for love's worthiness. In so doing, however, individuals often sacrifice their own needs, desires, and characteristics, making it difficult for them to function optimally. Moreover, children and adults may rigidly self-apply these standards so that they feel worthwhile only when satisfying these conditions of worth. Stated differently, exposure to conditions of worth leads people to develop contingent self-esteem, which requires continual validation of self-worth through specific behaviors, achievements, or accolades. Contingent self-esteem is fragile, precisely because it may plummet in the absence of continual validation. In contrast, healthy or secure self-esteem reflects the sense that one is inherently worthy by virtue of who one is and not what one accomplishes.

Research on Use of Conditional Regard by Parents

Until recently, scant research specifically focused on outcomes associated with parental use of

conditional versus unconditional regard. Some psychologists have asserted that the use of conditional regard improves children's ability to discriminate between desired and undesired behaviors, thereby increasing the likelihood that they will enact desired behaviors. Other psychologists counter with the assertion that although conditional regard may be a reasonable approach for eliciting desirable behavior, it does so at substantial costs to the recipient and to the relationship between provider and recipient. Recent research supports this latter position. Specifically, recent findings indicate that parental conditional regard relates to greater feelings of internal pressure (because one should, not because one wants) to adhere to parental expectations, pressure which in turn relates to greater performance of the desired behaviors. These findings suggest that even though children perform the desired behaviors, they do not truly internalize the behaviors' underlying values. If they did, they would report wanting to perform the behaviors rather than feeling compelled to do so. Additional findings indicate that conditional regard relates to greater self-esteem fluctuations (unstable self-esteem, another form of fragile self-esteem), heightened feelings of shame and guilt after failure, greater resentment toward one's parents, and feeling more disapproved by them.

Implementing Unconditional Positive Regard

Research and theory suggest a number of guidelines for parents and other individuals who want to utilize principles consistent with Rogers's notions of unconditional positive regard. First, it is important to give affection and love unconditionally rather than conditionally, as already described. Second, when making requests, disciplining the target person, or giving positive or negative feedback, focus on the target's behaviors and the natural consequences of the behaviors and not on the person's character or worthiness. For example, state "I would like for you to sit here quietly," not "I would like for you to be a good girl and sit here quietly." Or state "If you don't finish your dinner, you likely will be hungry later" instead of "If you don't finish your dinner, I will not spend time with you tonight watching television." Importantly, at all times statements should reflect disapproval of

behavior and not that the agent loves the target person any less (e.g., “Although I do not approve of your doing drugs, I still love you very much and want to help you”).

Positive and Negative Conditional Regard and Psychological Control

Recent research suggests that it is useful to distinguish between positive and negative conditional regard. Whereas positive conditional regard involves providing greater than usual attention and affection to an individual for performing a desirable behavior, negative conditional regard involves providing less than usual attention and affection to an individual for acting in an undesirable manner. An example of negative conditional regard is withholding affection and ignoring one's partner for several hours to punish him or her for being late to the movie. Although many of the negative consequences of conditional regard are attributable to negative conditional regard, compulsion to perform desired behaviors, rather than real self-endorsement, is associated with positive conditional regard. Further research is needed, however, to fully understand the consequences of positive and negative conditional regard.

Other research on the negative consequences to children of parental psychological control indicates that it is beneficial for parents to avoid controlling children's unwanted behaviors by arousing guilt (e.g., “If you love me, you will stop making noise in your room”) or by withdrawing their love (e.g., acting cold when their child gets a poor grade on an exam) because they unwittingly create situations in which children feel worthy and valuable when their actions meet others' standards but unlovable and unworthy when their actions do not meet others' standards. As described earlier, children tend to self-apply the conditional approval of important others and only feel worthy when matching those established criteria.

Conclusion

The beneficial consequences of unconditional positive regard generalize to all types of interpersonal relationships, including friendships, romantic relationships, and marriages. Involvement in

relationships where one is loved for who one is and not for what one does or achieves promotes healthy self-esteem, interpersonal functioning, and psychological well-being, regardless of whether one is a child, adolescent, or adult. Likewise, treating others with unconditional positive regard fosters healthy people and healthy relationships.

UNDERSTANDING

In a relationship context, understanding can acquire two different meanings. First, understanding can refer to a person's knowledge of a partner's dispositions, thoughts, and feelings. This type of understanding is defined as people's capacity to accurately perceive another person. For example, when John perceives Mary as extravert and Mary views herself as extravert, John understands Mary because he accurately knows that she is extravert. Second, understanding can refer to a person's sense of validation and acceptance by a partner. This type of understanding is defined as the feeling that others value, accept, and care for

the self. For example, when Mary discloses that she is nervous about giving a public presentation, John's response is cognizant of her feelings and reassuring, a reaction which makes Mary feel accepted, validated, and cared for. In this case, because John is responsive to Mary's needs, she feels understood. Thus, in the context of the first meaning "I understand you" means "I know who you are," whereas in the context of the second meaning "I understand you" means "I accept, value, and care about you." This entry discusses both types of understanding and examines their role in the maintenance of harmonious and long-lasting relationships.

Often, the two types of understanding are related. Knowledge of the partner facilitates a validating response, and by exchanging validating responses, people may gain knowledge about each other. Nevertheless, the two types of understanding are independent as well: Knowledge of someone's thoughts, feelings, and needs can be used exploitatively, and a validating response can occur even among complete strangers.

Undoubtedly, almost all relationships require both types of understanding. Relationships involve two people who are interdependent. Partners affect each other's thoughts, behavior, feelings, and well-being over time. Not surprisingly, both types of understanding are assumed to be particularly important when partners are highly interdependent, such as in close relationships. Indeed, knowing one's partner is more important when people interact on a daily and intimate basis than when they interact only sporadically. The coordination of life activities simply works better when people know each other. Similarly, feeling validated is more important to people when the partner is close and significant. Thus, both types of understanding should facilitate the maintenance of harmonious and stable relationships with frequent and positive interactions between partners. In the following section, this entry will describe psychological research examining this suggestion.

Understanding as Knowledge

When understanding refers to knowledge, researchers distinguish trait accuracy from empathic accuracy. People who are high in trait accuracy are able

to correctly infer the other's personality traits and dispositions, such as extraversion, shyness, or dominance. Trait accuracy is established by using questionnaires in which partners rate their own personality and their partner's personality. People who are high in empathic accuracy are able to correctly infer the other's thoughts and feelings. Empathic accuracy is established by videotaping interactions between partners who subsequently rate their own and their partner's thoughts and feelings during that interaction. In both cases, accuracy represents the agreement between Partner A's own ratings and Partner B's ratings of Partner A and is conceptualized as knowledge. Thus, people high in trait and empathic accuracy understand their partner because they accurately know his or her personality and thoughts and feelings. Although research often investigates either trait or empathic accuracy, the results of these studies show similar patterns and paint a consistent picture on the role of knowledge in close relationships.

Understanding as knowledge increases with acquaintanceship and closeness in relationships. Dating couples know each other better than friends, and friends know each other better than strangers. To explain the link between closeness and knowledge, researchers have investigated four factors that may contribute to better understanding, namely the good judge (e.g., some people are better at understanding others), the good target (e.g., some people are better understood by others), the good trait or behavior (e.g., some traits are easier to understand), and the good relationship knowledge (e.g., partner-specific memories, shared experiences). Overall, good relationship knowledge emerged as the most important determinant of understanding. Close relationship partners have specific information of how each partner felt, thought, and reacted in the past and can use this knowledge to infer what the other person is thinking and feeling in a given situation or to anticipate how she or he will think or feel in a future situation. So closeness contributes to understanding because it increases both the quantity and the quality of partners' knowledge about each other.

One common belief is that understanding as knowledge contributes to relationship quality. People who know each other well should have more harmonious interactions and fewer conflicts, and indeed, there is empirical evidence to support

this idea. Empathic accuracy promotes prorelationship behavior, such as forgiveness and accommodation (i.e., when one partner acts destructively, to respond constructively and inhibit the impulse to react destructively in turn). Also, when people know what they need to know and what is relevant to the relationship, they have better relationships. Finally, people are happiest in their relationships when they believe that their partner knows their true self, including virtues and faults, and accepts them nonetheless. Thus, the perception that the partner understands and accurately knows the self is experienced as reassuring and enhances relationship quality.

Nevertheless the link between understanding as knowledge and relationship quality is not as straightforward as it may appear. In certain circumstances, inaccurate, rather than accurate, understanding of the partner enhances relationship quality. First, when people feel their relationship is threatened, instead of facing an unpleasant truth, they prefer to misinterpret reality to preserve a positive image of their partner and their relationship. To illustrate, if Mary has a very good looking girlfriend, she may underestimate the degree to which her husband is attracted to her girlfriend, and this inaccuracy helps Mary to maintain high satisfaction with her relationship. Second, when people are especially fond of their partner they show positive illusions. Dating partners and married people tend to systematically overestimate the virtues of their partner, seeing their partner more positively than the partner sees him or herself. This inaccurate understanding of the partner fosters commitment to a relationship and increases relationship stability. Third, inaccurate understanding may contribute to relationship quality when people overestimate the degree to which the partner is similar to the self. People egocentrically assume that their partner's personality mirrors their own and often see similarities that do not exist. This type of egocentrism may be beneficial for the relationship because it elicits the feeling that one's partner is just like the self and therefore able to know and appreciate the true self (as in the case of understanding as validation). Relatedly, inaccurate understanding may contribute to relationship quality when people overestimate the degree to which people see them as they see themselves. Self-Verification Theory proposes that people are

motivated to maintain their self-concept, even if their self-concept is negative, because it allows them to see their social world as predictable and controllable. This type of egocentrism may be beneficial for the relationship because it makes people choose relationship partners who are perceived as knowing the self and who are hence able to verify the self.

Understanding as Validation

When understanding refers to validation, researchers emphasize that it is an inherently social phenomenon. It emerges as the result of two partners interacting with each other and reacting to each other. Mary's disclosure elicits a response from John, a response which conveys that John accepts, validates, and cares for Mary. This response in turn causes Mary to feel that John understands her. Understanding as validation is established by using questionnaires in which people rate the extent to which they feel understood, validated, accepted, and cared for by their partners. Thus, people who feel understood by their partner perceive that their partners are validating and accepting of the self.

The idea that this type of understanding increases with closeness is irrefutable. In close relationships, people open up to each other and share more and more intimate information about themselves with their partner. By revealing personal information about the self, partners become vulnerable because they may potentially be hurt, rejected, ridiculed, or humiliated. To feel safe in the face of this vulnerability, people need to know that their partner will react with acceptance and responsiveness, that is, with understanding as validation. This kind of understanding also includes sympathy, caring, and respect.

Research confirms that understanding as validation is strongly linked to closeness and also to relationship quality. Happy couples carefully listen to each other and respond to each other in an empathic, accepting, and supportive way, whereas distressed couples fail to listen to each other and respond to each other in a rejecting, critical, and disinterested way. An understanding response by the partner communicates recognition and validation of the self and elicits a feeling of being accepted and cared for, hence of being understood.

This feeling of being understood in turn increases closeness and relationship satisfaction. Not surprisingly, understanding as validation is central to the development of all kinds of relationships and contributes uniformly positively to relationship quality. It is crucial not only in relationships between equals, such as romantic partners or best friends, but also in relationships between unequal partners, such as parents and children.

Clearly, the process that leads to the feeling of being understood by one's partner is a social process that starts with one person revealing some aspect of the self (of various degree of intimacy depending on the nature of the relationship). This disclosure then creates an opportunity for the partner to respond. This response can vary in the degree to which it is understanding. What is important, however, is that this response is interpreted by the person, who will subjectively react to (make sense of) it. This latter personal reading determines whether one feels understood and validated.

People's interpretation of their partner's response can be biased, leading to either an overestimation or an underestimation of the partner's understanding. Research suggests that feeling understood is more important than being understood. For example, people who are more satisfied with a relationship report greater partner understanding and validation than is seen by uninvolved observers and even the responding partners themselves. When people overestimate their partner's similarity to the self, as mentioned above, they feel understood by their partner (e.g., "He is like me and thus knows how I feel"), which in turn increases relationship satisfaction. Conversely, when people perceive their partners as not understanding (in the knowledge sense), they may discount their validating responses (e.g., "You just don't understand"), which in turn decreases relationship satisfaction. Certain individual differences may cause people to feel more or less understood by others. For example, people with high levels of rejection-sensitivity or insecure attachment feel less understood by others than people with low levels of rejection-sensitivity or secure attachment. Thus, the mere perception of being understood regardless of the partner's actual understanding can have important effects for relationship quality.

Conclusions

Research and theory demonstrate that understanding in relationships can refer to knowledge of the partner or validation by the partner. Whether knowledge is always beneficial for relationships is uncertain. Generally speaking, a good knowledge of the other enhances harmonious relationships, but under certain circumstances accurate knowledge may reduce relationship quality and people may prefer to have inaccurate knowledge of the partner. Validation is uniformly beneficial to the quality of the relationship. When partners express acceptance, validation, and caring for each other, they foster their mutual sense of closeness and relationship security. This increases interpersonal trust, facilitates the deepening of the relationship, and leads to relationship satisfaction. Thus, although both types of understanding are at the heart of relationships, feeling understood and validated seems more important than being understood and known.

UNMITIGATED COMMUNION

Successful relationships require an individual to focus on the needs of others while also attending to their own needs. Many individuals have difficulty striking this balance, to the detriment of their personal and relational well-being. Unmitigated communion (UC) is a construct that describes one form of this imbalance. UC refers to a pattern of focusing excessively on caring for others while failing to assert and protect one's own needs in relationships. This entry will define the construct of UC and review research that demonstrates the importance of UC for well-being and relationship functioning.

Conceptualizing UC

The term UC refers to communion that is not mitigated by an appropriate level of agency. David Bakan originally identified agency and communion as two fundamental modalities of existence. Agency refers to a focus on self and separation, whereas communion refers to a focus on others and connection. Although Bakan identified agency as the male principle of existence and communion as the female principle, he also believed that healthy functioning requires some level of balance between the two constructs in all individuals. UC is one form of imbalance, described by Vicki Helgeson as a pattern of overinvolvement with others and self-neglect in relationships. Consistent with Bakan's ideas and traditional gender role stereotypes, women generally report higher levels of UC than men. It has also been found that self-reports of UC are significantly correlated with

levels reported by peers, suggesting that UC is observable to others. In one study, cardiac patients who had spouses with high levels of UC reported that their spouse engaged in overprotective behavior, such as constantly reminding them about healthy behaviors. Another study found that persons scoring high on UC reported engaging in submissive and self-effacing behavior such as continually apologizing for a minor mistake, tolerating verbal abuse, agreeing that they were wrong even though they were not, and accepting insults. Such behavior would be clearly visible to others.

UC and Well-Being

Also consistent with Bakan's ideas, a growing number of studies have shown that this form of imbalance does indeed relate to increased physical and psychological distress. For example, one recent series of studies found that UC was associated with a wide range of adjustment-related outcomes, including higher levels of depressive symptoms, lower levels of subjective well-being, lower levels of psychosocial adjustment, and higher levels of daily depressed mood. Importantly, the relation between UC and well-being has been found using cross-sectional and longitudinal designs and using diverse methods of assessing well-being.

Relational Implications of UC

The link between UC and psychological distress can perhaps best be understood by considering its role in relationships. People with high levels of UC appear to be more negatively emotionally affected by the problems of others. Studies have shown that persons with high levels of UC also experience more psychological distress following interpersonal conflict, interpersonal stress, and relationship dissolution. Women with high levels of UC have been found to experience more depressive symptoms when their husbands expressed dissatisfaction with the marriage. These findings are consistent with what is known about the relational underpinnings of UC. People with high levels of UC lack a healthy sense of self, have more anxious attachment styles, and tend to formulate their opinion of themselves largely based on the perceived reactions of others. This dependence on

positive feedback from others gives tremendous power to relationship partners so that when conflicts or difficulties arise, people with high levels of UC are affected more strongly. Thus, people with high levels of UC may be especially likely to experience distress in the context of relationship stress or loss.

Interestingly, although people with high levels of UC may be motivated by the desire to develop and maintain harmonious relationships in order to bolster self-esteem, the interpersonal styles associated with UC may in fact make it harder for them to do so. A number of studies have identified problematic interaction patterns associated with UC. People with high levels of UC tend to have unbalanced relationships so that they provide social support to their partner but feel uncomfortable receiving support or disclosing their thoughts and feelings. UC has been associated with interpersonal problems such as intrusiveness, exploitability, and difficulty with assertiveness and with more negative interactions with family and friends. Recent work has further shown that UC may be associated with anger and hostility in interpersonal contexts. A daily diary study found that UC was associated with the experience of less meaningful and less positive interpersonal interactions, and this accounted for the relation between UC and depressed mood.

It may seem counterintuitive that a personality orientation described as a focus on the needs of others to the extent of self-neglect is associated with these negative interaction patterns. However, it is important to keep in mind that overinvolvement and self-neglect likely represent an attempt to appease others and create unbalanced relationships in which the other person needs them and values them. The self-sacrifice this pattern entails may result in a lack of authentic sharing of self, increased

anger, and ambivalence about relationships. Although little is known about how partners respond to such behavior, one recent study of dating couples found that partners of persons with high levels of UC reported that their own needs for competence, autonomy, and relatedness were less well met within their relationship. In fact, women with high levels of UC were more likely to experience relationship dissolution over the 5 months of the study, and breakup status was mediated by partner need satisfaction.

Thus, researchers find a dysfunctional cycle wherein people with high levels of UC may be motivated by a desire for positive relational experiences in order to bolster their self-esteem, yet in fact, they appear more likely to experience relational difficulties and are in turn more distressed by these difficulties than people low on UC. This research highlights the importance of considering unmitigated communion in clinical populations of individuals and couples.

V

VALIDATION IN RELATIONSHIPS

People's existence depends on validation. Humans survived the past 2 million years because of an ability to forge connections with others, and these connections depend on validation of people's physical and psychological selves. This entry documents key theory and findings pertaining to the forms of validation relevant to interpersonal relationships.

The *Oxford English Dictionary* defines validation as the act of rendering something valid. In its general use, the term *valid* means effective, effectual, and sound. From a methodological point of view, the validation of an instrument involves demonstrating its effectiveness and ability to perform the function for which it was intended.

The importance of validation in relationships was first popularized by Harry Stack Sullivan, who noted that intimacy results when people acknowledge and support key elements of their partner's self-worth, self-definition, and worldviews. From Sullivan's early writings, and from more recent relevant work on the topic, one can glean that when it comes to the topic of relationships, two forms of validation get implicated. The first consists of validation of one's personhood. This type of validation involves acts that convey the message that one's whole being is sound and thus worthy of respect. The second form of validation consists of validation of one's beliefs, which attests to their validity or soundness. As will be noted, this type of validation can predict

relationship satisfaction just as strongly as can the validation of one's personhood.

Validation of One's Personhood

Validation of one's personhood starts with the recognition of one's existence. Research suggests that those lacking this most rudimentary form of validation for their personhood—homeless individuals or children raised in grossly abusive contexts, for example—will struggle to forge satisfying relationships with others. This is not surprising when one considers that William James likened the denial of a person's existence to the most heinous forms of punishment. Indeed, after being ignored for just short periods of time in computerized interactions, people lash out aggressively at others, suggesting that even momentary failures to validate a person's existence can foster psychological distress.

Luckily, the typical person receives daily validation for his or her physical existence. Receiving validation for one's personhood extends beyond acknowledging one's existence, however, to acts that indicate a person's soundness and worthiness of respect. From the cradle to the grave, such validation plays a pivotal role in relationships.

Consider the writings of John Bowlby and Mary Ainsworth and the work on attachment more generally. This work spotlights the importance of validation in the infant-caregiver attachment bond. The extent to which primary caregivers exhibit sensitivity (i.e., noticing and responding) to the

cues put forth by the infant determines the working models of self and other. Infants raised by attentive caregivers who respond to their cues (and in so doing validate their soundness and worthiness of respect) grow up to display positive views of self and positive views of others. Infants raised by inattentive caregivers—caregivers who imply that the infant somehow is not worthy of attention—have the misfortune of developing more negative models of self and other. These internal working models developed in infancy, in turn, shape the interpersonal territory that people navigate as they emerge into adulthood and beyond. In short, early in life—perhaps even from the beginning—the degree of validation for one's person that one receives from a primary caregiver can have important ramifications for present and future relationships.

Of course, having an attentive and responsive caregiver does not just matter in the early years. Harry Reis and colleagues note that perceived partner responsiveness, the degree to which people sense that their current partner attends to them and supports them, represents a central process in relationships across the life span. In a similar vein, marriage researchers have noted higher levels of relationship satisfaction among people who perceive that their partner attends to, acknowledges, and, in so doing, validates their verbal and nonverbal cues.

In addition to receiving validation from attentive and supportive partners, people receive validation for their personhood from partners who think highly of them. Decades of research attest to the importance of establishing one's self-worth, and this seems particularly true in the context of relationships. Perhaps for this reason, people like those who reciprocate this liking. Research also shows that people dating people who hold them in high regard, relative to people dating people who see them negatively, report the highest levels of relationship satisfaction. People in romantic relationships also exhibit high levels of satisfaction to the extent that their partners see the same promise they see in themselves. In short, relationships satisfy to the extent that they involve a certain amount of validation of one's personhood.

Validation of One's Beliefs

Another form of validation that takes on a pivotal role in relationships consists of the validation of

one's beliefs. The socially constructed nature of reality makes it so that people rely on others for the confirmation of their interpretations of reality. Indeed, Curtis Hardin and Tory Higgins go so far as to say that people's experience of reality does not become real unless it gets shared with others.

If people rely on those around them to validate their conceptions of reality, one might expect signs of this dependence to emerge in the development and maintenance of relationships, as well as in the satisfaction people report in their relationships. Consistent with this line of thinking, research shows that people feel especially drawn to those who validate their beliefs and that they shy away from people who do not.

Validating Self-Conceptions

Most research in this area concentrates on what happens when people do or do not receive validation (i.e., evidence for the soundness and validity) of their self-conceptions. This type of validation can differ dramatically for validation of one's personhood, insofar as it can involve validation of a self-conception that is quite negative and thus implies that one does not deserve respect. Despite this, research makes it quite clear that people in relationships also require validation for their self-conceptions, even the negative ones.

According to William B. Swann, Jr., people want their self-conceptions validated because they rely on these self-conceptions to meet specific needs. Our self-concepts—our self-perceived strengths and weaknesses, how we react to stimuli (among other things)—can help us meet our needs for prediction and control. We thus want to be certain that we know ourselves and so we do what it takes to assure ourselves of the veracity of our own self-knowledge. Interpersonally, we surround ourselves with people who validate our self-conceptions, and we avoid people who do not. This is true for a wide range of relationships, including those with roommates, friends, romantic partners, coworkers, and even therapists. Moreover, researchers see this interpersonal dynamic in the context of laboratory experiments as well as in the real world. In many laboratory investigations, people with negative self-views even prefer to interact with someone who sees them negatively than with someone who sees them positively. In

the field, married couples exhibit more satisfaction with partners who validate their self-conceptions than with partners who do not, even if those self-views that get validated happen to be negative.

People's desire for validation for their self-conceptions might, under certain conditions, seem at odds with their desire for validation of their personhood. Someone who sees himself negatively on a specific dimension (e.g., athleticism), to the extent that he prefers a partner who also sees him negatively on this dimension, might run the risk of finding a partner who does not validate his personhood. Relevant research on this topic suggests that people *can* have their cake and eat it too: the key rests in drawing a distinction between specific and global evaluations. People in satisfying relationships tend to have partners who validate their specific self-conceptions while simultaneously validating their global sense of self-worth.

Implicit Belief Validation Via Validation of the Subjective Self

Recent work on I-sharing reveals another way in which the validation of beliefs enters relationships. Here, a more implicit form of belief validation takes hold, one that requires an appreciation for James's distinction between two general aspects of the self: the objective self (or, the *me*) and the subjective self (or, the *I*). The objective self consists of everything that one would list in response to the question: "Who are you?" It would include (among other things) one's autobiography, demographics associated with the self, a description of how one spends one's days, a review of the people associated with the self, self-perceived strengths and weaknesses, one's hobbies and interests, descriptions of one's personality, and feelings about the self. The subjective self, in contrast, refers to the moment-to-moment experiencer of reality. The *I* sees, feels, thinks, laughs, breathes, runs, talks, does, reflects upon the *Me*; in short, the *I experiences* and *reacts*.

Drawing on the distinction between the *Me* and the *I*, Elizabeth Pinel and her colleagues emphasize the importance of I-sharing in relationships. *I-sharing* refers to those moments when two or more people believe that they have had the same subjective experience, when they believe their subjective selves have overlapped. People can use

many cues to infer I-sharing. The most foolproof indicators of I-sharing occur when people respond simultaneously and identically to the same stimulus, such as when people see the same shape in an inkblot, utter the same word spontaneously, or laugh at the same joke. Research on I-sharing indicates that people feel particularly drawn to I-sharers and that this is particularly true when they have a high need for belief validation. Apparently, I-sharing validates people's beliefs implicitly, and this accounts for some of the allure of I-sharing. Once again, the importance of belief validation in the relationship process is highlighted.

VALUES AND RELATIONSHIPS

Human relationships are certainly what human beings value the most in their lives. Therefore, human relationships are central to many personal and cultural value systems, which in turn influence virtually all aspects of everyday existence. Personal values define the desired behaviors or principles for an individual, whereas cultural values define the desired behaviors or principles for a group, society, or culture (i.e., others). This entry examines personal and cultural values and to what extent human relationships are central to these values.

Values and Value Systems at the Individual and Cultural Levels

Values have been studied by psychologists, anthropologists, political scientists, and sociologists, which has led to various definitions and classification of values. The general tendency is to define values as (a) guiding principles in individuals' and groups' lives, and (b) trans-situational goals that serve the interest of individuals or groups. A parallel to these two general definitions can be seen in the distinction that Milton Rokeach made between instrumental values (i.e., modes of conduct; e.g., broad-minded) and terminal values (i.e., goals; e.g., self-esteem). Some social scientists such as Kurt Lewin claimed that values-as-principles is a more appropriate definition than values-as-goals because individuals do not try to "reach" a value; rather a value "guides" behaviors, judgment, and goals. However, contemporary researchers do not make such distinctions and tend to use both definitions of values, which can lead to some confusion between the concepts of values and goals.

For several decades, social scientists focused on individual and cultural differences in value priorities. Guided by the assumption that a finite number of value types exist, philosophers and social scientists have proposed various organizations and

classifications for the relative importance that people and cultures place on various values. Perhaps the most influential framework for conceptualizing personal values is Shalom Schwartz's Circumplex Model, in which 10 universally relevant value types are organized along two motivational dimensions. A first dimension contrasts the valuation of self-determination and change to the importance of stability and conservation. In other words, one may orient one's life toward independence of thought and action (Self-Direction) and seeking pleasure and sensuous gratification for oneself (Hedonism), excitement, novelty, and challenge in life (Stimulation) and exploring. Alternatively, one may choose the certainty that is provided by respect and commitment to traditional customs and ideas (Tradition), the endeavor for safety and stability of relationships and society (Security), and the avoidance of intentions and actions that could upset or harm others and violate social norms (Conformity). A second dimension contrasts self-enhancement and self-transcendence motivations. On one side (self-enhancement), life is guided by concern for the individual's outcomes and how to maximize them. This concern may be translated into the enhancement of social status and the control of people and resources (Power), or the endeavor for personal success and demonstration of competence (Achievement). On the other side (self-transcendence), life is guided by concern for social outcomes, which means understanding, protection, and enhancement of the well-being of significant and less significant others (Benevolence), as well as the welfare of all people and nature (Universalism).

Schwartz's two-dimensional value system is not unique, and one can find echoes in the literature on cultural values. For example, Harry Triandis and Geert Hofstede studied peoples and cultures according to orientations toward individualistic and collectivistic values. At the individual level, the terms *idiocentrism* and *allocentrism* have been proposed to define the tendency to see the self as distinct from others or as interconnected with others, respectively. Values can then be organized along the idiocentrism/individualism versus allocentrism/collectivism dimension. Because of the focus on independence and individual outcomes, value types such as Self-Direction, Stimulation, Hedonism, Power, and Achievement are considered as idiocentric/individualistic. In contrast, Benevolence, Universalism, Tradition, Security,

and Conformity are more characteristic of allocentric/collectivistic value types because of the focus on interdependence and others' outcome. Although the individualism–collectivism dimension has been extensively and successfully applied to the study of individual and cultural cognitions, affects and behaviors, value systems are sufficiently complex that a second dimension is needed. Consequently another value dimension, previously neglected by researchers, has recently received more attention. Hofstede named this dimension Power Distance (low versus high) whereas Triandis conceptualized it as orthogonal to the individualism–collectivism dimension, making a distinction between vertical and horizontal individualism (or idiocentrism), and between vertical and horizontal collectivism (or allocentrism). Vertical-ism (or high power distance) is characterized by an emphasis on hierarchy and the dominance of certain people or group on others. Value types such as Power and Achievement fit within this orientation, making them typical of vertical individualism. Because Tradition, Security, and Conformity are generally associated with the protection and conservation of established hierarchical ideologies, these value types can be labeled *Vertical*, and more specifically *Vertical Collectivistic*. In contrast, Horizontal-ism (or low power distance) is characterized by valuing equality across individuals and groups. That can be reflected by individuals' equal chance to make personal decisions and experience the world by themselves (i.e., Self-Direction, Stimulation, and Hedonism—or Horizontal Individualism), or equality in the concern about welfare for all people and for nature (i.e., Benevolence and Universalism—or Horizontal Collectivism).

In sum, both personal and cultural values are organized in a two-dimensional space, but the labels of the two orthogonal dimensions differ. The values that fall into each resulting quadrant are still consistent: Self-Direction, Hedonism, and Stimulation characterize horizontal (or nonhierarchical) individualism; Power and Achievement characterize vertical (or hierarchical) individualism; Benevolence and Universalism characterize horizontal (or nonhierarchical) collectivism; and Tradition, Security, and Conformity characterize vertical (or hierarchical) collectivism.

A similar two-dimensional structure has recently been proposed by Frederick Grouzet and Tim Kasser to represent personal goals. In their

Circumplex Model of goal content, a distinction is made between intrinsic (self-acceptance, authentic relationship, helping) and extrinsic goals (e.g., materialism, fame, image) that parallels the vertical-horizontal value dimension. As well, their second proposed goal dimension (representing a continuum from physical self, to individual self, to collective self, to Self-Transcendence) serves the same role as individualism–collectivism in distinguishing self-oriented intrinsic/extrinsic goals (e.g., intrinsic: self-acceptance; extrinsic: material wealth) and other-oriented intrinsic/extrinsic goals (e.g., intrinsic: helping; extrinsic: conformity). Although values and goals are distinct psychological constructs, both can be represented in a two-dimensional space (or Circumplex Model) where the axes refer to the same underlying psychological dimensions.

Values Guiding Human Relationships

The organization of values into two dimensions and four quadrants is especially important for understanding and explaining how values are related to relationships. By definition values guide perceptions and behaviors, therefore human relationships. More specifically, values influence the nature of relationships, coordinating social interactions and facilitating interpersonal and group functioning. This section explores the value types and value orientations that are related to the development and maintenance of egalitarian versus hierarchical relationships, where the main issue concerns the distinction between the individual's own outcomes and those of relationship partners.

Values and Hierarchical Relationships With a Focus on Individual's Outcomes

When societies and people value personal and social success (Achievement), striving for higher position in a hierarchy and gaining and controlling material and human resources (Power), and appearance and material wealth (Extrinsic Goals), relationships tend to be more hierarchical, differentiating individuals who succeed and those who don't, individuals who possess power and those who don't, and those who are dominant and those who are subordinate. These relationships are thus

guided by competitive principles that emphasize both maximizing one's own outcomes and minimizing the other's outcomes. Power and Achievement value types are often associated with authoritative leadership and interpersonal conflict. The main concern is to impress others, using self-presentation and self-serving strategies, and adopting a public identity that tends to be incongruent with the true self. One consequence is the development and maintenance of nonauthentic relationships, where others are often approached in an objectifying and strategic way.

*Values and Egalitarian Relationships
With a Focus on Individual's Outcomes*

People who prioritize their own pleasure, excitement, and autonomy tend to have less conflictual relationships. Although the goal is to maximize one's own outcomes, this is not realized in a way that is detrimental to others. For example, several individuals can experience sensual pleasure, discover new things, and seek challenges in life, all without competition. As well, the development of independent thought, actions, and autonomy is not necessarily associated with the others' loss of independence and autonomy. The distinction between horizontal and vertical values is thus important to represent the critical difference between Self-Direction and Power/Achievement. Finally, value types such as Self-Direction, Stimulation, and Hedonism are associated with nonhierarchical or egalitarian relationships. Although the welfare of others is not necessary to these values, valuing Self-Direction may be associated with authenticity and thus authentic and harmonious relationships.

*Values and Egalitarian Relationships
With a Focus on Other's Outcomes*

People who live according to principles such as Benevolence and Universalism tend to focus on the welfare of others. They stress maintenance and enhancement of the well-being of others, that is, people with whom one has frequent personal contacts (Benevolence) or all people and nature (Universalism). The principle of equality is important in Benevolence and Universalism values, leading to nonhierarchical or egalitarian relationships.

Therefore, Benevolence and Universalism are associated with cooperation, altruism, communal living, sharing, trust, mutual respect, and feelings of equality. People with these values are also willing to have contact with other groups, despite any history of conflict. Although others' outcomes are the target of attention, individuals benefit because they are part of the group and are considered equal in status with others.

*Values and Hierarchical Relationships
With a Focus on Others' Outcomes*

Values that are oriented toward the stability and continuity of groups and societies require subordination of individual interests to the priorities of their group and its leaders, in a well-structured hierarchy of power. In contrast to Benevolence and Universalism, Tradition and Conformity values are translated into avoidance of movement or growth and promotion of stability. This perspective on others' welfare thereby can be detrimental to individuals' own aspirations. Therefore, value types such as Tradition, Conformity, and Security tend to be associated with loyalty and willingness to sacrifice in interpersonal relationships (as well as marriage), and associated with obedience and compliance in groups. These values are often associated with authoritarian personality, political conservatism, rejection of diversity, "hierarchy-enhancing legitimizing myths" such as racism and sexism, and intergroup conflicts.

In sum, values guide relationships in a way that their nature is transposed on the nature of relationships. This values-relationships link is bidirectional. Indeed relationships guide values and more specifically the socialization processes by which individuals learn the values of their groups and culture. People's lives are not only guided by their own value system but also by the perceptions of others' value systems (e.g., those of parents, role models, religious congregations, organizations, societies, and cultures). Future research is needed to examine this bidirectional association and how the two psychological dimensions (i.e., Hierarchical vs. Egalitarian; Allocentrism vs. Idiocentrism) can be used in studying and understanding human relationships.

VENGEANCE

Vengeance, synonymous with revenge, is an act of (or motivation for) retribution in response to a perceived transgression. This definition implies that a transgressor has incurred a social debt, and although the greatest satisfaction might come from forcing the actual transgressor to pay that debt, sometimes a “payment by proxy” will do. Thus, it is possible for the target of vengeance to be someone merely *associated* with the transgressor rather than the actual transgressor. Although vengeance is typically a behavior or motivation to act, speech acts and even inactions (e.g., failing to show up for a meeting) can function as types of vengeance. This entry describes the nature of vengeance as a function of characteristics of the individual, relationships, and the broader social context.

To Blame or Not to Blame

Research on aggression has much to offer our understanding of vengeance. For instance, aggression studies point to the critical element of attributing blame to specific individuals as instigators of

harm or provocation. If a victim does not attribute blame to a particular person, that person tends to be safe from aggressive retaliation. However, researchers have also found evidence for “triggered displaced aggression,” which occurs when hostility has been aroused in one provoking incident and a relatively minor event later triggers the expression of that hostility, even against persons who were unrelated to the initial incident. Thus, not being seen as the direct cause of a victim’s frustration, hostility, or hurt feelings does not always protect innocent parties from retaliation. When vengeance turns especially violent (e.g., school shootings, suicide bombings), innocent bystanders can also become accidental victims.

Sometimes the attribution of blame goes awry, as when a person is hypervigilant and overly suspicious, looking everywhere for evidence to support a predetermined judgment of another’s blameworthiness. When this occurs, it can produce a hostile attribution bias, in which the suspicious individual makes unwarranted inferences, misconstruing ambiguous acts and intentions in the most negative ways possible. Evolutionary psychologists have noted that such biases may occur when a person feels threatened by potential rivals, which can lead the threatened partner to engage in aggressive tactics designed to defend his or her social territory. Sometimes these tactics can turn violent, especially when one partner suspects the other of infidelity. Indeed, infidelity and suspicion of infidelity are among the leading causes of homicide across cultures, putting vengeance at the heart of one of society’s greatest ills.

Culture, Personality, and Saving Face

Cultures differ in the degree to which they accept vengeance as a response to perceived transgressions. Research on “cultures of honor,” found in the southern United States, Latin America, the Middle East, and elsewhere, reveals that some cultures tolerate vengeance as a means of restoring a threatened sense of honor, especially for threats to one’s family, reputation, or property. When infidelity occurs in a culture of honor, severe retribution by the wronged party (particularly by males) is often accepted by society, and sometimes *expected*. Vengeance norms also operate at more

local levels, such as within organizations or families, and to the extent that victims within such defined groups believe that their grievances will be handled fairly by those in power, they are less likely to seek personal vengeance. Likewise, research with romantic couples has shown that more constructive responses to conflict are associated with preconflict levels of commitment and intimacy, as well as with the perception by each party that the quality of alternative partners is relatively low—thus, they perceive it to be worthwhile to work through their conflicts constructively rather than escalating to the level of vengeance and the possible dissolution of the relationship. Similarly, recent research on forgiveness in close relationships has shown that revenge and avoidance (precursors to relationship dissolution) are two key indicators that a victim has failed to forgive his or her offender. Within close relationships, avoidance of intimacy (giving one's partner the "cold shoulder") might even serve as a non-violent and subtle form of vengeance.

Contemporary aggression theories also note the importance of hostile thoughts and feelings in producing aggressive behaviors, factors that likewise figure prominently in acts of vengeance. Among the personality factors predictive of such hostile thoughts and feelings are high levels of Neuroticism (defined either as negative affectivity or emotional instability) and low levels of Agreeableness. Neuroticism especially may facilitate *hostile rumination* following offense experiences, and rumination is a key predictor of vengefulness. Narcissism is another individual difference associated with vengeance, both because it heightens sensitivity to interpersonal offenses, and because it emboldens victims to seek revenge. Narcissists believe they are special and powerful, so when they feel mistreated, they may react with unwarranted degrees of retaliation to reaffirm their power and worth and to restore their social face.

Victims of transgressions need not be narcissists, though, to feel the sting of mistreatment as a loss of social face. People who are uncertain of their social status or who desire to achieve a higher level of status may be particularly likely to seek vengeance for perceived transgressions. Such people may feel they have less to lose by acting vengefully than by allowing others to see them as weak and vulnerable. A similar dynamic can also operate at

a group level. When group members are wronged, fellow group members may rise up in vicarious retribution, escalating conflicts to incorporate a wider audience. Such escalation can be seen in incidences of "blood feuds" and intergenerational hostilities between and within countries, in which wrongs suffered by a few are responded to by the collective, leading to a cycle of violence that can last for decades or centuries. At both the individual and group levels, those engaging in acts of vengeance frequently proclaim their motives as just—the equitable redress of a social wrong—and although the desire for justice might play a role in motivating vengeance, such value-based factors can also function as principled rationalizations for more powerful emotional concerns tied to the self-concept and the desire to save face.

VIRGINITY AND VIRGINITY LOSS

In William Faulkner's 1929 novel *The Sound and the Fury*, Quentin Compson is shocked to hear his father declare that men "invented" virginity and that it matters more to men than women. In fact, scholarly research in the Western context indicates that virginity is socially created and deeply gendered. This entry defines virginity and virginity

loss, provides a historical perspective to this topic, and presents data on average age at virginity loss in different groups.

Broadly speaking, *virginity* refers to the state of having never had sex and *virginity loss* refers to a person's first sexual encounter. (Some object to the term *loss* as pejorative.) Distinguishing between virgins and nonvirgins is an ancient practice. Early Greeks, Romans, and Jews valued virginity in unmarried women and believed virgins of both genders to possess special powers. Early Christians were urged to reject sin by embracing virginity, preferably as a permanent state, but minimally until marriage. Although lifelong virginity lost prestige after the Protestant Reformation, premarital virginity remained the widespread ideal, especially for women. Alternate perspectives also existed, however, coming to the fore in the United States during the sexual "revolution" of the late 1960s. Competing understandings of premarital virginity as desirable and undesirable have subsequently coexisted, often uncomfortably.

What sorts of sexual encounters, between what sorts of people, result in virginity loss is disputed. Before the Enlightenment and during the Victorian era, *virginity* was defined primarily in terms of spiritual or moral purity. Since about 1900, *virginity* has been defined primarily in terms of specific physical acts. The traditional—and most common—definition posits that virginity is lost the first time a person engages in vaginal sex. Some people believe, however, that engaging in anal or oral sex can also result in virginity loss. Others see these practices as foreplay and thus consistent with maintaining "technical" virginity—whereby an individual engages in "everything but" the activities thought to result in virginity loss (common since the 1920s at least).

Historically understood as exclusively heterosexual, virginity loss between same-sex partners is increasingly deemed possible, largely because of the growing visibility and acceptability of gay, lesbian, bisexual, and queer (GLBQ) people from the late 20th century on. According to one common formulation (favored especially by heterosexuals), GLBQ individuals can lose their virginity via oral or anal sex, whereas heterosexual virginity loss requires vaginal sex.

Tensions between moral/emotional and physiological definitions of virginity persist. Historically,

coerced sex was thought to compromise virginity. Yet, feminist analyses framing rape as violence, not sex, have led to new claims, common especially among women, that forced sex cannot result in virginity loss. Whether a sexually experienced person can resume her or his virginity is also debated. Most contend that virginity can only be lost once (a source of its significance). Others propose that, by being deliberately abstinent for a designated period of time (often until marriage), a sexually experienced person can become a secondary (or born-again) virgin. This view was popularized in the United States in the late 1980s by an increasingly influential conservative Christian movement.

In the United States, average ages at virginity loss (defined as "first vaginal sex") declined steadily from about 18 for men and 19 for women in the early 1970s to between 16 and 17 for both genders in 1995, then rose slightly in the early 2000s, especially among men. Historic differences in virginity-related beliefs and behaviors by race/ethnicity, social class, religion, and region diminished considerably during the late 20th century. However, virginity loss occurs on average earliest for African Americans, followed by Whites, then Latinos and Asian Americans; later for conservative Protestants than for other religious groups; later for well-off than poor youth; and later in Southern, Midwestern, and Mountain states than in other regions. Most youth who pledge to remain virgins until marriage engage in sex while single, practicing safer sex at significantly lower rates than do nonpledgers.

The meanings attributed to virginity and virginity loss are likewise diverse. In the United States, most individuals interpret virginity through one of three metaphors, comparing it to a gift, a stigma, or a step in the process of growing up. A fourth metaphor, framing virginity as a way of honoring one's commitment to God, may be (re)gaining popularity, because of the expansion of conservative Christianity and abstinence-focused sex education. These metaphorical perspectives influence people's decisions about when, where, and with whom to engage in sexual activity; their safer sex and contraceptive practices; and their satisfaction with virginity-loss encounters.

Historically, women have been encouraged to view virginity as a gift whereas men have seen theirs as a stigma. Women's sexuality has long

been guarded more closely than men's, partly because of women's biological capacity for pregnancy, which societies almost universally strive to restrict to certain kin relationships. Gender differences in the interpretation of virginity diminished in the late 20th century, however, thanks to second-wave feminism, effective birth control, and the sexual revolution—which encouraged women to adopt the same (permissive) sexual standards as men—and the HIV/AIDS epidemic, which made sex more consequential for males. A study by Susan Sprecher and Pamela Regan found that college women were more likely to remain virgins for relationship-related reasons and to avoid pregnancy, whereas men more often remained virgins because of concerns about sexual adequacy. Women expressed more pride and happiness about virginity, whereas men reported more guilt and embarrassment; however, male virgins in more recent cohorts felt more pride and happiness than did their earlier-born counterparts.

According to research by Laura Carpenter, men and women who share an interpretation of virginity tend to make similar sexual decisions and report similar experiences before, during, and after virginity loss. Interpreting virginity as a step in a process is especially common among lesbian and gay youth, for whom virginity loss is often closely intertwined with the process of coming out.

Empirical studies consistently find no evidence that losing virginity outside of marriage causes lasting psychological or physical harm. Nor do relationship solidity and sexual satisfaction appear to be affected by early or late virginity loss. People whose virginity-loss experiences diverge dramatically from their metaphor-based expectations may suffer considerable dissatisfaction, however, and individuals who lose their virginity earlier are at higher risk of unintended pregnancy and sexually transmitted infections. Conversely, people, especially men, who remain virgins at significantly older ages than average report more problems with arousal and orgasm (the causal direction is unclear). Unlike previous eras, many adults today prefer sexually experienced partners—making it more difficult for people who remain virgins relatively “late” to become sexually active.

VULNERABILITY-STRESS-ADAPTATION MODEL

The *Vulnerability-Stress-Adaptation Model* (also called the *Trait-Context-Process Model*) is a framework for understanding how satisfaction in intimate relationships may change or remain stable over time. Building on cognitive-behavioral approaches, the model describes partners' evaluations of their relationships as a direct reaction to their interactions with each other. The model then expands this idea by suggesting that a couple's interactions are themselves determined by (a) the abilities, personalities, and personal histories of each partner; and (b) the demanding or supportive circumstances that confront the couple. This entry explains the elements of the model in greater detail, describes how the model assembles these elements to explain the course of relationship satisfaction over time, and reviews the implications of this model for research and practice.

Elements of the Model: Three Broad Themes

At the start of an intimate relationship, most couples evaluate each other and the relationship exceedingly positively, and express hope that their positive feelings will last. Despite these promising beginnings, many couples are unable to maintain their initial feelings of satisfaction over time, and substantial research on relationships has explored

why this should be so. This research has identified hundreds of specific variables associated with change and stability in relationship satisfaction. A premise of the Vulnerability-Stress-Adaptation Model is that almost all the variables that have been studied can be summarized by three broad themes. Within each theme, different specific variables may exert their influence on relationships in more or less the same way.

Enduring Vulnerabilities

Each partner brings to their relationships a unique set of qualities, dispositions, and experiences, including attachment styles, personality traits, levels of psychopathology, and family history. What links all these disparate variables is that they are presumed to be relatively stable by the time a specific relationship begins. Each of these enduring traits may then contribute to or detract from an individual's ability to function effectively within the relationship. All else being equal, individuals with enduring sources of vulnerability (e.g., parental divorce, substance abuse, personality problems, a history of depression or trauma) have greater difficulty maintaining satisfying and enduring intimate relationships than do individuals with fewer sources of vulnerability.

External Stress

Every relationship takes place within a physical, social, cultural, and historical context. Elements within this context may support or interfere with a couple's efforts to maintain the quality of their relationship. For example, financial strain, demanding friends or relatives, and health problems all present couples with difficult issues to resolve, taking up time that might otherwise be spent promoting and maintaining intimacy. In contrast, supportive family and friends, financial assets, and good health serve as sources of resilience, buffering couples from the effects of other stressful circumstances and freeing time for enriching the relationship.

Adaptive Processes

Adaptive processes include all the ways that couples interact, understand, support, and react to each other. These processes include overt

behaviors that take place within the dyad, such as showing affection and resolving conflict, as well as cognitive and emotional reactions that take place within each partner, such as how they explain behavior and evaluate an interaction. Processes are adaptive to the extent that they minimize negativity and capitalize on positive aspects of the relationship. Satisfied couples, for example, are able to discuss differences of opinion without involving negative emotions, and are able to acknowledge specific problems without threatening their generally positive views of their relationships. Processes are maladaptive to the extent that they exacerbate negativity. Distressed couples, for example, tend to reciprocate each other's negative behaviors, leading to destructive cycles of escalating conflict.

Assembling the Elements

The Vulnerability-Stress-Adaptation Model assembles these three broad classes of variables within a single framework to account for change and stability in initially satisfying relationships. The engine of change in the model is the reciprocal association between adaptive processes and relationship satisfaction. Drawing from cognitive-behavioral perspectives, the model suggests that effective adaptive processes (e.g., positive interactions, charitable interpretations of partner behaviors) sustain and reinforce positive feelings about the relationship, which in turn make effective adaptive processes more likely in the future. In contrast, each experience of maladaptive processes (e.g., hostile interactions, blame, negative emotions) chips away at positive evaluations of the relationship. As negative experiences accumulate, evaluations of the relationship suffer, making further negative interactions more likely in the future.

Yet, by themselves, cognitive-behavioral approaches do not examine how more or less effective adaptive processes arise in initially satisfying relationships. Nor do these approaches speak to the question of how initially effective adaptive processes may deteriorate over time, or maladaptive processes may improve. The Vulnerability-Stress-Adaptation Model addresses these questions directly by placing adaptive processes within a broader framework that acknowledges the enduring

qualities of each partner and the supportive or stressful circumstances to which the couple must adapt.

In the resulting model, the quality of a couple's adaptive processes is viewed as the direct product of the personal characteristics of each partner and the ecological niche that the couple inhabits. Each partner's strengths and vulnerabilities affect relationship outcomes only indirectly, through their direct effects on the quality of the couple's adaptive processes. Partners with few vulnerabilities and many strengths should be able to interact well, manage negativity, and provide each other support, and these processes function to maintain satisfying relationships over the long term. Partners with many vulnerabilities and few strengths should have trouble managing negativity and differences of opinion, and these troubles detract from relationship satisfaction over time.

External stresses and challenges similarly affect relationship quality through direct effects on adaptive processes. Couples facing serious demands outside the relationship have more issues to resolve within their relationships and less capacity to resolve them in a positive and loving way. Couples in supportive involvements have more time to devote to relationship maintenance, and a greater capacity to use that time effectively. The model thus describes adaptive processes not as causes of relationship change, but as the mechanism through which aspects of individuals and their environments may interact to affect the development of satisfaction in an intimate relationship.

Explaining Stability and Change in Relationship Satisfaction

By acknowledging the interactions between the enduring traits of each partner and the varying demands of the couple's environment, the Vulnerability-Stress-Adaptation Model addresses how initially satisfying relationships may change over time and makes specific predictions about when changes are likely to occur. In general, the model suggests that relationship satisfaction declines when couples face challenges that rise beyond their ability to adapt effectively. This straightforward principle suggests several different paths through which relationships may decline or remain stable over time. For example, vulnerable

couples may endure stably while they are surrounded by support and have access to resources, but may decline when challenges arise that inhibit effective interaction. The most resilient couples may be able to maintain their relationships effectively even when facing great hardships, but even highly resilient couples may be prone to declines should they face catastrophe (e.g., chronic illness, the death of a loved one, bankruptcy, etc.). Among couples confronting a common stressor (e.g., unemployment, natural disaster), the most vulnerable couples are likely to experience the steepest declines in their satisfaction. Among couples whose satisfaction has already declined, those who experience improved fortunes outside the relationship (e.g., obtaining a coveted new job, receiving a bonus or raise, giving birth to a healthy child) are most likely to experience improvements within the relationship. Thus, in the interplay between partners, their contexts, and their interactions, the Vulnerability-Stress-Adaptation Model accounts for differences in relationship satisfaction between couples as well as changes within couples over time.

Implications for Research and Treatment

The Vulnerability-Stress-Adaptation Model has specific implications for research on how relationships change and the treatment of relationship distress and dysfunction. With respect to research, assembling three broad domains of variables into a single model draws attention away from main effects (that is, effects of one variable that do not involve other variables) and toward interactions. For example, although stress is associated with poorer relationship satisfaction for most couples (a main effect), couples with few vulnerabilities and effective adaptive processes may endure stress without declines in their satisfaction, and may even emerge from stressful periods with renewed confidence in the relationship (an interaction). Because the effects of variables in one domain on the course of a specific relationship will be imperfectly understood without data on variables in the other two domains, the model calls for research that adopts a wide focus. Research guided by this model has therefore tended to assess multiple domains of predictors at once.

As a model specifically designed to explain change over time, the Vulnerability-Stress-Adaptation Model also calls for a more refined perspective on the dependent variables in research on relationships. Rather than accounting for the state of a relationship at any one time, the model highlights the trajectory of the relationship across time. As a consequence, research guided by this model has tended to collect multiple waves of longitudinal data and has generally used sophisticated data analytic techniques, such as growth curve modeling, that allow a multifaceted view of those data.

With respect to treating distressed relationships and strengthening happy ones, the Vulnerability-Stress-Adaptation Model suggests that different strategies are likely to be most effective for different types of couples. Conventional skills-based approaches may be effective for couples with few enduring vulnerabilities and living in supportive environments that offer them space and time in which to interact with each other. However, highly vulnerable couples, or couples facing difficult life circumstances, may find it hard to interact effectively regardless of their skills. During a financial or health crisis, for example, the quality of couples' interactions tends to suffer, even if their interactions are generally effective when stress is light. For these couples, promoting specific behaviors and communication skills may prove difficult, and may offer fewer benefits than would interventions that address couple's problems and vulnerabilities directly (e.g., mental health service, financial support). Indeed, government policies that are most consistent with the Vulnerability-Stress-Adaptation Model emphasize assessing couples' needs in detail before they are assigned to a particular program. The more general implication of this approach is that interventions that target relationships directly are not always the best way to support relationships. Rather, programs that promote couples' well-being overall have the potential to benefit relationships indirectly. Consistent with the model,

when couples' personal and material circumstances improve, their adaptive processes have been shown to improve even in the absence of direct intervention.

W

WAIST-TO-HIP RATIO AND ATTRACTION

This entry deals with important biological information conveyed by physical attractiveness. Physical attractiveness, despite exhortations that it is subjective and only skin deep, significantly influences the selection of romantic partners in practically all cultures. According to evolutionary thinking, the power of attractiveness results from its conveying of biologically significant information. It is postulated that natural selection shaped mental mechanisms to solve problems encountered by the human ancestral environment. One such problem that our male ancestors regularly faced was to assess a female mate's value or the degree to which she would enhance his reproductive success.

Potential mates necessarily varied in their mate value, just as potential foods varied in their nutritional value. Female mate value was determined by numerous variables such as hormone profile, reproductive age, fecundity, and resistance to diseases, none of which could be directly observed. However, some of these variables are reliably conveyed by specific characteristics of female bodies, and natural selection produced psychological mechanisms to attend to bodily features in assessing a female's mate value. Furthermore, as females vary in their mate value, the intensity of male sexual attraction was designed to vary directly to perceived cues of female mate value. Although people may not be consciously aware of the link

between health and fertility and beauty, herein lies the power of physical attractiveness.

Basis for Attractiveness of Waist-to-Hip Ratio

A straightforward test of this evolutionary explanation would be to identify a feature of the body known to be linked with health and reproductive capability and to demonstrate that systematic variation in that feature produces systematic changes in judgment of female attractiveness. Body fat distribution as measured by waist-to-hip ratio (WHR) may be an ideal feature. First, WHR, unlike overall body weight, is an unambiguous indicator of age in men and women. Before puberty, both boys and girls have WHR in the range of .95 to .98 because body fat distribution is essentially similar in both sexes. However, during puberty, both men and women experience reduction in the size of their WHR. Increases in women's sex hormones induce an increase in pelvic width and regulate the anatomical location of body fat deposits. Simply stated, estrogen selectively inhibits fat deposits in abdominal and waist regions and facilitates fat deposits in the buttocks and thigh regions in women. Testosterone, on the other hand, inhibits fat deposits in buttocks and thighs, and facilitates fat deposition on the waist and upper body in men. After puberty, healthy women have a WHR between 0.67 and 0.79, whereas healthy men have a WHR between 0.8 and 0.95. As women age and their production of estrogen decreases, their WHR moves into the male range. Thus, WHR reliably signals the

reproductive age of the female unlike any other observable body feature.

Second, WHR is a reliable indicator of reproductive capability of women. Compared with women with high WHR, women with low WHR have fewer irregular menstrual cycles, optimal sex-hormone profile, and ovulate more frequently. Low WHR is also an independent predictor of pregnancy in women participating in artificial insemination. Third, women with low WHR have lower risks for diseases that manifest in later adulthood, such as heart diseases, stroke, breast, endometrial, and ovarian cancers. Women less susceptible to health problems would likely have more energy to attend to their family and children and, as many health problems are inheritable, their offspring would receive the genetic gift of good health.

To establish that selection process designed the mental mechanism for assessing attractiveness, one needs to demonstrate that (a) systematic changes in the size of WHR alone will produce systematic changes in the judgment of attractiveness, (b) that the judgment of attractiveness based on WHR should have cross-cultural consensus, and (c) that cross-cultural consensus is evident across longer time periods or has cross-generational consensus.

In the initial study, 12 line drawings of female figures representing three body weight categories (underweight, normal, overweight) and two levels of feminine (0.7, 0.8) and two levels of masculine (0.9, 1.0) WHR within each body category were created. Participants rated figures with lower WHR as more attractive than figures with higher WHR in each weight category. Figures with extremely low WHR are not judged as very attractive. The lower limit of WHR size is constrained by internal organs and the spinal cord. Therefore, a figure with extremely low WHR looks deformed. Body weight also affected the attractiveness judgment: the normal weight figure with 0.7 WHR was judged to be most attractive, followed by the underweight figure whereas the overweight figure, despite low WHR, was not judged to be attractive. It seems that, to be attractive, a woman must have a low WHR and deviate little from normal weight. These findings have been replicated with African Americans, British, Germans, Australians, Indonesians, Azores Islanders, and subjects from Guinea Bissau and the Shiwiar tribe of Ecuador.

Studies of temporal stability or cross-generational consensus are restricted to archival data. The first source was 286 ancient sculptures from India, Egypt, Greece (Greco-Roman), and some African tribes. Results indicated that the mean female WHR was significantly lower (0.7) than was the mean male WHR (0.9) despite some cultural variability. Another way to infer the temporally stable appeal of WHR is to look at ancient references to beauty: consider inscriptions on the tomb of the favored wife of Ramses II, Nefertari (dating from the second millennium BCE), which described her full buttocks and narrow waist or a description of beauty from the 1st- to the 3rd-century CE Indian epic *Mahabharata* that details the form of a beautiful woman as having full hips and breasts with a slender waist. Taken together, it is difficult to conclude that this aspect of beauty is in the eye of the beholder or dynamic over time. The persistent appeal of a certain WHR across cultures and time suggests that this aspect of beauty is ingrained in the human mind.

One implication of this research should be stressed—though it is a common practice to equate thinness with beauty and to argue that females are dissatisfied with their body image because of weight, perhaps this is not altogether correct. It could be that some women of normal weight but high WHR are dissatisfied with their body shapes and trying to lose weight to achieve that shape. The Victorian custom of corsets and later use of wide belts to make oneself have a narrow waist did not reduce overall body weight but still has tremendous appeal.

WARMTH, INTERPERSONAL

Interpersonal warmth is a dimension of individual differences in personality. People high on this dimension are described as warm and affectionate, whereas people low on the dimension are described as cold and indifferent. Languages around the world reflect this distinction, presumably because it is an important thing to know about people when interacting with them. This entry discusses interpersonal warmth as a dimension of personality, as a component of parent-child relationships, and as an aspect of close relationships, including romantic relationships and friendship. This entry also discusses the research on the neuropsychology of warmth, and it presents current thinking on the evolutionary functions of warmth.

Interpersonal Warmth as a Personality Dimension

Research on personality shows that people describe themselves as ranging from loving, nurturing, friendly, affectionate, agreeable, and trusting on the high end of the warmth dimension to antagonistic, cold, cruel, and suspicious on the low end. These results can be obtained by giving subjects lists of these adjectives and having them state how closely the adjective describes them; similar results are obtained if people are rated by others who know them well. People high on warmth have closer, more intimate friendships and are more likely to be trusting, cooperative, and helpful.

There is a strong sex difference in warmth, with females being higher on this dimension than are males. Girls are more prone to be involved in intimate, confiding relationships than are boys throughout development. Women also generally tend to place greater emphasis on love and personal intimacy in sexual relationships. Women are more empathic, and both sexes perceive friendships with

women as closer, richer, more intimate, and more empathic. Developmentally, sex differences related to intimacy peak during the reproductive years, a finding that is compatible with the theory that a basic function of warmth is to facilitate close family relationships and nurturing children. This is consistent with the finding that later in life there is more convergence between the sexes, with men becoming more nurturing and more attracted to intimate relationships and women becoming more independent and autonomous. Nevertheless, the average sex difference in favor of women remains throughout life.

Neuropsychology of Interpersonal Warmth

Interpersonal warmth therefore is a characteristic of a wide variety of close relationships, including friendships, heterosexual or homosexual pair bonds, and relationships between parents and children. Recent work in neuropsychology shows that close relationships activate specific reward areas in the brain and the neurotransmitters oxytocin and vasopressin. People high on the warmth dimension are relatively sensitive to the reward value of close relationships. They find intimate, affectionate relationships to be highly rewarding and eagerly seek out relationships, including peer relationships of friendship, in which this stimulation is available. Because the other person in such a relationship also finds this stimulation rewarding, the relationship is characterized by reciprocal positive affective exchanges. Friends are intimate associates, and their relationships are characterized by reciprocity, commitment, cooperation, and engaging in reciprocated prosocial support, intimacy, and affection. Because of the motivating role of affection for nurturance, people high on the warmth dimension tend to be relatively empathic and altruistic, especially within friendships where these feelings and actions are reciprocated.

Nevertheless, despite these general features of warm relationships, there are different types of warm relationships; this is reflected in neuropsychological differences unique to particular types of relationship. For example, long-term pair bonds and maternal love share a common neuropsychology of positive social reward and inhibiting negative emotions such as fear. Sexual relationships add

an erotic component beyond interpersonal warmth; it is generally thought that in long-term relationships, sexuality contributes to warmth and vice versa.

Warmth as a Component of Parent–Child Relationships

Warmth has also been identified as one of two major dimensions of parent–child relationships, the other being parental control (i.e., discipline and monitoring of children's behavior). Parents who are high on the warmth dimension are accepting, affectionate, and child-centered, and parents at the opposite end of the dimension are cold, rejecting, and self-centered. Warm parent–child relationships are correlated with the development of conscience and an internalized moral orientation (that is, acting morally because of internal standards of proper behavior rather than fear of punishment). Lack of warmth, on the other hand, is associated with delinquency and aggression rather than relationships based on reciprocated positive interaction. Studies have shown that this effect is found in many different cultures.

Warm parenting is also correlated with accepting and internalizing parental values. Given that warmth is a reward system, warm parent–child relationships can be seen as involving reciprocated positive exchanges of affection. Parental warmth therefore plays a motivating role in children's internalization of parental values. Children in warm parent–child relationships are positively motivated to seek the approval of their parents and to identify with their parents. Warm parents are more effective role models because children are motivated to maintain the warm relationship with their parents. For a child who has developed a strong relationship with the parent based on warmth and affection, behavior in opposition to the parent's standards may produce guilt and anxiety. Children in warm parent–child relationships are therefore less likely to be involved with peer groups, especially delinquent peer groups, disapproved by parents.

Parental warmth is not all powerful in motivating behavior. It must compete with other motivational systems, such as children's desire to fit into peer groups and normal attractions to sexual and

other forms of excitement that parents might disapprove. Nevertheless, parental warmth tends to push children to be more attentive to adult values.

Individual differences in interpersonal warmth are heritable, with about half of the variation because of environmental differences and half the variation because of genetic differences. Moreover, environmental differences are unshared within families, meaning that different children in the same family often experience different environments related to warmth. For example, research suggests that parents respond to genetically driven differences in their children. Thus, a child who is high on warmth may elicit more parental affection and nurturance than would a child who is not as high on the warmth system. These are termed *genotype-environment correlations*: Some children seek affection from their social environment more than others do (called an active genotype-environment correlation); some children evoke more affection from their social environment (called an evocative genotype-environment correlation). There are also passive genotype-environment correlations between children and their social environments. These result from parents transmitting genes that make their children more likely to be warm and affectionate but also treating their children with affection.

Finally, the finding that there are reward centers in the brain for interpersonal warmth and for several different types of close relationships (i.e., friendship, romantic love, parent–child affection) is highly compatible with an evolutionary perspective. As is often the case, evolution results in mechanisms that make adaptive behavior pleasurable and rewarding. Similarly, evolutionary theories propose that warmth originally evolved as a motivational component of maternal nurturance of offspring. Mothers high on warmth took pleasure in nurturing their children and keeping them safe. Because of the care of their mothers, the offspring survived better, so the genes for interpersonal warmth spread.

The preexisting system of maternal warmth then became elaborated as natural selection resulted in a biological basis for paternal investment in children and other types of close relationships. Humans are one of the few primates and relatively few mammals among whom fathers typically invest in their children. The primitive mammalian

pattern is for the males to simply mate with the female and then leave the rearing of offspring to the female. However, if investment by the father results in benefits for the children, there will be natural selection for paternal investment.

There is good reason to believe that this happened. As a thought experiment, imagine a woman having to support herself and her family in inhospitable environments without help from others while in the late stages of pregnancy or caring for young children. Cross-cultural research shows that children with fathers who invest in their welfare have lower mortality and greater cultural success. Although men are lower than women in interpersonal warmth, most men are attracted to close relationships and nurturing children. As noted, recent research in neuroscience shows that men as well as women have reward centers in their brains that promote pair bonding and nurturing children. Indeed, men living with pregnant women have increased levels of more characteristically female hormones such as prolactin and, to some extent, estradiol. Warmth, then, is part of the psychological basis of pair bonds and male investment in children: Males high on the warmth system find close relationships with family members rewarding and are motivated to be nurturant and affectionate toward children.

The evolutionary perspective also proposes that the primitive warmth system was also elaborated to motivate close relationships of friendship with nonfamily members. Evolutionary perspectives conceptualize friends as allies—people with whom one cooperates in pursuit of goals. During the early stages of friendship formation, future friends closely monitor their partners' behavior to make sure that they can trust them and that the relationship will be mutually beneficial. As friendship develops, the social reward areas of the brain are activated as the friendship begins to have positive emotional overtones. This emotional component of trust is a feeling of warmth toward the friend—a feeling that taps into the brain's reward centers for social relationships.

WEAK TIES

Weak ties are best defined in contrast to *strong ties*. Strong ties involve relationships with intimate social partners. Researchers have devoted considerable attention to close relationships and have linked these ties to lower morbidity and mortality throughout life. Yet, people also retain an array of nonintimate social ties. These ties have received less attention in the research literature. Scholars who study nonintimate ties refer to them as *weak ties* or *peripheral ties*. In everyday parlance, people call them “acquaintances.” The key features of these ties involve the social partners’ mutual recognition and repeated interactions but an absence of intimacy or commitment. In early scholarship, frequency of contact distinguished these ties from strangers in the public realm known as “nodding relationships” or “familiar strangers”; weak ties involved more frequent contact than with people who were truly strangers. With technological

advances such as text messaging, listservs, blogs, and social networking sites, these distinctions are blurred. Even individuals who are little more than strangers establish repeated interactions and weak ties. This entry discusses the places where individuals encounter weak ties, historical changes in weak ties, and the functions of weak ties.

Weak ties arise in a wide array of settings. The development of relationships often involves a stage as weak ties; acquaintanceship often precedes friendship. Likewise, the disbarring of intimate relationships can engender weak ties, particularly when relationships move from active to passive. Friends who have drifted apart may rest on the periphery of the social network. Other ties may remain perpetually weak, particularly in the business world. Coworkers who do not progress to friendship, clients who frequent a business where they recognize the staff, and professionals such as haircutters, lawyers, or doctors with repeat customers establish such loose relationships. Some weak ties are steeped in a shared environment (neighbors), affiliation (clubs or churches), or Internet sites of various sorts. Close social networks also may engender weak ties; friends-of-friends or distant relatives are tenuously linked. Finally, individuals also may actively seek weak ties to people who have resources they need at different points in their lives.

Scholars interested in social networks sometimes refer to weak ties as *peripheral relationships* and closer ties as *core relationships*. Core relationships may vary from very intimate to less intimate, and peripheral ties are a subset of weak ties that individuals might list as members of their network, but not among their close ties. Research on social networks reveals that peripheral ties are more fluid than core ties are. Intimate ties are fairly stable over time, but weak ties tend to vary. At one point in time, an individual's cadre of peripheral ties may be distinct from the cadre of peripheral ties at a subsequent point in time. Peripheral ties by definition require less investment than do core ties and thus, are more expendable. Core intimate relationships often are steeped in longer-term family ties or commitments and are harder to form or disband.

The pervasiveness of weak ties in daily life is a fairly modern occurrence. Three shifts in human history account for increases in contact with

peripheral social ties: (1) the shift to intensified agriculture, (2) industrialization and urbanization, and (3) recent technologies facilitating contact with distant social contacts. Starting with horticultural societies, individuals began to interact with non-intimate social partners on a periodic basis to facilitate trade. More recently, industrial economies have required a surge in connection to people outside the family. Individuals employed for pay may spend more time with coworkers than with their intimates. Finally, beginning with the pony express, people have been able to communicate with social partners outside the intimates in their immediate environment. Technological advances proliferated in the 20th century with telephone, fax machines, and computers facilitating communication. In the 21st century, social networking Web sites encourage individuals to connect to a range of weak ties via friends-of-friends, common interests, and shared affiliations, and technological advances facilitate the maintenance and management of a large array of weak ties.

Weak ties may complement intimate ties and serve distinct functions. In one of the most widely cited studies in the field of sociology, *The Strength of Weak Ties*, Mark Granovetter documented the benefits of weak ties. He examined the mechanisms through which people obtained new jobs and found that people gathered information via weak ties. Studies have replicated these findings during the past 35 years. By contrast, intimate social partners are not as facile at providing new information because they come from similar backgrounds, have access to the same resources, and are often part of a "dense" network (e.g., everyone knows everyone else). Weak ties may encompass a broader array of social connections. Your dentist is unlikely to know your next-door neighbor. Thus, each weak tie may be a repository for diverse knowledge.

The primacy of weak versus intimate ties appears to vary throughout life, with the desire to establish weak ties greatest in adolescence and early adulthood. Socioemotional Selectivity Theory suggests that when individuals view their future as limited (as in old age), they focus on their emotionally rewarding close relationships. By contrast, when the future is open (as in young adulthood), individuals are motivated to seek new information and, thus, desire contact with

peripheral social partners. In Western cultures, many adolescents and young adults have considerable leisure time and few responsibilities. Young people also may seek weak social ties for entertainment and diversion.

Research suggests an array of other functions that weak ties serve as well. Community psychologists in the 1980s determined that haircutters, bartenders, and divorce lawyers sometimes served emotionally supportive functions equivalent to psychotherapists. Sociologists have been interested in role complexity and have suggested that peripheral social partners can enhance a multifaceted sense of identity. Individuals may behave and define themselves in distinct ways with family, boss, a yoga instructor, people who post on a Web site, community activists, their children's friends, and former neighbors. Social psychologists also suggest that individuals use social comparisons with weak ties when they are uncertain of their abilities. Comparison with similar others is needed for people to situate themselves within broader social hierarchies. Finally, recent research suggests that social networks containing diverse types of social ties (i.e., an array of weak ties as well as intimate ties) may enhance mental and physical functioning, but the mechanisms accounting for these associations remain unclear.

WEDDINGS

Weddings are one of the most important cultural rituals, reinforcing conventional cultural values and the social structure. Weddings recognize a legal relationship marked by a ceremonial rite of passage. Leslie Baxter and Dawn O. Braithwaite explain that weddings are rituals because they are voluntary, patterned communication events guided by cultural norms that pay homage to something considered sacred, and that produce and reproduce identity of the couple and family. Weddings are patterned in the sense that most ceremonies follow models or a broad script. Weddings are guided by cultural norms, meaning culture influences expectations for the ritual and the couple's marriage to follow. That weddings pay homage to something sacred means that weddings honor something, for example, the relationship, family, religion, or marriage as a social institution. Weddings involve identity of the individuals and the newly married couple. Weddings are not something a couple can do alone—they are inherently social. Most often weddings occur in the context of social interaction within the web of relationships (e.g., family, friends, church, community) surrounding a couple. However, even if a couple has a wedding in which the couple's social network members do not participate, others, for example, a justice of the peace and witnesses, still need to be involved. This entry discusses weddings past and present, functions of weddings, and the topics of weddings and consumerism, gender, culture, heteronormativity, and remarriage.

Although U.S. weddings take various forms, some specific practices are present in nearly every wedding: an engagement period, setting a date to be married, a ceremony including the exchange of vows, a member of the clergy or legal system officiating, and a reception celebrating the couple following the ceremony. Whether small and informal or large and formal, U.S. weddings are laden with cultural artifacts including special clothing for the bride, groom, and members of the wedding party; flowers; photography; and a ring for one or both partners. Weddings involve at least two witnesses who are required to sign a legal document, but often involve several hundred family, friends, and community members. Although there

are considerable differences in weddings, they share a common core—what scholars call canonical stories. *Canonical stories* are narratives familiar to members of a culture that prescribe behaviors and the boundaries of acceptable practices. Thus, although weddings take many different forms, most of us could step into a stranger's wedding ritual and recognize a wedding is taking place. The consistency of the wedding ritual speaks to the social construction of weddings.

Weddings Past and Present

Before the 18th century, U.S. weddings were small and informal and involved active participation of friends and members of the community, usually involving the church. However, as Jaclyn Geller explains, by the 18th century, the focus of wedding ceremonies shifted from the community to the bride, changing the ceremony to a personal one. Still, middle-class weddings were simple affairs, usually conducted in the home or a church, without elaborate costumes, and often with a brief engagement period. Although witnesses were present, usually these were small gatherings of close family and friends. During the mid- to late 19th century, the formal “white wedding” hosted by the bride's family became the standard in the United States.

At present, weddings may be classified on a continuum from eloping, small home wedding, informal chapel wedding, small wedding in church, home/garden/club wedding, formal church wedding, to a large cathedral or hotel wedding. Most U.S. weddings today are held in a church with a member of the clergy officiating. Even couples not highly committed to religious practices in everyday life often include religion in the wedding ceremony.

The median age of marriage has risen in the United States; for example, the age of brides has risen from 21.7 years in 1970 to 25.1 years of age in 2000; ages for grooms have also increased from 23.3 years to 26.7 years in the same period. Although weddings are a happy time for couples, they are a source of stress as well. Couples worry about whether they are making the right decision, managing finances, becoming a part of a new family and getting along with in-laws, as well as the

ceremony itself. Although many couples anticipate that marriage will be easy and similar to what they experienced in the premarital period, many are surprised at the stress weddings and the newlywed period bring.

Functions of Weddings

Weddings are rituals laden with symbols. They regulate and organize marriage and family and confirm heterosexuality as an acceptable social practice. For most families, weddings are centrally important social rituals that create a new family of the marital couple. As weddings unite marital couples, they also bring families together, display family solidarity, and knit together the couple's social networks of family, friends, and community members. Members of the couple's social networks come together to demonstrate their loyalty and support of the couple and the institution of marriage. Social network members also serve as witnesses to the couple's vows, as couples make a public commitment.

Traditionally, weddings symbolized the change of status and identity from individual to couple and began the cohabitation of the marital couple. Today, many couples cohabit before marriage and the identity shift into a spousal role is not as clear-cut as in the past. Interestingly, although many couples cohabit before marriage as a period of testing or rehearsal for marriage, researchers have found that cohabitation does not lessen chance of divorce. Because of the onset of sexual relations before marriage and premarital cohabitation of many couples, weddings may function less as a rite of passage, and more as a symbolic and legal legitimization of the couple's relationship.

Weddings and Consumerism

For many families today, planning and holding “the perfect wedding” is important. Weddings are an industry in the United States, and their cost continues to rise. Spending on weddings in the United States is estimated to be about \$50 billion annually, and in 2006, the average cost of a wedding was \$30,000 in U.S. dollars. Weddings give families the opportunity to demonstrate their

wealth or the illusion of wealth, as many families move temporarily out of their socioeconomic class in spending and activities for the wedding. Traditionally, parents of the bride were expected to cover the cost of the wedding, but today it is common practice for both families (and sometimes the bride and groom themselves) to share the expenses.

The influence of the media and of the growth of the wedding industry has created the norms for proper weddings. The wedding industry has transformed how couples marry, introduced new traditions, and produced new meaning for weddings. Bridal magazines, Web sites, and businesses reinforce the perfect wedding. Television shows about weddings are tremendously popular among young women and give illusions of the perfect wedding. The bridal industry reinforces the normalcy and desirability of heterosexual, Christian marriages and reaffirms the tradition of the white wedding captured in wedding photos.

A tension exists between two U.S. cultural ideologies of the romanticism of tradition and the “must haves” for perfect wedding, and individualism, where the couple may exert their own identity in the wedding ceremony. Through the couple’s symbolic choices as they plan the event, weddings become a reflection of unique couple identity manifested in the tradition of the ritual. In this way, weddings communicate individual identity as well as the ability to conform and adapt to the larger social norms.

Weddings and Gender

Traditional, romance-based weddings are an aspiration for many women, especially for first weddings. Although men are presently more involved in wedding planning than in previous generations, women are prepared by tradition, the media, cultural institutions, and the wedding industry to take the lead role in wedding planning. The wedding industry offers women many options to help prepare for weddings, and many women devour magazines, books, Web sites, or television shows dedicated to wedding planning, or hire wedding consultants. Not surprisingly, studies reveal that brides experience more stress while preparing for weddings than do grooms.

The gendered nature of wedding ceremonies has altered little during the last century despite changes in the role of women in U.S. culture. There seems to be surprisingly little resistance among young women to the white wedding, and traditionally gendered practices associated with weddings, for example, being escorted down the aisle by fathers or other males, wearing a veil or other head-covering, or adopting the husband’s surname upon marriage. Some feminist scholars point out that traditional white weddings mirror the gendered role of wives in U.S. culture. Despite greater participation of men in the home and caregiving for children and family, most of this labor still falls to women. Feminist scholars point to the irony that many women (and men for that matter) who label themselves *feminists* choose traditional white weddings.

Weddings and Culture

The U.S. white wedding has been exported and translated to other cultures. It is not unusual to see brides and grooms dressed in traditional U.S. bridal gowns and tuxedos. For example, in Japan, it is not uncommon for couples to adopt Christian symbolism and U.S. wedding artifacts.

Wendy Leeds-Hurwitz explains that interracial and intercultural couples may face additional challenges with their weddings. Weddings that unite persons from different cultures, ethnicities, or social classes are inherently more complex because these couples must co-construct a relational identity from among cultural expectations that may differ. Some interracial or intercultural couples may encounter anything from misunderstanding to intense family or community opposition to their decision to marry. Negotiating different cultural expectations in the course of planning and holding the wedding may be challenging, as couples must find ways to negotiate cultural conflicts. In the best of circumstances, couples are able to address and often combine their individual cultures in ways that are acceptable to their families and relevant others. If they can do this successfully, the wedding may provide an opportunity for the couple to establish and model for their families and communities (and themselves) how they will address and negotiate their cultural differences in the future.

Weddings and Heteronormativity

Weddings also function to reify heterosexual love and relationships in the United States and to institutionalize heterosexuality. Despite the denial of rights and recognition to same-sex couples, many gay, lesbian, bisexual, and transgender (GLBT) couples are holding weddings, often called commitment ceremonies, to affirm the permanency of their relationship. These ceremonies range from being virtually indistinguishable from heterosexual weddings to those that are different. Depending on the level of acceptance of their homosexuality by family members, family may or may not play a prominent role in these ceremonies. Some GLBT couples turn to friends and voluntary (fictive) kin to support their relationship and wedding.

In addition to the challenges experienced by GLBT couples concerning their own weddings, Ramona Oswald and Elizabeth Suter explain that tensions are created when heterosexual weddings exclude GLBT family members or friends, or when they are placed in awkward positions of enacting heterosexual practices. For example, the ritual of the bride throwing the bouquet to the single female guests may be awkward for a wedding guest who is lesbian and pairing a GLBT member of the wedding party with a member of the opposite sex in the walk down the aisle may be discomforting. For GLBT guests, the wedding ceremony may seem to be replete with explicit anti-GLBT messages, especially in those weddings that highlight conservative religious values. Heterosexual family members may struggle over whether or how to invite partners of GLBT family members to the wedding. When they are invited, GLBT individuals may perceive they are expected to remain silent about their identity.

Weddings and Remarriage

To date, there has been little research about weddings in couples marrying for the second time (or more). Where one or both partners have been married before, some couples hold understated, simple wedding rituals and others engage in traditional white weddings. For some couples, this decision may be influenced by whether this is a first marriage for one of the partners, especially if

this is the case for the bride. The presence of children also affects the wedding for remarriage couples. Researchers have found that weddings are often empty rituals for children. Stepchildren who perceived that the parents are celebrating the creation of a new family, rather than an exclusive focus on the couple, are more likely to find the wedding meaningful.

WILLINGNESS TO SACRIFICE

“No relationship would survive if partners were not willing to sacrifice.” Although this may sound like a strong statement, it is likely to be true.

Indeed, one could go so far as to claim that relationships exist by virtue of mutual sacrifices—because mutual sacrifices add extra value to the relationship. If partners “give and take” in their choices for food, they will every now and then have their own favorite food while being able to enjoy one another’s company. If they do not, they will probably end up eating alone, and living alone. *Willingness to sacrifice* is defined in terms of the readiness to forgo immediate self-interest to promote the well-being of a partner or a relationship—for example, to do something for your partner that you would otherwise not do. Sacrifice can take a variety of forms—it can consist of giving up desirable behaviors (*passive sacrifice*) or enacting undesirable behaviors (*active sacrifice*), it can consist of minor requests that occur every day in a relationship (e.g., going out with your partner’s friends whom you find terribly boring) or more substantial ones (e.g., moving to another city for your partner’s career). This entry discusses what promotes willingness to sacrifice and what sacrifice promotes close relationships.

What Promotes Willingness to Sacrifice?

One key variable in promoting willingness to sacrifice is one’s commitment to the relationship, which is defined in terms of the degree to which an individual experiences a long-term orientation toward a relationship, including the intent to persist, feelings of psychological attachment, and implicit recognition that one “needs” the relationship. Empirical evidence strongly indicates that commitment promotes willingness to sacrifice. The various components of commitment—satisfaction, investments, and quality of alternatives—predict willingness to sacrifice. That is, willingness to sacrifice is greater for people who are happier in their relationships (satisfaction), for people who have made greater investments to the relationships (material investments such as shared mortgage, furniture, and the like, or subjective investments, such as mutual friends, exchange of secrets, and so on), and for people who fear that they have not much to fall back on because they would not like to be single, or because their alternatives do not look good (perceived quality of alternatives). Commitment summarizes and explains the links

between satisfaction, investment size, and perceived quality of alternatives on the one hand, and willingness to sacrifice on the other hand. So, what then might explain why commitment is such a powerful predictor of willingness to sacrifice?

First, committed individuals are dependent on their partner and literally need their relationships. The more they have to lose, the more they will be willing to give up to hold on to what they have. This explanation is consistent with the negative association between perceived quality of alternatives and willingness to sacrifice. Evidence does suggest that people who believe that they would “lose everything” if the relationship were to end are more likely to be helpful to the partner, often at significant cost to themselves.

Second, committed individuals are likely to adopt a communal orientation to respond to the partner’s needs in a rather unconditional manner without counting what they receive in return. Such communal orientation has often been linked with commitment. This makes sense: In a strongly committed relationship, it would be unusual if partners need to think carefully whether or not to do the partner a favor, and to bring to mind a record of exchanges. Such an exchange orientation might even be taxing because “counting” and “book-keeping” may be disruptive for smooth and easy interactions.

Third, commitment involves psychological attachment. The committed person feels linked to his or her partner emotionally and, as a consequence, departures from self-interest to benefit the partner may not be experienced (or at least, less so) as departures from self-interest. This occurs when committed individuals sacrifice to make their partner feel good and, at the same time, knowing that they have benefited their partner makes them feel good. For example, parents often help their children automatically, presumably because of their attachment and resulting desire to benefit them. In this regard, during airplane flights, it is often announced that in case of an emergency, parents should first help themselves, and then their children. Evidence indicates that several physiological responses are activated in mothers when their young children start to cry, preparing mothers to provide immediate help even after losing many hours of sleep (e.g., providing milk when a baby signals hunger). Thus, mothers seem to be

genetically predisposed to sacrifice for their offspring, even at considerable risk to their own welfare. When they sacrifice for their children, they do not experience it as a departure from self-interest but as the natural thing to do (“What makes the children feel good, makes me feel good”).

Fourth, commitment involves adopting a long-term orientation. In a short-term interaction, individuals may achieve good outcomes by pursuing their immediate self-interest. On the contrary, in long-term relationships, it is beneficial to develop patterns of reciprocal prorelationship behaviors, and acts of sacrifice may represent a conscious or unconscious means to encourage reciprocity and maximize long-term self-interest. This interpretation is supported in research showing that although people whose personal values predispose them to be generally “prosocial” (i.e., helpful, cooperative and friendly) exhibit large sacrifices whether or not they are strongly committed to their relationships; self-centered people are likely to exhibit high levels of willingness to sacrifice only if they are committed. Presumably, they do so in their pursuit of long-term self-interest.

What Does Sacrifice Promote?

Sacrifices are one of the most important and effective ways to build trust. If Hal does something nice for Dorothy, and Dorothy realizes that Hal did this at some major cost to himself, then Dorothy’s feelings of trust will be bolstered. In other words, sacrifices make one feel that a partner is considerate of, and responsive to, one’s basic needs, which is essential to the future of the relationship, especially given the many uncertainties likely to arise. Sacrifice also helps the recipient to feel validated, as the partner is supporting one’s feelings of self-esteem and self-worth. Altogether, it might be argued that partners in close relationships seek to symbolically confirm and express their mutual commitment to help one another under most kinds of circumstances. Indeed, the marriage vow is an expression not only of one’s commitment to stay together, but also to help each other through rough times (a key demonstration of the willingness to sacrifice). With this in mind, what are the main outcomes shown in research to result from sacrifice?

One relatively straightforward outcome of sacrifice is *direct reciprocity*. That is, sacrifices often inspire the partner to make sacrifices in return. For example, in ongoing relationships, there is a significant association between each partner’s willingness to sacrifice. Also, studies have shown that over time, one person’s sacrifice increases the partner’s trust, which in turn enhances the first person’s willingness to sacrifice. Such evidence is consistent with the large literature on reciprocity in cooperation. For example, past research using the prisoner’s dilemma game has revealed that even strangers are likely to respond cooperatively to another’s cooperative behavior. Although such tendencies may be mediated by trust, they sometimes occur in a relatively automatic manner, without much calculation or thought, and perhaps even beyond our awareness. Also, although there is reciprocity in sacrifice, there is also reciprocity in the failure to sacrifice, and these may even have stronger effects on relationships.

Second, in the context of groups, willingness to sacrifice may also be inspired by the desire to maintain or improve one’s reputation. For example, group members want other group members to trust them. If other group members have a reason to distrust a person, then a variety of sanctions can be imposed, such as being marginalized (e.g., not being invited to contribute to important group decisions) or even excluded from the group. Studies have shown that members of a group have a strong tendency to monitor and evaluate one another’s input to the group. Evidence indicates that people sometimes tend to do too much for the group (“wasteful altruism”), perhaps in an effort to ensure that no one doubts their willingness to sacrifice for the group. As such, members may sometimes compete for a self-sacrificing (or altruistic) reputation, or, at a minimum, to avoid any possibility of being seen as one of the lesser contributors. Finally, self-sacrificial acts in a group may also lead to indirect reciprocity, whereby people reciprocate favors and sacrifices to third persons, rather than to the original helper.

Third, sacrifice, and acts of generosity more generally, serve an important function in helping to increase trust, which may be essential in coping with unintended errors. For example, a single unintended error by an untrusted other (e.g.,

saying the wrong thing, arriving too late for a date) can create a cycle of noncooperative exchanges. Sufficient levels of trust thus may be helpful in coping with the uncertainty and unintended errors of social life. Research has revealed that acting a bit more cooperatively than one's partner is an important means by which to build such trust. Such findings also suggest that acts of sacrifice are functional, not only because of the support received, but also because of the "surplus value"—the communication of trust and love. In the contexts of groups, acts of sacrifice help solve a problem, and contribute to a positive, trusting group atmosphere that is essential for future interactions.

Conclusion

Sacrifice is central to the functioning of human relationships. One of the most central determinants of trust that helps people to reciprocate acts of sacrifice is helping people give one another the benefit of the doubt in coping with unintended errors and misunderstandings. The motivations underlying sacrifice can range from selfish to altruistic. Sometimes people sacrifice because they believe that sacrifices ensure good outcomes for themselves in the long-term, and sometimes people may sacrifice because they are deeply concerned about another person's well-being. However, sacrifice can be a product of systematic thought as well as a product of virtually no thought at all. Finally, some people believe in the risks of "too much sacrifice," because it can invite exploitation, and some argue that people with chronic self-esteem and dependency problems are overly likely to sacrifice, which may hinder their healthy development. Although there are many examples of both phenomena, the existent literature indicates that these are exceptions. The rule is that sacrifices are helpful to the well-being of relationships *and* individuals, including the one who sacrifices.

WORK-FAMILY CONFLICT

Changes in the family and the composition of the labor force are reshaping the relationship between work and family life in the United States. During the past 40 years, women have greatly increased their participation in paid employment, men have increased time spent on housework and childcare, and the proportion of households involving two earners or an unmarried parent has grown. Such shifts have sparked a large and vibrant body of research on the interface between work and family life. Much of this research considers work-family conflict, broadly defined as conflict experienced because of incompatibilities between the demands of work and family roles. Work-family conflict is associated with a variety of individual-level outcomes including reduced life satisfaction, reduced marital quality, and emotional distress and can also negatively affect employers through increased rates of absenteeism and employee turnover, reduced productivity, and lower employee satisfaction. This entry reviews the meaning and correlates of work-family conflict and suggests directions for future research on this topic.

Although a growing body of research also considers the ways in which work and family roles may enhance one another, this work is beyond the scope of the current entry.

The Meaning of Work-Family Conflict

Work-family conflict arises when the demands of work and family roles are perceived as interfering with one another. This concept originates from Robert L. Kahn and colleagues' theory of interrole conflict and William J. Goode's theory of role strain. Jeffrey Greenhaus and Nicholas Beutell identify three potential sources of work-family conflict: time-based conflict, strain-based conflict, and behavior-based conflict. *Time-based conflict* stems from the idea that resources of time and attention are finite, such that participation in one role limits the time and attention that can be devoted to another role. Work-family conflict results when these resources are insufficient to meet the demands of both work and family roles. *Strain-based conflict* arises when symptoms of stress associated with performance in one role (e.g., tension, anxiety, fatigue) interfere with performance of the other. *Behavior-based conflict* occurs when behavior(s) required in one role are incompatible with those required in another role. For example, aggressiveness and independence may be necessary for success at work whereas nurturance and warmth may be expected at home.

Although Greenhaus and Beutell emphasize the simultaneous and bidirectional incompatibilities between work and family roles, much recent research separately considers conflict arising from work sources (work-to-family conflict) and conflict arising from family sources (family-to-work conflict). The latter approach is supported by growing evidence that work-to-family conflict and family-to-work conflict tend to have different determinants and consequences. Yet, consistent with Greenhaus and Beutell's original conceptual definition, a positive association exists between levels of work-to-family conflict and family-to-work conflict. This points to a reciprocal relationship where demands associated with unfulfilled role obligations in one domain may in turn make it difficult to fulfill role obligations in the other.

Scholars also increasingly acknowledge that personality characteristics such as Neuroticism or Extraversion influence whether a given set of work and family role demands result in the perception of work-family conflict for a particular individual.

Measurement

Early research on work-family conflict tended to rely on global measures that failed to distinguish between work-to-family conflict and family-to-work conflict or on measures that assessed only the extent to which work demands interfered with family life. More recent research uses scales constructed from multiple self-reported items that separately assess work-to-family conflict and family-to-work conflict to better capture the bidirectionality of the relationship between work and family. Many of these measures are based on Greenhaus and Beutell's conceptualization, although commonly used scales include time and strain-based items more often than behavior-based items. Researchers use a wide variety of specific instruments to measure work-family conflict. For example, Michael Frone and colleagues' commonly used scale includes such questions as, "How often does your job or career interfere with your responsibilities at home, such as yard work, cooking, cleaning, repairs, shopping, paying the bills, or childcare?" and "How often does your home life keep you from spending the amount of time you would like to spend on job- or career-related activities?" Richard Netemeyer and colleagues' widely used scales also include strain-based dimensions of work-family conflict such as, "My job produces strain that makes it difficult to fulfill family duties." And, "Family-related strain interferes with my ability to perform job-related duties."

Work Sources of Conflict

Individuals generally report higher levels of work-to-family conflict than family-to-work conflict. A number of specific characteristics of work roles are associated with elevated perceptions of work-family conflict. For example, nonstandard or inflexible work schedules, job stress, lack of autonomy or time pressure on the job, work role

ambiguity, and job dissatisfaction are generally associated with higher levels of perceived work-family conflict. Some studies also find job insecurity, job involvement (i.e., viewing one's job as central to one's identity), and the number of hours worked per week to be positively associated with work-family conflict. Other research considers specific features of workplaces. For example, a supportive work-family culture at one's workplace (e.g., programs that support parental leave or flexibility to attend to personal or family issues) and work-family support from a supervisor (e.g., supervisor accommodates family or personal issues or the supervisor is perceived as supportive) tend to be associated with relatively lower levels of work-family conflict.

Family Sources of Conflict

Relatively less scholarly attention considers how family demands contribute to perceptions of work-family conflict. Hours spent on housework, child-care, or other family demands are often related with higher levels of work-family conflict. Marital tension or conflict is also associated with the experience of work-family conflict, although the causal direction of this relationship is unclear because work-family conflict may itself cause marital tension to increase. Employed parents tend to experience the most work-family conflict when children are young or if they have many children. High family involvement (viewing one's family as central to one's identity) is frequently associated positively with work-family conflict, but some studies find that this relationship exists only among women. Other characteristics of the marital relationship may also influence perceptions of work-family conflict. For example, individuals generally report more work-family conflict when a spouse is perceived as unsupportive or when one's spouse reports higher levels of work-family conflict.

Individual-Level Factors and Work-Family Conflict

Characteristics of individuals such as personality traits and coping strategies may also influence whether work and family demands are perceived as being incompatible with one another. Negative

affectivity (predisposition to negative feelings) and Neuroticism are associated with higher levels of work-family conflict whereas Extraversion, Conscientiousness, and Agreeableness are associated with less work-family conflict. In addition, hardiness—being strongly committed, having a high sense of control, and viewing changes as positive challenges—is negatively related to work-family conflict. Individuals who have better strategies to cope with competing demands are less likely to report work-family conflict. Goal setting and achieving is associated with lower levels of work and family stress, which subsequently is associated with less work-family conflict. Likewise, individuals who use time management strategies or prefer organization are less likely to report work-family conflict because of higher levels of perceived control.

Many studies also explore gender differences in perceptions of work-family conflict, although most find women and men report similar levels of conflict. When a gender difference is identified, women generally report higher levels of work-family conflict than men do, perhaps because women still tend to hold primary responsibility for duties at home. Yet, most studies of work-family conflict exclude individuals who have left the labor force. Women may be more likely than men to reduce their work demands in response to work-family conflict or to family-based stressors. However, other research also finds that women, and men as well, may increase time spent at work when faced with marital conflict or a stressful home environment.

Directions for Future Research on Work-Family Conflict

Despite the abundance of informative research on work-family conflict, much remains to be learned. Most prior studies of work-family conflict rely on cross-sectional study designs, such that characteristics of work and family environments are measured simultaneously with perceptions of stress and well-being. Such studies are not well designed to untangle the nature and direction of causal relationships or examine change over time in work-family conflict. For example, does work-family conflict cause

increased marital tension or does marital tension lead to increased perceptions of work-family conflict? Prospective longitudinal studies may be especially helpful for understanding the nature of gender differences in work-family conflict by examining the impact of selection. For example, researchers can investigate which types of people are more likely to modify employment obligations (e.g., move from full-time to part-time work or leave the paid labor force altogether) in response to work-family conflict. Such designs can also shed light on the extent to which individuals may modify family obligations (e.g., decisions to marry, to stay married, to have a child, to use nonparental childcare) in response to existing or anticipated work-family conflict. Longitudinal designs make it possible to study both the short-term and longer-term consequences of work-family conflict.

Future research would also benefit from additional efforts to understand heterogeneity in the experience of work-family conflict. For example, continued attention should be paid to conditions under which individuals exposed to the same objective work and family role demands perceive different levels of work-family conflict. Focusing on personality factors and coping styles seems key here. Existing research also points to meaningful differentials in the experience of work-family conflict across social class groups, but in general, this topic remains understudied. Future research should use diverse samples to better understand these and other group differences.

In conclusion, as work-family conflict is associated with lower productivity and increased distress, additional efforts to ease incompatibilities between work and family roles, either at the family level or in the workplace, are clearly needed. For example, flexible work schedules and employer-supported dependent care are associated with reductions in employees' perceptions of work-family conflict. Future studies should further examine the effects of interventions designed to make work and family roles more compatible in practice.

WORK-FAMILY SPIOLOVER

The term *work-family spillover* is often used in a general way to refer to the effects that paid employment has on family relationships. Initial research focused on maternal employment, based on the idea that a mother's work outside of the home might adversely affect her children and family. This assumption was incorrect, however, and painted a far too simplistic picture of work and family life; rather, the specific characteristics and experiences of jobs—not merely employment itself—have both positive and negative consequences for the family. This entry discusses the effects that work can have on family relationships, as well as the processes by which these effects may occur.

Effects of Job Characteristics and Work-Related Experiences on Family Relationships

Studies of job conditions and job characteristics now commonly include subjective appraisals of work to understand how individuals' experiences or views of their jobs might bring about changes in family dynamics. Job satisfaction is one of the chief features of work life that is studied. In general, parents who are more satisfied with their careers show greater warmth and responsiveness to their children and report greater marital satisfaction. Workers who experience more autonomy and complexity on the job also display more positive parenting and less harsh and restrictive parenting. Characteristics that select individuals into jobs with certain degrees of complexity and autonomy—educational level for instance—may also help shape parenting behavior. Researchers rely on longitudinal designs, with the same group of participants followed for months or years, to tease apart the impact that jobs have on parenting from the influence of factors that underlie both. The evidence from the longitudinal studies indicates that jobs can serve as an arena outside the household where workers may experience achievement and fulfillment that can carry over into the family with positive implications for those relationships.

Research also consistently indicates that chronic job stress affects family relationships through a negative impact on individual well-being. For example, the subjective experience of job stress has been associated with self-reports of personal distress, such as depression, that have then been linked to poorer marital and parent–child relations. In the absence of individual distress as an intervening link, however, there is no connection between chronic job stressors and family outcomes.

One facet of job stress is the social climate or quality of social relationships at work. Parents who experience a noncohesive or conflictive work atmosphere seem to have more negative interactions with their children (e.g., they are less affectionate, more angry), with longitudinal studies suggesting that these effects may hold up for months. Similarly, couples who report negative and unsupportive relationships at work also experience more marital tension and arguments. Social

support in the workplace has been linked with greater individual health and well-being; these links are thought to have positive implications for family life. However, because investigators have tended to focus on the impact of a negative work atmosphere, there is not as much evidence that supportive relationships at work benefit family social life.

Another aspect of job stress is time pressure and work overload, which can lead to parents feeling overwhelmed by and conflicted about their work and family roles. Similar to the association between the social atmosphere at work and family relations, studies reliably show that overloaded parents have poorer relations with their children (e.g., more conflict, less acceptance). In addition, more time pressure at work has been connected to reduced parental monitoring, meaning less knowledge about children's activities and whereabouts, and less allocation of time to parenting. For couples, time pressure and work overload are associated with greater marital tension and poorer marital adjustment. Overall, the subjective appraisal of job demands as being stressful or overwhelming seems to have a greater influence on family interactions and relationships than do the objective job conditions.

One such objective measure is the length of the workday, or the number of hours spent on the job. Initially, it was assumed that long hours at work would be associated with poorer family outcomes. However, research indicates that long work hours do not predict individual or family functioning, with most studies reporting no reliable linkages between time on the job and lower marital quality or poorer home environments for children. This likely results from the many benefits (income, access to health care, social support) that typically increase with more hours of employment. However, the distribution of parents' work hours over the day (e.g., amount of overlap with spouse's work schedule and child's school day) and the subjective appraisal of those work hours (e.g., do work hours fit one's needs) do influence family relationships. In particular, among two-parent families in which one parent works a nonstandard shift (e.g., at night), there is often a disruption of family routines. Increased rates of marital dissatisfaction have also been observed. In single-parent households, shift work can place an extreme burden on the family.

Researchers have also turned their attention to experiences that occur *in transit* between work and home. Although commuter stress is associated with negative individual health outcomes, such as high blood pressure, there does not appear to be a substantive link between commuting and family relations and functioning. Studies have implicated the length, unpredictability, and uncontrollability of commuting as characteristics that help explain commuter stress via their associations with worker's greater negative mood and decreased frustration tolerance and task motivation. However, no conclusive evidence indicates that these effects contribute to increased tension in the home.

Short-Term Processes

Because chronic job stressors can affect family relationships, researchers have been interested in understanding just *how* experiences at work come to have an impact at home. One approach to this question puts families under the microscope, focusing on a short period (days or weeks), to see if day-to-day fluctuations in stressors at work correlate with day-to-day changes in family behavior. This strategy differs from approaches that consider the effects of stable job characteristics or conditions. For example, instead of comparing an ER trauma nurse (who generally perceives high job stress) with a florist (who generally perceives little job stress), the researcher is comparing the same person, say the florist, with himself or herself on different days with different levels of job stress (Valentine's Day versus the day after). Thus, the effects of both stable job characteristics and individual characteristics on family behavior are eliminated; the focus is exclusively on the effects of short-term variations in experiences at work. Using this strategy, work-to-family effects are often observed and they seem to fall into two categories—social withdrawal and increases in anger and conflict. Interestingly, these short-term consequences of job stress are observed both in marital and in parent-child interactions and they are found in studies that use objective measures of daily job stressors.

The social withdrawal response to job stress consists of short-term decreases in the employed individual's usual level of social engagement at home. Coming home after a stressful day at work,

he or she might speak less, express less positive and less negative emotion, and be less interested and less involved in social interaction. For instance, a parent may be less likely to help with homework or to discipline a child. The second type of response is quite different. After more difficult or stressful days, the employed family member may express more anger and be more critical than usual. Researchers have found that a one-day increase in stress at work is associated with increases in marital arguments and use of disciplinary tactics with children later that day. In one investigation, air traffic controllers were both more socially withdrawn and expressed more anger when they came home from a shift at the airport characterized by higher air traffic volume or lower visibility conditions.

How does a high-stress day at work affect behavior in the family? Researchers believe that job stressors leave a cognitive, affective, and physiological residue, such that the employee's thoughts, feelings, and biology are changed, at least in the short-term, by his or her experiences at work. For example, the employed person may return home at the end of the day preoccupied with worries about an impending deadline at work, or with lingering feelings of anger and physiological arousal because of an argument with a coworker. This is the more technical and narrow meaning of the term *spillover*: the experience of a mood or a biological response in one setting that originated in a different setting. Negative mood and arousal caused by stressors experienced at work sometimes do persist when the employed person returns home, and evidence suggests that those spillover effects account for some of the increase in anger and conflict that were described previously.

There is, of course, an alternative to simply experiencing and directly expressing the residue of job stress at home; employees can attempt to change their physical and psychological state, perhaps by relaxing, or distracting themselves from thoughts about a difficult day, or engaging in any one of a number of coping tactics. The social withdrawal response to job stress may be one such coping strategy. In other words, rather than discuss job-related worries or problems at home, the employee may avoid social interaction, perhaps to reduce the chances that negative mood or irritability will lead to arguments and to facilitate a process of relaxation and unwinding.

Whether the residue of stress at work directly affects the employed family member's social behavior through spillover processes or indirectly affects his or her behavior through a coping response, partners in the social interaction feel the impact. Researchers are beginning to investigate processes of emotion transmission, whereby emotions are transferred from one member of a dyad to another through their social interactions. Likewise, some evidence indicates that stress hormone levels, such as cortisol, in couples are synchronized when spouses are at home together and are less closely linked during the workday. The field is thus beginning to see how stress at work can ultimately affect the psychological and biological functioning of other family members. However, spouses and children are active participants in the daily social life of families and contribute to the dynamics of the employed family member's reactions at home to stress at work. For example, studies have uncovered different ways that spouses and children can either encourage or disrupt an employee's attempts at social withdrawal. In the end, the impact of job stressors on family relationships and well-being depends on the reactions of all its members.

Individual and Family Differences

Although the research summarized here indicates that jobs do influence family relationships, both in the short-term and in the long-run, not every family is affected in the same way or to the same degree. For example, some individuals and families do not show any impact of job stressors on home life. A variety of individual and family characteristics—such as the socioeconomic status and life stage of the family; the gender, personality, and psychological well being of the employee; existing patterns of conflict, parenting styles, and division of labor in the home—all help to shape work–family dynamics. For example, parents who are psychologically distressed seem to be more vulnerable to the effects of job stress on interactions with their children, and family relationships that are generally satisfying and harmonious seem to protect families from the short-term repercussions of job stress.

Family-to-Work Spillover Effects

Although most investigations focus on work-to-family effects, there is also interest in bidirectional models. Studies have found evidence for both a negative (e.g., stress contagion) and a positive (e.g., useful skills and attitudes) impact of home life on work life. Of note, recent longitudinal research has suggested that marital quality has more influence on job satisfaction than vice versa, such that increases in marital satisfaction contributed to increases in job satisfaction over time, and increases in marital discord predicted declines in job satisfaction over time. Hence, evidence suggests that reciprocal effects between work and family simultaneously occur, and that these bidirectional pathways warrant further study.

In conclusion, although many employed adults say they worry that time spent at work may harm their families, on the whole, employment benefits the family environment. Jobs typically bring income, health care, social support, and a sense of accomplishment that contribute to the well-being of workers and their families. Only under certain circumstances (e.g., high job stress, mismatch of work shift with family schedule) does employment also bring negative consequences for the family.

WORKPLACE RELATIONSHIPS

Workplace relationships include any associations that are initiated, maintained, or dissolved at work. Workplace relationships include relationships between superiors (e.g., bosses, supervisors, leaders) and subordinates (e.g., employees, direct-reports), relationships between coworkers in the same unit, or relationships among a number of members of the workplace such as groups, within unit teams, and cross-functional teams, including telecommuting teams who seldom see each other face-to-face. This entry distinguishes between workplace relationships and other types of relationships, and expounds upon what is known about different types of workplace relationships such as those between superiors and subordinates, romantic partners, friends, and enemies. The entry also discusses the nature of workplace conflict, coping with conflict, and the future of workplace relationships.

Distinction Between Workplace Relationships and Other Relationships

Workplace relationships differ in two fundamental ways from other adult relationships. The first difference is that these relationships involve a background of structure, with role expectations about who may issue commands, what actions should follow, and how individuals are expected

to spend their days. This structure can impose limits on the development, form, and expression of relationships. No matter how much coworkers might enjoy each other's company, structural boundaries may inhibit the development of the relationship.

The second difference is that the relationships tend to be semi voluntary, at best. Workers generally do not have the opportunity to select their supervisors, their coworkers on a project team, or the occupants of the offices, cubicles, or desks adjacent to theirs. As a consequence, employees must adjust to, accommodate, and try to find redeeming value in people with whom they would not otherwise choose to associate.

Superior-Subordinate Relationships

The owner/supervisor-employee/subordinate relationship is a relatively new invention in human history and shares some features with other hierarchical relationships, such as parent-child and leader-subordinate. In the parent-child relationship, the parent is normatively expected to focus simultaneously on the well-being of the family as a whole, and on the nurturance and growth of the individual child. In the tribal leader-subordinate relationship, such as that of the regent-vassal, the leader has certain obligations, and the subordinate has certain rights, but the well-being and even life of the subordinate can be sacrificed during combat or religious rituals.

Business owners and managers differ in the extent to which they adopt a parental or regal attitude in their efforts to enhance the performance and retain the loyalty of their employees. Subordinates also differ in the extent to which they expect nurturance versus military-style commands from their supervisors.

Bosses and supervisors who are appropriately structured, supportive, fair, and clear in their communication tend to have the most effective employees, who are loyal to the organization. This effect runs throughout the organization, in that leader-leader exchanges affect leader-member exchanges. The more positive the exchanges between leaders, the better the leader-subordinate relationships are, and the more positive the subordinates are about the organization. However, when bosses and

supervisors do not behave in an ideal fashion or, worse, when they are dictatorial, incompetent, or play favorites, they can wreak havoc upon their employees.

In a study conducted by Michael Cunningham and his colleagues, with a sample of 112 employees, as many as two thirds of managers are seen by their employees as either incompetent or interpersonally unskilled and are the main source of stress for those workers. Although most people in the workforce simply accommodate to the poor behavior, or change jobs, some react to feeling overcontrolled and unjustly treated by becoming psychologically or physically aggressive toward their supervisors. This is a primary contributor to the rare, but serious, problem of workplace violence.

Coworker Relationships: Friends and Enemies

Despite the involuntary nature of employee relationships, human resource departments hope that everyone can retain a professional demeanor toward everyone else at work and neither become too close nor too acrimonious with coworkers, superiors, or subordinates. The reality is that people do form close friendships with many from the workplace and become the enemies of a few others.

Consistent with the outcomes in other spheres of life, people tend to be more friendly with and altruistic toward coworkers and employees who are similar to themselves. This is unfortunate because the workplace is becoming more demographically diverse and the need for cooperation between people who are different from one another is more important than ever.

Peer friendships at work tend to develop in three phases, from coworker or acquaintance to friend, friend to close friend, and close friend to almost-best friend, although most never develop beyond the first stage. The coworker-to-friend transition is brought about by working together in close proximity, sharing common ground, and engaging in extra-organizational socializing. Communication at this transition covers a broader range of topics, but is still relatively superficial. The friend-to-close-friend transition is associated with sharing pleasures and problems in one's personal and work experiences. Communication at

this transition is broader, more intimate, and less cautious than in the previous stage. The close-friend-to-almost-best-friend transition results from life events, work-related problems, and the passage of time. Workplace friendships and group cohesiveness, defined as occurring between members who cooperate and feel comfortable with one another, offer individuals companionship, work assistance, understanding, and emotional support, and are associated with the outcomes of well-being, job satisfaction, organizational commitment, low turnover intentions, and productivity.

Although most organizations encourage coworkers to socialize and become cohesive, competitive businesses with hierarchical, regal management norms discourage the formation of close attachments. Such organizations prefer to push their employees to the maximum and want to minimize collateral demoralization among coworkers if they cause burnout or quitting, or if they fire some employees to boost profitability. Employees who have lost good friends to downsizing may resent management, may go through a period of mourning and reduced productivity, and may be less open to forming new workplace relationships in the future. Nurturant parental managers may be so sensitive to the human costs of job cuts that they are unwilling to trim a bloated department. Regal managers are indifferent to them, or revel in the bloodletting as a display of their toughness.

Although cooperation and building team spirit is valued in many workplaces today, there is still some level of competition, because of limitations in the opportunity for promotion and the constant need for increased project budgets. This competition can lead coworkers to promote themselves and undermine their rivals to superiors. If supervisors are not careful to regulate competition, office politics can be waged frequently. This can create a tactical disadvantage, and resentment, if, because of gender, one coworker shares an extracurricular interest with the superior such as golf, and the other coworker cannot even enter the same locker room.

Envy is one of the main factors that can undermine workplace friendships and potentially create enemies. Envy has an emotional component, characterized by feelings such as rancor, hatred, and bitterness, and a social comparison component, characterized by a desire to have what the other

has and avoiding the other person having an advantage over oneself. People become envious when they are similar in profession and qualifications to another person, and when they are in close contact with a person who is doing better than they are. That situation can lead to a feeling of inequity if the greater success appears undeserved, or inferiority if it seems that the other person has greater talent.

The workplace provides an opportunity to make friends of the opposite sex. Unfortunately, employees must be concerned that their coworkers, out of envy or ignorance, will misinterpret their cross-sex friendships as romantic or sexual. Although women can learn the business from other women, the fact that most CEOs and other top executives are men means that women in particular need to form cross-sex friendships and mentoring relationships to move up the hierarchy. Informal barriers to cross-sex friendship at work can form a “glass partition,” and the potential impact of this glass partition can have an adverse effect on women’s careers.

Negative relationships can have greater power than can positive relationships to affect outcomes. The quality of relationships at work affects sustainable organizational performance and effective individual development. When relationships are positive, they can be a source of vitality and learning that helps people grow, thrive, and flourish. When relationships are negative, they can be a toxic source of pain, depletion, and dysfunction.

Conflict and Coping

Different types of work entail different levels of demand and stress and have different balance points between expectations of productivity and of civility. In jobs that involve a great deal of physical effort and stress, such as military combat and iron smelting factories, gruff orders from superiors and terse responses from subordinates are the norm. In jobs that offer lower physical demands and stress, and greater stability, such as teaching in a well-disciplined school and nursing in a small-town hospital, politeness and dialogue are the norm. The extent to which a given business follows the norms of gruffness versus civility varies depending on the training and attitudes of

the supervisor and the subordinates. Hurt feelings can develop whenever the communications or behavior that the individual receives from a supervisor or coworker suggests a less positive evaluation of the relationship and the self than the individual expects. Although workplace relationships tend to be less close and personal than romantic relationships or friendships formed elsewhere, social acceptance in the workplace is associated with material, as well as emotional, well-being. A sense of rejection in the workplace can affect an individual’s feelings of social desirability and self-confidence, and may have a tangible impact on the individual’s career prospects and likelihood of maintaining a stable income, which can ripple through many domains of life.

Many books on coping with workplace issues focus on identifying and labeling the perpetrator of distress, rather than focusing on the processes of miscommunication or misunderstanding. For example, a large-scale study of employees in various companies conducted by Cunningham and his colleagues nominated peers as the most troublesome, followed by supervisors, and then subordinates. A dozen types of annoying people were identified and given colorful names by the investigator, such as Lord of Power, Busybody, Backstabber, and Sexual Harasser.

Recently, attention has been devoted to specific forms of uncivil workplace communication behavior that causes hurt feelings and social allergies. A social allergy is an individual’s tendency to experience a disproportionately intense emotional reaction in response to small behaviors that seems unpleasant to onlookers, but may not warrant such an intense reaction. People generally do not cope well with conflictual feelings. Instead, they tend to avoid the person who is grating on their nerves or seek social support from colleagues in the office rather than finding a mutually beneficial solution to the problem. Human relations professionals emphasize more mature strategies, but the regal norm of sucking it up and soldiering on still pervades many offices.

Romance at Work

Historically, superior–subordinate romantic relationships were either forbidden or strongly

discouraged. The intensity of that sentiment grew in the 1990s with the development of the statutes concerning sexual harassment. Nonetheless, workplace romances are quite common, at all levels of organizations. In fact, a recent study by the American Management Association found that 30 percent of managers and executives admitted to having dated someone from work. Forty-four percent of them married that dating partner and 23 percent more had a long-term relationship.

With the number of hours at work growing longer and the age of marriage approaching 25 for women and 27 for men, the workplace will increasingly be the place where eligible singles meet. There is an increase of management acceptance of employee dating, although there are continuing concerns about power differentials, and the consequences to the workplace in the event of a bad breakup.

Future of Workplace Relationships

The location of work is changing to match the nature of work. Concentrating employees together in a factory is an effective strategy to enhance the speed and efficiency of material production. By contrast, the products of most offices consist of decisions and documents. Concentrating employees together in an office is effective to the extent that the production of decisions and documents requires face-to-face interaction among the work team members. With current communication and computer technology, coworkers can share information, collaborate on decisions, and jointly produce documents from remote locations. Companies that adopt flexible time schedules and telecommuting options have the opportunity to recruit and retain employees who might be unavailable because of commuting distances and childcare responsibilities. The employees appreciate the increased freedom, as well as reduced clothing and transportation

expenses. However, because telecommuting conference calls tend to be highly focused, they may miss some opportunities for cross-fertilization, socialization, and recognition that are available to those in more traditional roles.

As today's workers gain more education, they develop more independent modes of thinking, and more self-respect. Such qualities are valued in industries that emphasize creativity and innovation. These qualities lead to pressure for less hierarchical and more collaborative and informal organizational structures. Coworkers may treat each other like (kissing) cousins rather than like squabbling siblings or expendable soldiers. The mature organization of the future will likely have supervisors behaving toward subordinates like aunts and uncles rather than like parents or kings.
